Editorial Board

2012-2016

The *World Journal of Clinical Cases* Editorial Board consists of 519 members, representing a team of worldwide experts in clinical medical research. They are from 55 countries, including Albania (1), Australia (8), Bangladesh (3), Belgium (3), Botswana (1), Brazil (10), Bulgaria (1), Canada (11), China (24), Colombia (2), Croatia (4), Cuba (1), Czech (2), Egypt (5), France (5), Germany (14), Greece (15), Hungary (1), India (56), Indonesia (1), Iran (11), Iraq (1), Ireland (1), Israel (5), Italy (56), Japan (33), Lebanon (3), Malaysia (2), Mexico (1), Morocco (2), Netherlands (3), New Zealand (1), Nigeria (1), Oman (1), Pakistan (1), Peru (2), Poland (4), Portugal (3), Qatar (1), Romania (3), Saudi Arabia (4), Serbia (6), Singapore (3), Slovakia (2), Slovenia (1), South Korea (27), Spain (11), Sudan (1), Taiwan (21), Thailand (2), Trinidad and Tobago (1), Tunisia (1), Turkey (28), United Kingdom (26), and United States (82).

Abstract

Degenerative disease of the lumbar spine is a common and increasingly prevalent condition that is often implicated as the primary reason for chronic low back pain and the leading cause of disability in the western world. Surgical management of lumbar degenerative disease has historically been approached by way of open surgical procedures aimed at decompressing and/or stabilizing the lumbar spine. Advances in technology and surgical instrumentation have led to minimally invasive surgical techniques being developed and increasingly used in the treatment of lumbar degenerative disease. Compared to the traditional open spine surgery, minimally invasive techniques require smaller incisions and decrease approach-related morbidity by avoiding muscle crush injury by self-retaining retractors, preventing the disruption of tendon attachment sites of important muscles at the spinous processes, using known anatomic neurovascular and muscle planes, and minimizing collateral soft-tissue injury by limiting the width of the surgical corridor. The theoretical benefits of minimally invasive surgery over traditional open surgery include reduced blood loss, decreased postoperative pain and narcotics use, shorter hospital length of stay, faster recover and quicker return to work and normal activity. This paper describes the different minimally invasive techniques that are currently available for the treatment of degenerative disease of the lumbar spine.

Key words: Minimally invasive surgery; Spine surgery; Lumbar spine; Degenerative disease; Interbody fusion; Posterolateral fusion; Decompression; Indirect decompression techniques

Core tip: Degenerative disease of the lumbar spine is a common and increasingly prevalent condition that is often implicated as the primary reason for chronic low back pain and the leading cause of disability in the western world. Compared to the traditional open spine surgery, minimally invasive techniques require smaller incisions and decrease approach-related morbidity. The benefits of minimally invasive surgery over traditional open surgery include reduced blood loss, decreased postoperative pain and narcotics use, shorter hospital length of stay, faster recovery and quicker return to work and normal activity.

Skovrlj B, Gilligan J, Cutler HS, Qureshi SA. Minimally invasive

procedures on the lumbar spine. *World J Clin Cases* 2015; 3(1): 1-9 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/1.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.1

INTRODUCTION

Modern minimally invasive spine surgery (MIS) was introduced in the 1990s with the description of tubular retractors for access to the lumbar spine and the report of the first lumbar microendoscopic discectomy[1,2]. Since that time, advances in technology and surgical instrumentation have led to MIS developing into an important and rapidly growing filed of spine surgery. Today, MIS techniques and approaches are used in the treatment of a wide variety of spinal pathologies including degenerative disc disease, disc herniation, instability, deformity, fracture, infection and tumors[3]. Compared to the traditional open spine surgery, MIS was pursued as a means to reduce iatrogenic tissue trauma during surgery. The theoretical benefits of MIS over traditional open surgery include smaller incisions, less soft tissue damage, reduced estimated blood loss (EBL), decreased postoperative pain and narcotics use, shorter hospital length of stay (LOS), faster recover and quicker return to work and normal activity[4,5]. Traditional open spine surgery approaches often require extensive muscular and ligamentous disruption during the surgical approach to the spine resulting in decreased spinal stability and subsequent associated morbidities[6]. MIS minimizes approach-related morbidity by avoiding muscle crush injury by self-retaining retractors, preventing the disruption of tendon attachment sites of important muscles at the spinous processes, using known anatomic neurovascular and muscle planes, and minimizing collateral soft-tissue injury by limiting the width of the surgical corridor[7]. The decrease in the approach-related morbidity and indirect iatrogenic destabilization of the spine are important advantages of MIS over open spine surgery.

MIS approaches have been increasingly used in the treatment of degenerative diseases of the lumbar spine. As microsurgery, endoscopy and various percutaneous techniques advance and our rapidly aging population drives greater demand for spinal care, MIS will likely play an increasingly important role in the treatment of lumbar degenerative disease. This paper describes the different MIS techniques that are currently available for the treatment of degenerative disease of the lumbar spine.

MINIMALLY INVASIVE NON-FUSION PROCEDURES

MIS microdiscectomy

Lumbosacral nerve root compression or irritation secondary to an intervertebral disc herniation is a major cause of sciatica and low back pain. Patients with disc-related sciatica may be managed conservatively or *via* surgery when conservative treatment fails or symptoms worsen over time. It is estimated that over 250000 elective lumbar spine surgeries are performed in the United States each year for persistent symptoms of sciatica[8]. Of those, lumbar discectomy remains one of the most commonly performed procedures[9]. The goal of surgery is most commonly to remove intervertebral disc material and decompress the nerve root. Traditionally, the standard surgical treatment of lumbosacral disc herniation has been open microdiscectomy, however, with the rapid advances in surgical techniques and technology, there has been a growing trend towards MIS microdiscectomy.

An MIS microdiscectomy involves the use of serial tubular retractors to dilate the paraspinous musculature without stripping it off the spinous processes, and an endoscope or surgical microscope to visual the surgical field[10]. While the benefits of minimal soft tissue disruption appear to favor MIS microdiscectomy over open microdiscectomy, there is a significant learning curve associated with performing the procedure safely. Although many innovative techniques in the treatment of lumbar disc herniation have been developed, open microdiscectomy remains the standard of care at the current time[11].

A recent meta-analysis of controlled trials that compared outcomes of MIS and open microdiscectomy in patients with sciatica evaluated 29 studies (16 randomized controlled trials and 13 non-randomized studies) with a total of 4472 patients[11] (Table 1). Regarding clinical outcomes, the study found a moderate to low quality evidence of no differences between MIS and open microdiscectomy. Regarding perioperative outcomes, there was low to moderate evidence of no difference between MIS and open microdiscectomy; this was particularly notable for complications and reoperation rates. The study also found no significant difference in quality-adjusted life years (QALYs) or total costs from a societal perspective during the first year following treatment. The authors found low quality evidence that MIS took 10-15 min longer, resulted in a 52 cc reduction in EBL and reduced mean LOS by 1.5 d. The increased surgical time with MIS may be explained by the learning curve associated with MIS, variability in the techniques used and differences in how operative times were defined[11].

Currently, there is evidence from several comparative studies of MIS and open microdiscectomy suggesting that clinical outcomes between the two groups are similar. As surgeons become more proficient with MIS techniques and investigators conduct well-powered, randomized controlled trials, the indications favoring MIS microdiscectomy will be better defined.

MIS direct decompression

Lumbar spinal stenosis is the most common indication for spine surgery in patients older than 65, and its prevalence in the United States is expected to rise 59% by the year 2025[12]. Age-related degenerative changes

Table 1 Differences between outcomes of minimally invasive *vs* open surgical techniques

MIS techniques	Ref.	Differences in outcome compared to open techniques
Non-fusion techniques		
MIS microdiscectomy	Kamper *et al*[11]	Moderate to low evidence of no differences between MIS and open microdiscectomy
		No significant differences in QUALYs or total costs
		MIS took 10-15 min longer, resulted in 52 cc reduction in EBL and reduced mean LOS by 1.5 d
MIS direct decompression (Laminectomy/laminotomy)	Rahman *et al*[16]	Decreased EBL compared to open technique
		MIS procedures were 37-47 min shorter
		Decreased LOS by 2.52 d in patients undergoing decompression at ≤ 2 levels
		MIS had fewer complications (7.9% *vs* 16.1%)
	Anderson *et al*[17]	No significant differences in terms of ODI, Short-Form-12, and VAS
	Khoo *et al*[18]	Longer operative times in MIS group (109 min *vs* 88 min)
		Decreased EBL and postoperative stay in MIS group
	O'Toole *et al*[21]	0.10% surgical site infection rate
		Authors concluded that MIS technique may reduce SSI rate by 10-fold
MIS indirect decompression (Interspinous process devices)	Kuchta *et al*[26]	Statistically significant improvement in symptom severity and physical functioning throughout 2-yr follow-up period
	Bowers *et al*[27]	85% failure rate and 38% complication rate
	Brussee *et al*[28]	Poor outcome in 68.9% of patients
	Kim *et al*[29]	Cost analysis study found devices to be extremely costly and questioned cost-effectiveness
Fusion techniques		
Intertransverse onlay fusion	-	No literature available comparing MIS versus open posterolateral onlay fusion
Percutaneous pedicle screw fixation	Lehmann *et al*[34]1	EBL and muscle damage markers significantly lower in MIS group
		Compartment pressure, blood flow and EMG readings similar between both groups
		Radiation exposure greater in MIS group
MIS transforaminal lumbar interbody fusion	Seng *et al*[51]	Statistically increased fluoroscopic times (55.2 s *vs* 16.4 s) and operative times (185 min *vs* 166 min) in MIS group
		MIS had less EBL than open (127 cc *vs* 405 cc)
		Postoperative morphine use less in MIS group (8.5 mg *vs* 24.2 mg)
		Shorter LOS in MIS group (3.5 d *vs* 5.9 d)
	Parker *et al*[55]	MIS associated with reduction in mean hospital cost of $1758, indirect cost of $8474, total 2-yr social cost of $9295
		Similar 2-yr direct health care cost and QALYs gained
MIS direct lateral interbody fusion	Villavicencio *et al*[73]	Lower complication rate in MIS versus open (8.2% *vs* 16.7%)
	Rodgers *et al*[74]	Significantly lower complication rate in MIS cohort (7.5% *vs* 60%)
		Decreased EBL, lower transfusion rate and shorter LOS
	Deluzio *et al*[75]	Average LOS in MIS group 49% shorter
		Average cost savings for MIS group at 45 d of $2536/patient

[1]Animal study. MIS: Minimally invasive surgery; LOS: Length of stay; EBL: Estimated blood loss; ODI: Oswestry Disability Index; VAS: Visual analog scale; SSI: Surgical site infection; EMG: Electromyography; cc: Centimeter cubed; QALY: Quality adjusted life year.

in the lumbar spine such as hypertrophy of the facet joints with or without synovial cyst formation, foraminal stenosis due to decrease in the intervertebral disc height or osteophyte formation, ligamentum flavum thickening causing central and lateral recess compression and bulging or herniation of the intervertebral disc are all potential contributors to lumbar spinal stenosis. Surgery has been shown to decrease pain and improve functional status in patients with lumbar spinal stenosis[13]. Traditionally, an open midline approach involving a wide, bilateral laminectomy with medial facetectomy with or without foraminotomy has been the standard technique for surgical treatment of lumbar spinal stenosis. However, lumbar decompression surgery is increasingly being performed using tubular decompression, a MIS technique. This procedure utilizes a small paramedian incision and through the use of serial tubular dilators to reduce multifidus muscle injury while providing sufficient exposure of the surgical decompression site and allowing for bilateral decompression through a single incision[14]. Decompressing the contralateral side through a single unilateral paramedian incision allows the surgeon to spare the spinous process, rostral and caudal supraspinous and interspinous ligaments as well as the contralateral lamina and facet joint, thereby minimizing iatrogenic destabilization of the spine while achieving sufficient decompression for symptomatic relief. Furthermore, the use of an intraoperative endoscope or microscope for magnification and lighting allows for adequate visualization of the spinal anatomy[15].

Multiple studies have described shorter operating room times, decreased EBL, shorter LOS, lower surgical site infection rates, fewer complications and faster recovery times in MIS compared to the open lumbar decompression for spinal stenosis[16-20].

Rahman *et al*[16] retrospectively reviewed the medical records and relevant imaging of 126 patients (38 MIS *vs* 88 standard open technique) who underwent bilateral surgical decompression for lumbar stenosis to determine intraoperative EBL, length of operation, LOS, and

number and nature of complications. On average, patients undergoing open procedures had 194 cc more EBL than patients undergoing MIS procedures, with the greatest difference in patients undergoing procedures involving ⩾ 3 levels. MIS procedures were 37-47 min shorter than open procedures. Looking at the hospital LOS, the authors found that patients undergoing decompression at ⩽ 2 levels had a LOS that was 2.52 d shorter in the MIS group. In terms of overall complications, the MIS group had fewer complications than the open group (7.9% *vs* 16.1%). However, one limitation of this study was that it did not evaluate long-term outcomes of the two procedures.

Anderson *et al*[17] performed a retrospective analysis of 110 patients in two matched cohorts to compare the tubular retractor approach and traditional midline approach to decompressive surgery for unilateral lumbar radiculopathy. The two approaches were evaluated based on patient reported outcomes using the Oswestry Disability Index (ODI), Short Form-12, and visual analog scale. The authors found no significant differences between the surgical approaches with respect to patient reported outcomes.

Khoo *et al*[18] compared 25 patients undergoing microendoscopic decompressive laminotomy to 25 patients undergoing open decompression for lumbar spinal stenosis. The authors found that effective circumferential decompression was achieved in the majority of patients in both groups. Surgery was longer for the MIS procedure group compared to the open group (109 min per single level *vs* 88 min per single level). EBL was reduced by 125 cc in the MIS group and postoperative stay was decreased 48 h, from 94 h in the open group to 42 h in the MIS group.

O'Toole *et al*[21] performed a retrospective review of prospectively collected data in 1274 patients undergoing MIS decompression and found a 0.10% rate of surgical site infection. The authors concluded that MIS techniques may reduce postoperative wound infections as much as 10-fold compared to open techniques.

At the current time, favorable complication profiles and patient outcome studies with MIS tubular decompression makes this technique an acceptable treatment option in the surgical management of lumbar spinal stenosis (Table 1). Studies assessing long-term outcomes and cost-utility of MIS *vs* open lumbar decompression are needed to further establish the value of MIS decompression.

MIS indirect decompression

Lumbar interspinous process devices (IPDs) are a MIS technology intended to unload the facet joints, restore foraminal height, lower intradiscal pressure, restricts overextension and provide motion-preserving stabilization[22]. IPDs are used in the treatment of degenerative lumbar spinal stenosis and intermittent neurogenic claudication where they provide indirect decompression to the neural structures[23]. They have also been used in the treatment of discogenic low back pain, facet syndrome, disc herniation and lumbar spinal instability[24]. In 2005, the United States Food and Drug Administration (FDA) approved the first ever IPD (X-STOP, Medtronic, Memphis, TN, United States) for the treatment of patients aged 50 or older suffering from neurogenic intermittent claudication secondary to a confirmed diagnosis of lumbar spinal stenosis. The device was indicated for those patients with moderately impaired physical function who experience relief in flexion from their symptoms of leg/buttock/groin pain, with or without back pain, and have undergone a regimen of at least 6 mo of non-operative treatment. The device may be implanted at one or two lumbar levels in patients in whom operative treatment is indicated at no more than two levels[25]. Since the FDA approval of the first IPD, a growing number of devices have been introduced to the spine implant market and used for a wide range of lumbar spinal pathologies, many of them outside of the intended indications.

Outcomes with the use of IPDs have thus far been inconsistent. Kuchta *et al*[26] reported on a single-center clinical outcomes of 175 patients with symptomatic lumbar spinal stenosis treated with X-STOP implantation and reported statistically significant ($P < 0.001$) improvements in symptom severity and physical functioning throughout the 2-year follow-up period. Bowers *et al*[27] reviewed complications associated with the use of X-STOP in 13 patients and found a 85% ultimate failure rate with patients requiring additional surgery for symptomatic relief. The authors also reported a 38% complications rate, including 3 spinous process fractures and 2 instances of new onset radiculopathy. Brussee *et al*[28] review 65 patients with neurogenic claudication who underwent placement of X-STOP device and found poor outcomes in 68.9% of patients.

Multiple studies have also reported high complication and reoperation rates following implantation of IPDs. Complication rates published in the literature range from 11.6% to 38% while reported reoperation rates range from 4.6% to 85%[26-31]. Epstein *et al*[23] reported on the cost of the treatment of 16 patients with a total of 31 X-STOP devices and found a total cost of $576407 charge for the devices alone plus an added $80944 charge for the operating/recovery room. The authors concluded that IPDs appear to be extremely costly and questioned the cost-effectiveness of these devices.

At the current time, there is evidence of poor long-term outcomes as well as high complication and reoperation rates following the use of IPDs for the treatment of degenerative lumbar conditions (Table 1). Studies on the cost-effectiveness and value of IPDs are currently lacking and are needed to determine the future faith of these devices.

MIS LUMBAR FUSION PROCEDURES

MIS posterolateral intertransverse onlay fusion without instrumentation

In the traditional posterior midline approach to the

lumbar spine, access to the intertransverse region requires extensive stripping of the paraspinal musculature to the tips of the transverse processes. This process results in significant destruction, postoperative atrophy and scarring of the multifidus muscles which has been associated with significant postoperative morbidity[32]. For this reason, a MIS paraspinal muscle-splitting technique (modified Wiltse approach) using an expandable tubular dilator has become an increasingly popular technique used for exposure of the transverse processes and intertransverse space. The use of an expandable tubular retractor allows for both of the transverse processes and the fusion bed to be simultaneously exposed.

The theoretical advantages of this MIS technique are decreased paraspinal muscle destruction, decreased surgical incision size, decreased EBL, decreased postoperative narcotic use and shorter LOS. However, there are no studies in the literature comparing outcomes or cost-effectiveness of lumbar intertransverse onlay fusion utilizing the MIS muscle-splitting approach compared to the traditional open approach (Table 1).

MIS percutaneous pedicle screw fixation

Pedicle screw fixation allows for the creation of a solid and biomechanically rigid construct that allows for fusion to occur at the intended levels. Traditionally, open midline incisions were utilized for exposure of the spine in preparation for pedicle screw placement. Open procedures require extensive tissue dissection to expose the entry points and provide adequate lateral-to-medial orientation for optimal screw trajectory. This dissection in turn may result in muscular denervation, facet capsule disruption, damage to the proximal facet joints and weakening of other ligamentous structures, resulting in prolonged post-operative pain and morbidity[33]. Open lumbar fusion procedures are associated with increased operative times, increased EBL and risk of postoperative surgical site infection[34]. LOS and cost of treatment are also adversely affected by open pedicle screw fixation and spinal fusion techniques[35]. Recently, MIS percutaneous pedicle screw fixation has become an increasingly popular MIS technique for lumbar spine fixation[36-38]. Percutaneous pedicle screw placement offers several distinct advantages over the traditional open approach. It eliminates the need for a midline incision and extensive paraspinal muscle dissection. Kim *et al*[38] revealed that percutaneous *vs* open instrumentation was associated with decreased multifidus muscle atrophy, a superior postoperative trunk muscle strength, lower blood loss and less postoperative narcotic use. However, the authors did not find an improved clinical outcome in terms of patient satisfaction and pain scores. Muscle damage is also related to direct compression by muscle retractors, which result in ischemia of the compressed muscle groups and can lead to postoperative muscle necrosis. Percutaneous pedicle screw placement allows the surgeon to more easily achieve an ideal lateral-to-medial trajectory, especially advantageous in obese patients. The advantage of a minimally traumatic access to the lumbar spine carries the disadvantages of longer operative times and increased radiation exposure, both dependent on surgeon experience and comfort level.

Several authors have demonstrated reduced intraoperative EBL, perioperative risk of transfusion, improved cosmesis, decreased post-operative pain and narcotic use, decreased LOS, faster return to activity and reduced overall costs[39-43]. To date, however, there exists no high-quality literature to support the notion that MIS pedicle screw instrumentation is superior to the traditional open technique. Most of the studies evaluating open *vs* percutaneous pedicle techniques do so in context of interbody fusion techniques with no study directly evaluating the two instrumentation techniques alone. Lehmann *et al*[34] compared open *vs* percutaneous pedicle screw insertion in a sheep model and found that EBL and muscle damage markers were significantly lower in the percutaneous group while radiation time was significantly longer in the percutaneous group. In terms of compartment pressure, blood flow and electromyography measurements at different time points during the operative procedure, no significant differences were revealed.

Many technical challenges unique to the percutaneous pedicle screw placement technique and a steep learning curve exists, requiring different technical, psychomotor and cognitive skills. Mobbs *et al*[44] noted several challenges in percutaneous screw placement including changing direction of screw placement following initial pedicle cannulation, L5/S1 screw head proximity, cannulation of small pedicles, skin incision selection and insertion of rod for multi-segmental fixation, and difficult Jamshidi placement in hard pedicles. Surgeon experience plays a key role in perioperative outcomes of MIS techniques. It is recommended that surgeons have adequate experience with open techniques before attempting MIS fixation techniques and that they begin with simple MIS procedures[44].

Despite all the encouraging clinical data (Table 1), prospective outcomes studies with long-term follow up comparing percutaneous instrumented fusion to conventional open instrumented fusion are required to determine the safety, effectiveness and clinical benefit of MIS spinal fixation.

MIS transforaminal lumbar interbody fusion

The TLIF is a versatile surgical procedure modified from the posterior lumbar interbody fusion (PLIF) and pioneered by Harms and Rolinger in 1982[45]. Transforaminal lumbar interbody fusion (TLIF) utilizes the principles of load sharing to provide a circumferential fusion consisting of an anterior column support and a posterior tension band. It is designed to restore lumbar lordosis, widen neural foramina, restore disc height and indirectly relieve spinal stenosis. TLIF has been effective in the treatment of lumbar spondylosis with or without spondylolisthesis and has also been used successfully

in the treatment of lumbar degenerative disc disease, recurrent lumbar disc herniation and complex lumbar stenosis. One of the main disadvantages to TLIF is the significant postoperative morbidity due to the extensive paraspinal muscle and soft tissue dissection and retraction required in order to provide access to the vertebral column. This approach-related morbidity can potentially affect short- and long-term patient outcomes due to increased postoperative pain, delayed rehabilitation and impaired spinal function.

MIS TLIF was first described by Foley *et al*[46] in 2003 and has since become an increasingly popular MIS method to achieve lumbar arthrodesis[47-50]. MIS TLIF has been shown to have short- and long-term clinical outcomes comparable to open TLIF with the additional benefits of decreased postoperative pain, decreased EBL, faster recovery times, reduced postoperative narcotic use, faster postoperative ambulation and shorter LOS[51-54] (Table 1).

Seng *et al*[51] retrospectively analyzed 40 cases of MIS TLIF compared to 40 open TLIFs and compared fluoroscopic times, operative times, EBL, LOS, postoperative narcotic use, complication rates and patient outcomes. The authors found a statistically significant increase in fluoroscopic times in the MIS TLIF group (MIS: 55.2 s, open 16.4 s, $P < 0.001$) as well as a statistically insignificant increase in operative times for the MIS TLIF group (MIS: 185 min, open: 166 min, $P = 0.085$). MIS had less EBL than open (127 cc *vs* 405 cc, $P < 0.001$). Postoperative morphine use for the MIS group was significantly less than the open group (8.5 mg *vs* 24.2 mg, $P = 0.006$). The authors also found that patient in the MIS TLIF group ambulated on average 1.5 d earlier ($P < 0.001$) and had an overall shorter LOS (MIS: 3.6 d, open: 5.9 d, $P < 0.001$). The overall complication rate was 15% for the MIS group and 20% for the open group, however this did not reach statistical significance ($P = 0.774$). Fusion rates, assessed by the Bridwell classification, showed that grade 1 fusion was achieved in 97.5% of both groups at 5 years. Both groups showed significant improvement in ODI, neurogenic symptom score, back and leg pain and SF-36 scores at follow-ups of 6 mo up to 5 years with no significant differences between them.

Parker *et al*[55] prospectively evaluated 100 patients undergoing TLIF (50 MIS *vs* 50 open) for back-related medical resource use, missed work, and QALY. The authors found that LOS and time to return to work were less for MIS compared to open TLIF ($P = 0.006$ and $P = 0.03$, respectively). MIS and open TLIF patients demonstrated similar improvements in patient-reported outcomes assessed. MIS was associated with a reduction in mean hospital cost of $1758, indirect cost of $8474, and total 2-year social cost of $9295 ($P = 0.03$), but similar 2-year direct health care cost and QALYs gained. The authors concluded that while both MIS and open TLIF are effective treatments for degenerative spondylolisthesis, MIS TLIF may represent a valuable and cost-saving advancement from a societal and hospital perspective.

Disadvantages of the MIS TLIF are related to the decreased visualization of the surgical field and a steep learning curve for the procedure resulting in increased fluoroscopic times and operative times which may be more significant in less experienced surgeons.

MIS direct lateral approaches

The lateral transpsoas, retroperitoneal approach, also known as extreme lateral interbody fusion (XLIF) or direct lateral interbody fusion (DLIF) is a minimally invasive technique that has become an increasingly common method to achieve fusion in the lumbar spine. This MIS approach was intially described in by Pimenta[56] (DLIF) in 2001, and later by Ozgur *et al*[57] (XLIF) in 2006. The MIS direct lateral approach differs from the traditional anterior lumbar interbody fusion (ALIF) and open posterior interbody fusion techniques in several important ways. In addition to being an MIS technique, the direct lateral approach requires the patient to be in the lateral decubitus position. The technique utilizes specialized retractors allowing for direct visualization of the surgical approach corridor. Continual neurophysiologic monitoring and fluoroscopic guidance during the approach phase of the procedure is necessary as the psoas splitting technique exposes the lumbar plexus and predisposes it to injury, which can result in psoas muscle weakness and thigh numbness[58,59].

Initial studies evaluating the safety and postoperative results of the MIS transpsoas approach concluded that the MIS technique was safe and allowed for exposure of the lumbar spine without mobilization of the great vessels or sympathetic plexus[60,61].

Smith *et al*[62] compared the long term outcome of XLIF compared to ALIF in a group of 202 patients (115 XLIF *vs* 87 ALIF) and found that the overall general surgical complication rate was significantly lower for XLIF compared to ALIF (8.2% *vs* 16.7%). Rodgers *et al*[63] described the complications in a large prospective series of 600 patients who underwent XLIF. The authors found the overall incidence of perioperative complications was 6.2% (1.5% in-hospital surgery-related, 2.8% in-hospital medical events, 1.0% out-of-hospital surgery-related, and 0.8% out-of-hospital medical events). There were no wound infections, no vascular injuries, no intraperitoneal visceral injuries and a 0.7% transient postoperative neurologic deficit rate. These complication rates compared favorably to the ALIF risk of vascular injury (1.9%-3%)[64-66]. Another major risk of open ALIF approach is retrograde ejaculation, occurring in 0.6%-4.5% of men[67]. There are currently no reports of retrograde ejaculation following %g MIS lateral interbody fusion which can be attributed to the fact that the sympathetic plexus is not mobilized during the transpsoas approach. Motor deficits after MIS lateral interbody fusion have been reported to range from 0.3%-2.9% with the majority of cases resolving spontaneously within three months[63,68,69]. These rates are comparable to the

reported motor deficit rates after PLIF (1.0%-6.1%) and MIS TLIF (4.1%) procedures[70-73].

Rodgers *et al*[74] retrospectively compared lumbar fusion outcomes in geriatric patients over 80 years of age who underwent XLIF or open PLIF. The authors observed a significantly lower complication rate in the XLIF group compared to the open TLIF group (7.5% *vs* 60%) we well as less blood loss (hemoglobin change, 1.4 g *vs* 2.7 g), a lower transfusion rate (0% *vs* 70%) and shorter LOS (1.3 d *vs* 5.3 d). The authors also described a lower overall mortality rate in the lateral interbody group compared to the open PLIF group (2.5% *vs* 30%).

Deluzio *et al*[75] retrospectively reviewed 210 patients (109 MIS *vs* 101 open) who underwent 2-level lumbar spine fusion from L1-2 to L4-5. They found the average LOS in the MIS group to be 49% shorter than in the open group (1.2 d *vs* 3.2 d). The authors noted that the average cost for the entire perioperative period, including both surgical and post-surgical costs out to 45 d, showed an average savings of 9.6% or $2563/patient in the MIS group.

The MIS lateral interbody fusion appears to present a safe and effective technique for treating degenerative lumbar disorders (Table 1). Long-term outcome studies and cost-analysis and value studies are needed to further clarify the benefits of this MIS approach.

CONCLUSION

In the recent years, there has been a growing trend in MIS approaches for the treatment of degenerative diseases of the lumbar spine. Although traditional open approaches are still performed by the majority of spine surgeons, the body of evidence supporting the safety and efficacy of MIS approaches in appropriately selected patients is growing. MIS approaches for lumbar microdiscectomy, laminectomy, and lumbar interbody fusion by way of the transforaminal or direct lateral approach have shown favorable complication profiles and clinical outcomes compared to traditional open approaches. MIS interspinous process devices have shown poor long-term outcomes as well as high complication and reoperation rates.

While the disadvantages of MIS techniques are the steep learning curve, narrow operative corridor and diminished visual field, these are outweighed by the benefits of MIS techniques in many instances. Going forward, long-term outcome studies and cost-effectiveness studies will be needed to fully assess the benefits of MIS techniques for treating degenerative disease of the lumbar spine.

Abstract

Chronic kidney disease and its worsening are recurring conditions in chronic heart failure (CHF) which are independently associated with poor patient outcome. The heart and kidney share many pathophysiological mechanisms which can determine dysfunction in each organ. Cardiorenal syndrome is the condition in which these two organs negatively affect each other, therefore an accurate evaluation of renal function in the clinical setting of CHF is essential. This review aims to revise the parameters currently used to evaluate renal dysfunction in CHF with particular reference to the usefulness and the limitations of biomarkers in evaluating glomerular dysfunction and tubular damage. Moreover, it is reported the possible utility of renal arterial resistance index (a parameter associated with abnormalities in renal vascular bed) for a better assesment of kidney disfunction.

Key words: Heart failure; Biomarkers; Doppler; Renal resistance index; Chronic kidney disease

Core tip: In the clinical setting of chronic heart failure the evaluation of renal dysfunction is essential. This review revises the currently available markers of renal function in chronic heart failure for a better characterization of renal function. Moreover, it is discussed the potential utility of a Doppler derived parameter, the renal resistance index, which is associated with abnormalities in the kidney vascularization.

Evaluation of chronic kidney disease in chronic heart failure: From biomarkers to arterial renal resistances. *World J Clin Cases* 2015; 3(1): 10-19 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/10.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.10

INTRODUCTION

Subjects with chronic heart failure (CHF) often present

chronic kidney disease (CKD) as well as worsening of renal function (WRF), which are both responsible for a poor outcome[1-3]. Over the past few years interest in this link between the kidney and heart has increased as these organs share many pathophysiological mechanisms, and are therefore able to negatively affect each other. This reciprocal influence has recently been defined as cardiorenal syndrome[4].

In this clinical setting the pathophysiological background underlying renal impairment is, in part, different when acute and chronic heart failure are considered. In acute decompensated heart failure (ADHF) acute kidney injury (AKI) can often occur[5]. Both low cardiac output and venous congestion are the principal determinants of WRF. When cardiac output decreases, renal perfusion and, consequently, glomerular filtration rate are reduced. On the other hand, venous congestion is the cause of a rise in efferent arterioles and end glomerular capillary pressure thus inducing a decrease in net filtration pressure, an increase in interstitial pressure with damage to tubules[6].

In CHF patients, abnormalities in cardiac function lead to a gradual WRF rather than AKI and a steady decrease in renal perfusion due to low cardiac output which is associated with micro and macrovascular disease[5]. However, also the presence of increased central venous pressure in CHF can favour the occurrence of WRF[7,8]. Finally, neuro-hormonal activation further enhances pathophysiological mechanisms leading to WRF[1].

On the basis of these considerations it is clear that in ADHF and CHF patients the evaluation of kidney function is extremely relevant. The aim of this review is to revise the parameters currently used to evaluate renal function in the CHF clinical setting and discuss the usefulness and limitations of biomarkers in evaluating glomerular dysfunction and tubular damage. Moreover, it is reported the possible utility of renal arterial resistance index (a parameter associated with abnormalities in renal vascular bed) for a better assesment of kidney Dysfunction.

ESTIMATION OF GLOMERULAR FUNCTION

Glomerular filtration rate and serum creatinine

Currently glomerular filtration rate (GFR) is the most used index to assess kidney function. It measures kidney filtration capacity and all the guidelines on heart failure recommend its routine use in CHF patients[9,10]. GFR can be estimated using renal clearance of an exogenous substance (inulina or I-iothalamate), however, even though this approach is more accurate, it is limited as it is expensive and time consuming. Consequently, GFR estimation is generally performed using an endogenous marker, *i.e.*, serum creatinine[11]. Creatinine is produced in the muscles from creatine phosphate and it is removed by kidneys through glomerular filtration, but also by proximal tubular secretion.

The traditional method of measuring the clearance of creatinine requires a 24 h urine sample, which can be difficult for patients to perform and is often not done correctly. Therefore GFR is generally estimated by using serum creatinine levels[9]. For this purpose, Cockroft-Gault (CG), simplified Modification of Diet in renal disease (MDRD) and Chronic Kidney Disease Epidemiology Collaboration (CKD EPI) are the most widespread equations. These equations include creatinine serum levels, age, gender, race and, in CG, weight. However, they present an imperfect performance: GFR is underestimated by MDRD and CKD EPI and overestimated by CG, particularly at lower creatine serum levels[11].

Smilde *et al*[12] were the first to validate these creatinine based equations in a large cohort of CHF patients. In particular, they showed that GFR assessed by MDRD formula is underestimated in patients with normal and near normal values and overestimated in patients with worsening renal function. MDRD has a good prognostic significance, but is lower than that of the real GFR.

More recently the CKD EPI formula has been introduced. It is currently the equation most used to evaluate GFR in CKD as it has been found to be more accurate than MDRD in patients with a preserved renal function[13,14]. Moreover, the metanalysis by Matsushita *et al*[15] showed that CKD EPI formula allowed a better risk stratification for mortality and end stage renal disease in a general population and in patients with cardiovascular diseases.

Valente *et al*[16] first evaluated the role of this equation in the setting of CHF, showing that CKD EPI classifies KDOQI stages more accurately than the MDRD equation, especially in patients with a higher GFR. Furthermore, in the metanalysis of McAlister *et al*[17] the EPI formula was more accurate in estimating the risk of patients with CHF. According to these studies the CKD EPI formula is the preferred method to estimate GFR in CHF patients, particularly in those with preserved or moderately impaired renal function.

Creatinine serum levels and GFR are also used to estimate WRF. In CHF, WRF has generally been evaluated by assessing changes in creatinine[18]. In particular, an increase of > 0.3 mg/dL and/or > 25% between two time points[3] have been shown to be related to a worse outcome, hospitalizations for heart failure and higher mortality[19-23]. However, a rise in serum creatinine could be not associated with a significant reduction in GFR. A patient presenting higher baseline values of serum creatinine will show a less marked change in GFR than a patient with lower baseline values. Also the use of changes in GFR in order to assess WRF present some limitations due to the slight fluctuations in GFR which are common. For this reason current guidelines suggest that changes of 25% or more in estimated GFR should be considered as being associated with a change in GFR category[24].

Although creatinine serum levels and estimated GFR represent the corner stone in the evaluation of renal function and its worsening, several factors influencing the creatinine value and limiting its derived measures

should also be considered. Creatinine values show a significant between-person and within-person variability, they are influenced by age, diet, gender and body mass. Moreover, when kidney filtration capacity decreases, GFR can be overestimated because of creatinine tubular active secretion[25]. Finally, in CHF patients there are several factors that can affect the validity of equations used to estimate GFR, such as the hemodynamic component of renal dysfunction, drugs interfering with renal function and the loss of muscle mass that is frequent in the end stages of the disease[12].

It is also worth noting that the kidneys use only part of their filtering capacity. A normal GFR could subtend an impairment in this increasing filtration capacity, in other words it could be observed in kidneys with a reduced renal reserve[26].

In order to avoid the limitations of creatinine, new biomarkers estimating glomerular function, such as Cystatin C, have been introduced.

Cystatin C

This is a protein of cysteine proteinase inhibitor family (13 kdal) which is secreted by all cells with nucleus. It passes freely through the glomerular basement membrane and then it is reabsorbed, but not secreted in the tubules. As a consequence, it is an ideal marker of kidney filtration capacity. Moreover age, gender, food and body mass affect less its serum levels[27]. The only clinical conditions that can influence it are inflammatory status, the use of corticosteroids and thyroid diseases[28,29]. Several studies have shown that, in patients with moderate renal impairment, Cystatin C serum levels estimate GFR better than the equations based on creatinine serum levels[30,31].

In fact the KDIGO guidelines[32] for CKD management recommend assessing Cystatin C in patients with eGFRcr of 45-60 mL/min per 1.73 m^2 , on condition that they don't present other manifestations of CKD, such as albumin-creatinine ratio > 30 mg/g.

Formulas based on Cystatin C values have also been presented in order to obtain an estimate of GFR thus facilitating the clinical use of this marker. Moreover, equations based on combined creatinine-cystatin serum levels give a more accurate estimate of GFR than those based on each single level[33,34].

Cystatin C has also been demonstrated more accurate than creatinine in stratifying the risk of mortality and cardiovascular events in old subjects[35] and people with coronary artery disease[36]. High levels are also predictors of heart failure onset[37]. It is likely that the high Cystatin C levels reflect a mild or moderate decrease in renal function that is not detected by creatinine[33].

There are limited data on the role of Cystatin C in CHF[38-40]. Arimoto *et al*[38] showed the usefulness of Cystatin C in prognostic stratification of mild or moderate CHF. Moreover, Cystatin C has been found to better estimate the increased risk of cardiovascular death in elderly affected by CHF[39] as well as in patients with preserved renal function[40].

Although Cystatin C could be an interesting marker for an early assessment of renal function and for risk stratification in CHF, at present it is not widely used to estimate GFR. This is due to the widespread and consolidated use of creatinine, as well as to the fact that the Cystatin C measurement is more expensive, even if other markers, such as NT proBNP or troponin, have a similar cost[32].

Microalbuminuria

Albumin is the protein with the highest concentration in serum but has a low concentration in urine because of its large size, the selectivity of the glomerular filtration barrier and tubular reabsorption[11]. An increased albumin urinary excretion is a recognized early marker of kidney damage and its quantification is used for monitoring patients with CKD as well as for estimating the risk of kidney disease progression[24], as shown in Table 1. The urinary excretion of albumin is currently evaluated by calculating the albumin-to-creatinine ratio (UACR) in urine samples. An UACR < 30 mg/g is defined as normoalbuminuria, a UACR between 30 and 299 mg/g as microalbuminuria, and a UACR > 300 mg/g as macroalbuminuria[41].

Microalbuminuria has been shown to be associated not only with CKD progression, but also with an increased risk of cardiovascular death in the general population as well as in subjects with diabetes and hypertension[42].

The greater prevalence of microalbuminuria in CHF subjects than in the general population was demonstrated for the first time by Van der Wall[43]. In CHF albuminuria and reduced GFR can coexist, but sometimes only one of the conditions was found because they are caused by different pathophysiological mechanisms. Albuminuria can be the consequence of damage to the glomerular basement membrane secondary to endothelial dysfunction and inflammatory cytokine activation[44]. Moreover, it can be caused by hyperfiltration due to a reduction in the number of nephrons. This condition could occur in the event of a post glomerular ischemia which leads to hypoxia, oxidative stress and tubulointerstitial injury[45]. Other mechanisms involved in the genesis of microalbuminuria could be renal congestion[46,47] and reduced tubular reabsorption of albumin as a consequence of tubular dysfunction[48].

The large substudies from CHARM and GISSI HF trials[49,50] have confirmed the high prevalence of micro and macroalbuminuria in CHF patients (microalbuminuria was more common than macroalbuminuria) and its association with a worse outcome. HF patients with higher albumin urinary levels showed a greater mortality and an increased risk of HF hospitalizations. This prognostic value was independent from serum creatinine levels, eGFR and the comorbidities that worsen renal filtration function. Another important finding of these studies was that mortality risk increased with the increase in albumin excretion, even in the normal range (< 30 mg/g) suggesting that this parameter is a continuous measure of risk.

All of these studies showed that albumin urinary excretion is not affected by treatment with angiotensin

Table 1 Risk of chronic renal disease progression according to K/DOQI clinical practice guidelines[25]

Glomerular filtration rate categories			Microalbuminuria		
			A1 normal to mildly increased < 30 mg/g	A2 moderately increased 30-299 mg/g	A3 severely increased > 300 mg/g
1	Normal or high	> 90 mL/min	Low risk	Moderately increased risk	High risk
2	Mildly decreased	60-89 mL/min			
3a	Mildly to moderately decreased	45-59 mL/min	Moderately increased risk	High risk	Very high risk
3b	Moderately to severely decreased	30-44 mL/min	High risk	Very high risk	Very high risk
4	Severely decreased	15-29 mL/min	Very high risk	Very high risk	Very high risk
5	Kidney failure	< 15 or dialysis mL/min	Very high risk	Very high risk	Very high risk

receptor blockade, contrary to that observed in patients with diabetes, hypertension and renal disease. This may be due to the different pathophysiological mechanisms underlying albuminuria in CHF[51].

MARKERS OF TUBULAR DAMAGE

Different markers reflecting tubular damage have been studied in order to obtain a more accurate evaluation of renal function.

The Neutrophil gelatinase-associated lipocalin (NGAL) is a lipocalin protein (25 kdal), which is produced by the kidney, but also by other organs (the trachea, lung, stomach and colon). After being filtered through the glomerulus, NGAL is reabsorbed in the proximal tubule. When the proximal tubule is damaged, filtered NGAL can not be totally reabsorbed and its urinary levels increase[52]. Furthermore, during tubular damage NGAL mRNA is transcribed and overexpressed in loop of Henle and collecting duct and its plasma and urinary levels rise considerably[53,54]. NGAL plasma levels can also be increased by systemic diseases such as inflammation and cancer, but urinary levels are less influenced by these conditions[54].

The N-acetyl beta glucosaminidase (NAG) is a protein produced in the proximal tubular cells which is excreted into the urine when a tubular injury occurs[55]. Its urinary levels are increased in acute and chronic kidney disease[56] but also in diabetes and hypertension.

The Kidney injury molecule (KIM1) is a transmembrane glycoprotein and its expression in proximal tubule cells increases significantly after hypoxic or nephrotoxic tubular injury[57]. Its urinary levels are high also in patients with polycystic kidney[58] and renal cancer[59].

NAG, NGAL and KIM 1 have been widely studied in the setting of AKI (Acute Kidney Injury),where they have had a diagnostic and prognostic role, and show an increase 24 h prior to creatinine[60-63]. Recently, the utility of these markers in cardiorenal syndrome[25] has been evaluated by a number of studies, mainly involving patients with ADHF[64-67].

On the other hand, there are few studies which examine these markers in patients with CHF[68]. Damman *et al*[69] have shown a significant increase in urinary NGAL levels in these patients when compared to healthy controls, suggesting that renal dysfunction in CHF is characterised not only by a decrease in GRF and an increase in urinary albumin excretion but also by tubular damage. The renal perfusion decrease that occurs in CHF produces a GRF reduction and determines hypoxia leading to tubular damage.

Another study by Damman *et al*[70] showed that NGAL urinary levels were not correlated with prognosis, while urinary NAG and KIM1 were associated to a worse outcome (death, heart failure, hospitalisations and heart transplantation) and have an additional prognostic value compared to GRF. According to the authors, one explanation for this difference could be that NAG and KIM1 are produced in two different parts of the nephron and damage to the proximal part of the tubule may be more significant for the prognosis.

Finally, in a substudy of the GISSI HF trial[71] it has been confirmed that markers of tubular damage were strongly associated with HF hospitalizations and all cause mortality. In particular, NAG was the only marker remaining significantly correlated with a worse prognosis at multivariate analysis. This association was independent from estimated GFR and urinary protein excretion.

Markers of tubular function could be also related to WRF. In another substudy of the GISSI HF trial[47] patients with WRF had higher NGAL, NAG and KIM1 levels. These outpatients with WFR had a worse outcome. A possible explanation could be that the increase in these markers is caused by renal hypoxia, leading to a progressive deterioration of renal function that makes the kidney more vulnerable. At multivariate analysis KIM1 was the strongest independent predictor of WRF among all associated variables (eGFR and albuminuria included).

Beside NAG, NGAL and KIM 1, also other markers of tubular damage have been proposed.

IL 18 is a cytokine secreted by proximal tubular cells. When AKI occurs, it has been shown to increase more quickly than serum creatinine levels. It also increases in inflammatory status, therefore it is not highly specific[72,73]. Mallat *et al*[74] showed that, in ADHF, IL 18 plasma levels increased and were higher in patients who died during follow-up.

The fatty acid-binding proteins (FABPs) are proteins able to bind free fatty acids. Among the several tissue-specific isoforms, urinary levels of liver FABP (FABP-1)

and heart FABP (FABP-3) can reflect AKI, because excreted when an ischemic tubular injury occurs[25]. Moreover, serum FABP levels have been associated to worse outcome in CHF patients[75].

RENAL CIRCULATION AND RENAL RESISTANCE INDEX

Markers of GFR and tubular damage offer information about the status of nephrons. However, kidney circulation also plays a key role in renal function. Consequently, the evaluation of renal circulation could provide useful parameters to add to the information obtained from the above mentioned biomarkers.

Renal circulation

The kidney is a highly perfused organ, receiving 22% of cardiac output at rest[76]. After entering the hilum, the renal arteries divide into the interlobar, arcuate and interlobular arteries. Afferent arterioles originate from interlobular arteries, leading to the glomerular capillaries, and then to efferent arterioles. Efferent arterioles are followed by a second capillary network, *i.e.,* peritubular capillaries, and finally by the venous system. The regulation of renal blood flow (RBF) is not dependent on oxygen demand, but on reflex and neurohormonal mechanisms underlying the control of afferent and efferent arteriole tone. These mechanisms are not discussed in this review, however it is worth noting that arteriole tone changes are the main determinants of arterial renal resistance. The arteriolar tone is determined by reflex mechanisms, such as myogenic effect and tubular-glomerular feedback, and neurohormonal mechanisms. Of the neurohormonal systems, sympathetic and renin-angiotensin-aldosterone are those which most influence efferent arteriolar tone, determining vasoconstriction and increased water and sodium reabsorption. Endothelin, nitric oxide, prostaglandins, bradykinin and natriuretic peptides are also involved in the regulation of arteriolar tone.

The self-regulation of RBF allows renal perfusion to be kept constant through a wide range of arterial pressure (70-180 mmHg). On the other hand, changes in venous renal pressure could affect RBF more than those of arterial pressure. In 1931 Winton[77] evaluated the reduction of RBF by changing arterial and venous pressures in isolated kidneys. The results demonstrated that the changes were greater when renal venous pressure had been increased. More recent studies have confirmed the association between central venous pressure and renal function worsening in acute, as well as in chronic heart failure[77-79]. The mechanisms by which central venous pressure could affect RBF are different. In particular, it can increase both intra-abdominal pressure and renal venous pressure. This leads not only to an increase in capillary pressure and a reduction in artero-venous gradient but also to greater interstitial pressures and, consequently, greater arterial renal resistances.

Functional abnormalities of RBF and of renal resistances due to neurohormonal and hemodynamic changes could also lead to structural changes. Chade[76] demonstrated that the functional increase in renal vascular resistances could lead to ischemia, endothelial dysfunction, cytokine production and finally to fibrosis. This cascade of events causes a renal vascular rarefaction which could further induce CKD worsening.

On the basis of this pathophysiological background we can conclude that an increase in arterial renal resistances could represent an altered neuro-hormonal status, an increased central venous pressure, but it could also reflect the presence of parenchymal abnormalities and vascular rarefaction which favour CKD progression.

Arterial renal resistance index

Arterial renal resistance index (RRI) is a non-invasive measurement of renal arterial resistance which is easily evaluated by Doppler technique (Figure 1). It is calculated using Pourcelot's formula[80] since the peak systolic velocity and the end-diastolic velocity are obtained. Doppler evaluation of renal arteries is generally performed at the level of one or more interlobar arteries. In healthy adult subjects the RRI mean value is around 0.60 with no significant differences between the two kidneys[81]. An RRI greater than 0.70 is generally considered abnormal[82].

RRI has been found to be associated with renal parenchymal abnormalities. Platt e coll[83] first demonstrated the relationship between an increased RRI and parenchymal and vascular abnormalities assessed by renal biopsies. Later RRI has been found to be strongly associated with arteriolosclerosis, glomerulosclerosis, interstitial renal fibrosis and tubulo-interstitial lesions[84-88].

Our study group evaluated the independent predictors of RRI values in a large group of CHF outpatients with reduced ejection fraction. In a multivariate logistic regression model including univariate predictors, only age, systolic pulmonary pressure, central venous pressure, GFR, diabetes, logarithm of NT-proBNP, pulse arterial pressure and NYHA class remained significantly correlated to RRI. These results help to confirm the pathophysiological background responsible for the modification of RRI in CHF. In particular, RRI seems to carry information about renal artery abnormalities and/or alterations of arterial stiffness, as suggested by the correlation we found with the related parameters such as age, diabetes and pulse pressure. Moreover, the relationship between RRI and central venous pressure highlights the role of intra abdominal pressure and renal venous pressure in determining an increase in renal arterial resistances[89].

In a group of patients with CHF and preserved left ventricular ejection fraction, Ennezat *et al*[90] first demonstrated the significance of RRI in predicting prognosis. In our series of outpatients affected by CHF (mainly due to a reduced left ventricular ejection fraction), we have also demonstrated the prognostic significance of RRI[89]. The combined end-point that we considered was death, urgent heart transplantation or hospitalization due to heart failure worsening. RRI was associated with events in an univariate Cox regression model (HR

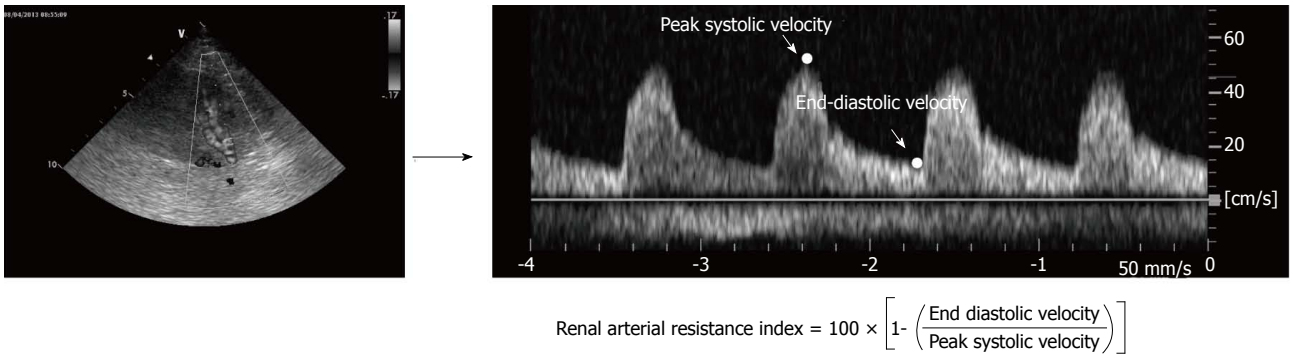

Figure 1 Calculation of Renal arterial Resistance Index. Renal arterial Doppler was performed using a 4 MHz probe, with the patient in the sitting position and using a posterior approach to visualise the kidney. The course of the right or left kidney segmental arteries is visualised by color Doppler flow and, at the middle tract level of the best one visualised, pulsed Doppler is performed. Peak systolic velocity and end diastolic velocity are used to calculate the renal arterial resistance index according to Pourcelot's formula.

= 1.14; 95%CI: 1.09-1.19; $P < 0.001$; C-index: 0.77), but also in a multivariate model (HR = 1.08; 95%CI: 1.02-1.13; $P = 0.004$; C-index: 0.86) correcting for the independent predictors, i.e. LVEF, GFR and logNT-proBNP. Moreover, with the addition of RRI, the reclassification model showed an important rise according to both category-free net reclassification improvement NRI (47%; 95%CI: 13%-80%; $P = 0.006$) and integrated discrimination improvement IDI (0.034; 95%CI: 0.006-0.061; $P = 0.016$). Likewise, in our series, RRI has been also found to be independently associated with an increased risk of death (at multivariate analysis: HR = 1.06; 95%CI: 1.01-1.12; $P = 0.023$; C-index = 0.783)[91].

The pathophysiological factors influencing RRI offer an explanation to the incremental prognostic value of this parameter when added to a model already including GFR. In addition to GFR, RRI could provide further information about renal function by reflecting not only glomerular function but also the other factors which influence the progression of kidney disease. Therefore, RRI could complete the information carried by GFR and allow a better characterization of renal dysfunction in CHF.

This is also supported by the fact that in our series RRI was able not only to predict heart failure progression but also worsening of renal function. At multivariate analysis a RRI > 70 was independently associated with an increase in creatinine > 0.3 mg/dL[92], regardless of baseline GFR values.

CONCLUSION

The evaluation of renal dysfunction is a cornerstone for CHF patients' management. GFR estimation is, at present, considered the best parameter to assess overall kidney function and it is recommended for routinely use. However, serum creatinine, traditionally used to estimate glomerular filtration rate, has several limitations. As a consequence the use of other parameters to evaluate hyperfiltration, tubular function and hemodynamic status could be useful in order to better define renal function. To this purpose RRI, an echo-Doppler derived parameter, which reflects abnormalities of the renal vascular bed, seems to be very promising as it carries an independent and incremental information to detect patients with worse prognosis and increased risk of WRF.

Abstract

Bioterrorism has received a lot of attention in the first decade of this century. Biological agents are considered attractive weapons for bioterrorism as these are easy to obtain, comparatively inexpensive to produce and exhibit widespread fear and panic than the actual potential of physical damage. *Bacillus anthracis* (*B. anthracis*), the etiologic agent of anthrax is a Gram positive, spore forming, non-motile bacterium. This is supposed to be one of the most potent BW agents because its spores are extremely resistant to natural conditions and can survive for several decades in the environment. *B. anthracis* spores enter the body through skin lesion (cutaneous anthrax), lungs (pulmonary anthrax), or gastrointestinal route (gastrointestinal anthrax) and germinate, giving rise to the vegetative form. Anthrax is a concern of public health also in many countries where agriculture is the main source of income including India. Anthrax has been associated with human history for a very long time and regained its popularity after Sept 2001 incidence in United States. The present review article describes the history, biology, life cycle, pathogenicity, virulence, epidemiology and potential of *B. anthracis* as biological weapon.

Key words: Anthrax; *Bacillus anthracis*; Biological warfare; Epidemiology; Infection; Public health

Core tip: Anthrax is primarily a zoonotic disease which is caused by *Bacillus anthracis* (*B. anthracis*) and for human it has both, public health as well as biodefence importance. Anthrax has been known since ancient times; however it acquired attention as biological warfare disease after 2001 incidence in United States. *B. anthracis* is supposed to be the most potent BW agent because of its hardy spores, various modes of infection and high mortality rate. Understanding about the life cycle, virulence, pathogenicity and detection and diagnosis of *B. anthracis* is important to curb the disease.

Goel AK. Anthrax: A disease of biowarfare and public health importance. *World J Clin Cases* 2015; 3(1): 20-33 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/20.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.20

INTRODUCTION

Bacillus anthracis (*B. anthracis*), the causative organism

of anthrax is a Gram-positive spore forming bacillus commonly found in soil of endemic areas. Anthrax is a zoonotic disease which is mainly associated with herbivores and domestic animals. The disease occurs regularly in countries where widespread vaccination of animals is not practiced. Human anthrax is less common and usually spreads to human populations through close occupational proximity to infected livestock by handling infected domestic animals including cattle and goats or their products like skin, meat, hides and bones. This bacterium can infect humans by cutaneous, gastrointestinal, or respiratory routes[1]. *B. anthracis* exists in two forms, vegetative cells (inside the host) and spores for persistence in the soil or environment[2]. In the soil, *B. anthracis* is generally found in endospore form where it can remain viable for decades in this form. As *B. anthracis* forms spores that can be aerosolized and sprayed to spread disease, the potential use of this bacterium as a bioterrorism agent has long been suspected. However, the events in 2001 have confirmed that bioterrorism is no longer a threat but a reality[3]. Owing to its highly pathogenic nature and spore forming capability, *B. anthracis* is considered as one of the most important biological warfare agents[4,5].

There are two major virulence factors in *B. anthracis*, poly-γ-D-glutamic acid capsule and a tripartite toxin[6]. Pathogenic *B. anthracis* bacteria produce capsule which mimics the immune system of host by masking the bacteria from macrophages[7]. The tripartite toxin of anthrax consists of three independently secreted proteins, *i.e.,* protective antigen (PA), lethal factor (LF) and edema factor (EF)[8,9]. Anthrax toxin is a binary A-B toxin, where PA acts as the binding (B) domain and LF and EF act as active (A) domains individually to form the binary toxins lethal toxin (LTx) and edema toxin (ETx), respectively[10]. After ingestion or coming in contact with skin lesions, bacteria multiply and within a few days or weeks cause the death of human or animal host.

Anthrax is not a major issue of health in developed countries as only a few incidences are reported from such countries. However, for developing countries whose economy is mainly agriculture dependent, cutaneous anthrax is still a major concern of health. India ranks first in having the world's largest livestock population. Therefore, animal anthrax is common in several regions in India. However, only a few intermittent cases of human anthrax are reported from the Southern states[11]. Human cutaneous anthrax is a concern of public health in some states like Orissa and Andhra Pradesh[12].

HISTORY OF ANTHRAX

Anthrax, caused by *B. anthracis* is a highly contagious and fatal. Anthrax has a long association with human history and was known in Europe (1190-1491 BC) and China (3000 BC). Anthrax was described in the early literature of the Greeks, Romans and Hindus. The name anthrax was derived from the Greek word "anthrakis" which means coal because coal black skin lesions are formed in cutaneous form of anthrax. The description of fifth plague of Egypt, an epidemic of ancient Egypt in the book of Genesis (1491 BC), which exterminated the Egyptian livestock including cattle, sheep, goats, camels, horses and donkeys without affecting the Israelites livestock, may be due to anthrax. The disease described by Virgil (29 BC) in his third Georgics (selection of poems on agriculture and animal husbandry) seems to be anthrax in domestic and wild animals as it was an economically important agricultural disease in Europe during the 16th to the 18th centuries[13].

In 19th century, research on anthrax led to a lot of medical developments. In 1850, Pierre Rayer first described filiform bodies (small rods, about half the length of a red blood corpuscle) in the blood of sheep that had died due to anthrax. Casimir-Joseph Davaine in 1863 suggested that the "corpuscles" were the etiology of anthrax that could be transmitted to sheep, horses, cattle, guinea pigs, and mice by subcutaneous inoculation of infected blood[14]. Tiegel and Klebs in 1864 demonstrated that anthrax-infected blood, if filtered through a clay candle (bacterial filter), lost its infectivity, while the deposit on filter remained infective[15]. These observations in absence of culture of the organism strongly supported the concept that the causative agent of anthrax was a living organism that multiplied in the body, invaded the blood stream, and produced death by septicaemia. Robert Koch derived his three postulates for germ theory of disease considering anthrax as prototype. In 1876, he conclusively proved that *B. anthracis* was the etiological agent of anthrax by applying his postulates for the first time during his research in Wollstein, Germany[16]. Thus, anthrax was the first disease whose causative agent was established as microbial agent. After isolating the anthrax bacteria from skin lesions of sheep, he obtained the pure cultures by growing the bacilli on the aqueous humor of ox's eye, and injected the bacteria into healthy sheep. He performed another experiment by growing pure cultures of rods from the aqueous humor of an ox's eye. By studying, drawing and photographing these cultures, he recorded the multiplication of the bacilli and found that under unfavourable environmental conditions, especially under conditions of oxygen deprivation, they produced round spores within themselves. The spores return to bacilli when growth conditions are favourable, proving the spore formation as self-protective mechanism of *B. anthracis*. Thus, by now it was clear how certain pastures or agriculture areas became dangerous. When any animal dies from anthrax infection, the infected blood and body fluids comes out in soil from the natural orifices of animal. The bacteria, which are in the vegetative form in the blood, convert into spores on exposure to air. These spores are extremely resistant to natural conditions and could remain dormant in the soil for decades. These spores remain available to cause new infections among susceptible animals that graze in the field.

Pasteur *et al*[17] proved the buried cadavers of anthrax

infected animals as important origin of new infections. They further revealed that spores from buried soil could be transported to the upper surface by the activities of earthworms[18]. He also confirmed Koch's discovery of the anthrax germ. He found that chickens were immune to anthrax, and postulated that it was because of high body temperature (43 ℃-44 ℃) of chickens. On lowering the body temperature to 37 ℃, chickens became susceptible to anthrax. For vaccination, Pasteur heated the anthrax germs and inoculated 25 sheep. He used the heated anthrax bacteria to inoculate sheep and found that all sheep survived (only one pregnant sheep died due to some other complications), whereas all un-inoculated sheep died after one or two days of challenge with virulent *B. anthracis*. Pasteur proved that the weakened anthrax lost its virulence but still could confer immunity and this technique was termed as "vaccination". Thus, first live bacterial vaccine was developed for anthrax by Pasteur *et al*[17]. During 1876-1877, a devastating anthrax outbreak affected several sheep and cattle in France's livestock. By that time, rod-shaped *B. anthracis* was established as the causative agent of anthrax by Robert Koch. However, still many people believed that instead of bacterium itself, some toxic substance produced by *B. anthracis* was causing the disease. But, Pasteur finally proved that anthrax was caused by living *B. anthracis* and not by some toxic substance.

Anthrax was also known as woolsorters' disease. Prior to 1837, no specific disease had been associated with wool. However, after that a large number of cases occurred in and around Bradford, England and the name Bradford disease became synonymous with woolsorters' disease. In 1879, Bell proved that woolsorters' disease (now inhalational anthrax) was due to anthrax[19]. This led to institution of Bradford rules which in 1897 became law. Consequently, incidences of inhalation anthrax among sorters decreased significantly. In 1913, Eurich found that blood contamination was the important factor in woolsorters' disease[20]. Blood seemed to serve as a glue to bind anthrax spores to the raw product. Washing of wool removed soil, dried serum and blood but anthrax spores remained adherent. Elimination of inhalation anthrax as an industrial hazard followed passage of the Anthrax Prevention Act in 1919. This law mandated the construction of a decontamination station in Liverpool whereby all dangerous wool and hair products entering England were disinfected with formaldehyde[21].

During 1979-1980, the world's largest ever recorded outbreak of anthrax occurred in Zimbabwe during the civil war. In a two-year period, over 9400 cutaneous anthrax cases, including 182 fatalities were reported. Before the war, anthrax was endemic in Zimbabwe and only a few cases of anthrax were reported. Number of human anthrax cases increased significantly during this period because lack of food due to civil war in country forced people to handle and eat anthrax infected animals. Anthrax being a zoonotic disease, it first appeared in cattle and then spread in human population in all the affected areas of Zimbabwe.

Anthrax has been supposed to be developed for use as a bioweapon during world war-1 and world war-Ⅱ. Recently, in 2001, envelopes containing the *B. anthracis* organism were sent through the mail to different dignitaries in United States affecting 22 people. This was considered as an act of bioterrorism[3].

BIOLOGY OF *B. ANTHRACIS*

B. anthracis is a Gram positive, rod-shaped, aerobic, facultative anaerobic, sporulating, capsulated bacterium. It measures 1-1.2 μm in width and 3-5 μm in length. Under microscope, it appears as chain like structure. Though an aerobic organism, yet *B. anthracis* can survive in anaerobic environment because of its property of sporulation. In fact, it can survive for several years in soil, air and water in the form of spores. Unaffected to harsh environment, spores are resistant to high temperature, pressure, pH, chemicals, UV and deficiency of nutrients[22-24]. The capsule is composed of γ-linked poly-D-glutamic acid which gives mucoid appearance to the colony. Formation of capsule decides the virulence of bacteria. The capsule itself is non-toxic and doesn't provoke immune system of the host. However, it contributes significantly in establishing the infection, once the organism escapes phagocyte action, later phase of disease is controlled by anthrax toxin[25].

Pathogenic strains of *B. anthracis* harbour two virulent plasmids[26]. Plasmid *pXO1* carries toxins encoding genes and plasmid *pXO2* carries capsule encoding genes. Size of *pXO1* is 184.5 kb that harbours three structural genes, *pag* (coding for PA), *lef* (coding for lethal factor) *and cya,* coding edema factor[1]. Plasmid *pXO1* also encodes *atxA* gene which regulates the expression of gene encoded on *pXO1* and *pXO2*. Another plasmid pXO2 is 95.3 kb in size and carries the genes for capsule production, degradation and regulation. Genes *capB, capC and capA* code for capsule synthesis, and gene *dep* codes for its degradation[1]. A gerX operon is also present on plasmid *pXO1* and its deletion affects the germination of spores in macrophages. The operon codes for three proteins GerXA, GerXB and GerXC. These proteins are supposed to form a receptor, which specifically detects germinant within the host[27].

POTENCY OF *BACILLUS ANTHRACIS* AS BIOWARFARE AGENT

Anthrax was linked to soil contamination long before the identification of *B. anthracis* as its causative agent[14,16]. Spores can resist prolonged exposure to stress as desiccation, solvents and extreme temperature, pressure, pH, ultraviolet and ionizing radiation[28,29]. Spores of *Bacillus* genus are known to have a half life of about 100 years[30]. Spores are dormant form of the bacterium which returns into vegetative form on receiving the signals for germination. The surprisingly resistant spores have earned the status of potential bio-

terror weapon for anthrax. The possibility to create aerosol from spores makes *B. anthracis* a lethal biological weapon. All the attributes of spores: high resistance to temperature, pressure, pH, ionizing radiations and half life of 100 years make them a suitable bio-terror agent. After production and purification, anthrax spores can be stored in a dry form which remains viable for decades. Spores may survive in the water, soil and on surface for several years. Inhalation of spores causes inhalational anthrax which is the most dangerous form of disease. Inhalational anthrax is dangerous for obvious reasons as initial symptoms resemble to that of flu, making its early diagnosis difficult; by the time disease is correctly recognized it's too late.

The use of microorganisms as a means of waging war or as bioterror agents is becoming a real possibility now around the world. Any biological agent from a large gamut of human infection causing pathogens could be considered a potential biological weapon. However, only a small number of these agents fulfil the desirable criteria like ease of cultivation and dispersal or dissemination for recognition as possible biological weapons. Anthrax spores pose the biggest bioterrorism threat because it is easier to produce and preserve them. Anthrax spores have already been used in United States and in future also it is most likely preferable agent to be used for biothreat because of high case fatality rates, rapid transmission by aerosol and its stability in the environment. The release of any bio-warfare agent by a militant or miscreant would likely be silent and untraceable or nearly so. Therefore, of the recognized possible biological weapons, anthrax bacilli are rated the most lethal.

Naturally, anthrax is a zoonotic disease, which primarily occurs in animals and then spreads to human. Several animal species like cattle, goat and sheep are susceptible to this disease. A major public health preparedness challenge is increasing the importance of recognition of individual, potential sentinel cases of biothreat agent disease. According to CDC norms, *B. anthracis* is placed in high priority- Category A due to its ease of dissemination, high mortality rates, epidemic potential and special preparedness it requires. In 2001, mails deliberately contaminated with *B. anthracis* spores were used to terrorize people and subsequently research for the development of anthrax vaccine speeded up. Moreover, each category A biothreat agent has its unique clinical and diagnostic features and no single system can meet the challenges of all the agents. Besides, anthrax is still a concern of human as well as veterinary public heath in several states of country like India. Bioterrorism itself is an emerging problem for public health. Hence, it is not possible to look into bioterrorism and public health separately. Rather, it is the need of time to give more emphasis on such diseases which have both the potential.

DOSE-RESPONSE RELATIONSHIP

The information on dose-response relationship is prerequisite for assessment of risk of any biothreat agent. The LD_{50} of human inhalational anthrax is not known, but has been estimated from the animal studies and disease outbreaks. After conducting experiments on 1236 cynomolgus monkeys (*Macaca fascicularis*), Glassman estimated the median lethal dose to be 4130 spores with 95%CI range of 1980-8630[31]. Further, he suggested that LD_{25} was associated with a 10-fold decrease in dose *i.e.,* 413 spores. In 1957 in Manchester, 16 susceptible workers were exposed to *B. anthracis* in a goat hair processing mill and 4 persons were infected. Based on the 8-h inhaled dose, LD_{50} of *B. anthracis* was estimated to be 6200-22000 spores[32]. The infectious dose for inhalational anthrax in 50% of susceptible human population (ID_{50}) was estimated to be 8000-50000 spores by biodefense experts from the United States Army Institute of Infectious Diseases (USAMRIID, Fort Detrick, MD)[33]. In 1998, a panel of seven subject matter experts on anthrax calculated the ID_{10}, ID_{50} and ID_{90} as 1000-2000 spores, 8000 to 10000 spores and 50000 to 100000 spores, respectively[34]. Another group extrapolated the lethal dose (LD_{50}) values of 4100 spores[31] and 8000 spores[33] and suggested an LD_{10} of 50 or 98; an LD_5 of 14 or 28, an LD_2 of four or seven, and an LD_1 of one or three spores[35]. Although they did not establish the validity of extrapolation, yet they cautioned about the low number of spores.

Theoretically, even a single spore of *B. anthracis* can cause anthrax. However, in the low dose range, there is high uncertainty between the dose-response relationships of aerosolized *B. anthracis* for human. Recently, on the basis of experimental data on primates and epidemiological data of human anthrax, a new quantitative model known as Exposure-Infection-Symptomatic illness-Death (EISD) has been suggested for the dose-response as well as time course of pulmonary anthrax in human[36]. According to this model, the ID_{50}, ID_{10} and ID_1 of *B. anthracis* spores were 11000 (95%CI: 7200-17000), 1700 (1100-2600) and 160 (100-250), respectively. The ID_{50} (7200-17000) and ID_{10} (1100-2600) confidence ranges produced by this model were remarkably consistent with the corresponding ranges produced by an expert panel surveyed in 1998, *i.e.*, 8000-10000 and 1000-2000, respectively[34]. The confidence range of ID_1 from 100-250 spores as suggested by this model indicates that a threshold of 600 *B. anthracis* spore to human infection is underestimated and infection by even a single spore is overestimated in the literature. This model also suggested the median incubation time from exposure to onset of symptoms. For exposure with ID_{50} of *B. anthracis* spores, it was 9.9 d with 95%CI of 7.7 to 13.1 d, where as for ID_{10} and ID_1, it was 11.8 (95%CI: 9.5-15) d and 12.1 (95%CI: 9.9-15.3) d, respectively.

DIFFERENT STRAINS OF *BACILLUS ANTHRACIS*

Three well known strains of *B. anthracis* are Ames, Sterne and Vollum. Ames is a well studied, highly virulent strain

containing both plasmids, *i.e., pXO1* and *pXO2*. Originally it was isolated from a dead cow in Texas in 1981. Its geographic region is United States and United Kingdom. Another isolate of Ames strain is Florida which was first isolated from a victim of anthrax attack in 2001[37,38]. *B. anthracis* Sterne is a toxigenic but avirulent strain as it carries the anthrax toxin plasmid pXO1 but lacks the capsule forming plasmid pXO2[39]. This strain is generally used for vaccine development for animals. Its geographic region is in Canada[37,38]. In contrast to Sterne, Pasteur strain carries pXO2 plasmid but not pXO1. Vollum is low virulent strain used in research studies and is found in the United Kingdom, Spain and Zimbabwe[37]. Along with Vollum and Sterne, strain V770 is also used for toxin production and various research related studies.

B. anthracis belongs to *Bacillus cereus* sensu lato group, shared by six other species including *B. cereus*, *Bacillus mycoides*, *Bacillus pseudomycoides*, *Bacillus thuringiensis*, *Bacillus weihenstephanensis*, and *Bacillus cytotoxicus*[40]. *B. cereus* primarily causes foodborne illness. Besides, *B. cereus* is considered as an opportunistic pathogen that can cause wound infections, endocarditis and urinary tract infections in humans. Recent studies indicate that a *Bacillus* species other than *B. anthracis* can cause anthrax-like disease and a few *B. cereus* strains have been found to be associated with "anthrax like" infections in human[41,42]. In India, a *B. cereus* strain TF5 was isolated from the tissue fluid of cutaneous anthrax-like skin lesions of a human patient from an anthrax endemic area in India[43,44]. The strain harboured a PA gene, however, the pXO1 or pXO2-like plasmids were not present. Exoproteome analysis exhibiting qualitative and quantitative differences between the two strains indicated an altered regulatory mechanism and putative role of S-layer protein and sphingomyelinase in the pathogenesis of strain TF5[43].

EPIDEMIOLOGY OF ANTHRAX

B. anthracis bacteria are very fragile and susceptible to disinfectant or exposure to moderate temperature. However, *B. anthracis* vegetative cells convert into spores on exposure to air. These spores are highly resistant to heat and to most of the disinfectants. Therefore, post-mortem of anthrax infected animals is never recommended to avoid the exposure of bacteria to oxygen. A peculiar feature of anthrax infection in animals is that blood does not clot and drains from the natural orifices like nose, mouth and bowl. This results in contamination of soil and water with bacteria which ultimately transform into spores[45]. As much as 10^9 *B. anthracis* bacteria may be present in the oozing blood[46]. Even the processed parts and products like leather, hides, wool, *etc.*, of an anthrax infected animal can carry spores for year. The spores can remain viable for a prolonged period in the soil, especially when deposited 15 cm below the upper soil levels.

Environmental and climatic factors have a great influence on the ecology of anthrax[47]. Climatic factors like rainfall and temperature play a pivotal role in incidences of anthrax cases[48]. However, it is not easy to understand the anthrax occurrence and its epidemiology due to large variations in timing of different outbreaks and associated deaths of a particular species even within a single ecosystem[49]. It has been hypothesized that some soil factors like alkaline pH, high organic content, moisture, and ambient temperature (in excess of 15.5 ℃) favor the germination of *B. anthracis* spores into vegetative bacteria, which ultimately results into amplification of number of spores[22]. It has been observed that high pH and high contents of calcium in soil contribute to maintain the spores viable for a longer time. These soil spores cause new infections when come into contact of a suitable new host[22,50,51]. Therefore, alkaline pH of soil, high moisture and organic contents, precipitation and ambient temperature in excess of 15 ℃ are deciding factors for triggering a large anthrax outbreak and can be considered to predict exposure and infection risk of anthrax in a particular area[48]. During grazing, herbivores animals are most likely to be exposed to *B. anthracis* spores by inhalation or ingestion during grazing. It has been observed that *B. anthracis* bacteria need specific nutrients (animal blood, viscera) and physiological conditions and therefore it is very difficult to survive outside a viable host and convert into spores. Moreover, the vegetative cells of *B. anthracis* are poor competitor and are easily killed by other bacterial species outside the host in environment. Moreover, virulence of *B. anthracis* is reduced when grown outside the host and bacteria with reduced virulence will not lead to an outbreak[22].

According to an estimate, every year about 2000 to 20000 human anthrax cases occur globally. Apart from India and Pakistan, anthrax has also been reported from Bangladesh, Zimbabwe, United States, South Africa, Iran, Iraq and Turkey. In India, southern states are more prone to anthrax. Reports of anthrax appear almost every year from Andhra Pradesh, Tamil Nadu and Karnataka but exact figures are not available. In 1980s, there were only 2000 cases reported worldwide most of them were of cutaneous anthrax. Most of the anthrax cases recorded were from the persons involved in industrial occupations related to processing of animal parts and products like meat packing, bone meal processing, tanning of leather and sorting of hair wool[52]. Several outbreaks have been recorded in recent history. Anthrax outbreaks in animals are more prominent and common than humans. From 1991 to 1996, a total of 1612 anthrax outbreaks occurred in India. In Nepal, a total of 222 animals were affected during 19 different outbreaks in 1996[53]. In 1996, about 1570 cases of ruminant anthrax were reported in China. The death of 204 livestock in Australia was reported in 1997[54]. From 1984 to 1989, thousands of wild animals were killed in an anthrax epidemic in Namibia and South Africa[53]. In Iran, about one million sheep were killed during an anthrax outbreak in 1945. In Manchester, United States, a large anthrax epidemic occurred in 1957 in a goat hair processing plant resulting in four fatalities

and nine cases[55]. In Russia during 1979, an unusual, accidental anthrax outbreak in a Soviet military laboratory of Sverdlovsk killed 68 persons out of 79 infected[56]. In Zimbabwe, 10000 cases occurred between 1979 and 1980 leading to 182 deaths. In Tibet, 507 anthrax cases resulted in 162 deaths in 1989 and in China, 898 and 1210 anthrax cases were recorded in 1996 and 1997, respectively. Between 1991 and 1995, a relatively large number of anthrax incidences was observed in Spain[49,57], Central America[57] and Africa[53]. In most of the cases, exposure was through cutaneous route which accounts for a total of 95% cases. The inhalational route accounts for 5% anthrax cases reported, while gastrointestinal anthrax is quite rare[58,59]. In 2007, a few animal and human cases of anthrax were reported from Orissa and West Bengal, India[60]. The most recent anthrax cases were found in 2010 in Bangladesh. More than 600 peoples were killed in the outbreak due to consumption of infected cattle meat[61].

As India stands first in having the largest population of livestock in the world, therefore anthrax is endemic in several regions. Based on the epidemiological study from 1991 to 2010 by National Animal Disease Referral Expert System (NADRES) in India, anthrax was found one of the ten major diseases causing deaths in livestock[62]. During 1991-2010, anthrax was reported in eighteen states of India *viz.*, Andhra Pradesh, Assam, Bihar, Chhattisgarh, Gujrat, Himachal Pradesh, Jammu and Kashmir, Jharkhand, Karnataka, Kerala, Madhya Pradesh, Maharashtra, Manipur, Meghalaya, Odisha, Rajasthan, Tamil Nadu, and West Bengal. Although several regions are endemic for anthrax, yet seasonal fluctuation in the number of anthrax outbreaks has been observed. Most of the anthrax outbreaks are reported in post-monsoon season, *i.e.,* from July to September and November to January in different parts of India. Anthrax epidemics are generally reported between July to September and also in November and January, coinciding with the post monsoon months across the country. Several Southern states such as Andhra Pradesh, Tamil Nadu, Kerala, Karnataka and Orissa are common endemic regions with sporadic human anthrax cases reported time to time. From the Union Territory of Pondicherry, 28 cases of anthrax were detected in 1999 and 2000[45]. Both, animal as well as human anthrax cases are reported usually from certain anthrax endemic districts like Chittoor, Cuddapah, Guntur, Prakasam and Nellore of Andhra Pradesh[63]. In 2006, some cases were noticed near Narsinghpur, Madhya Pradesh also. In 2007, 20 people were affected in two cutaneous anthrax outbreaks in Murshidabad district, West Bengal. These anthrax outbreaks were caused due to slaughtering of sick cattle and subsequently handling of meat without taking proper preventive measures[64]. An increase in number of animal and human anthrax cases has been observed in this area in recent past[65]. During a tenure of 10 years, anthrax outbreak were reported at least 61 times from Orissa affecting 750 people[65]. The anthrax outbreak is a common phenomenon in this area because tribal population mainly depends on forest for livelihood. Most of the human anthrax cases occur in agricultural workers due to handling of meat or hides of diseased animal. An anthrax outbreak was reported in Orissa, India in 2013 where several people died due to consumption of infected goat meat[66]. Recently, nine cutaneous anthrax cases were reported from the tribal population of Midnapur, West Bengal in India[67].

VIRULENCE OF *B. ANTHRACIS*

Anthrax, being a disease of mainly herbivorous is generally prevalent in those areas where animals like cattle, horse, sheep, goat, *etc.*, graze. Several animal species like pigs, dogs, cats, rats and chicken are fairly resistant to anthrax. Many scavenging birds like vultures which feed on dead animals have a natural resistance to anthrax. However, such birds may disseminate the anthrax spores from infected animals through claws, beaks or feathers.

The spores of *B. anthracis* that can remain in the environment for a prolonged time become the infectious form of anthrax. For causing anthrax, spores first germinate, *i.e.,* lose their dormancy and resistance properties, regain metabolism and start vegetative growth[68,69]. After getting favourable environmental and nutritional growth condition, spores convert into vegetative bacteria and result in further multiplication. Human skin generally does not permit spores to invade; however, spores find access through small cuts or abrasion in skin to cause cutaneous anthrax. After entry into host, *B. anthracis* remains in the capillaries of invaded organs and produce lethal and edema toxins which cause the local and fatal effects of infection.

TOXINS OF *B. ANTHRACIS*

In soil, *B. anthracis* is found in its highly resistant endospore form and therefore, can remain live for a very long period in this state. Spores of *B. anthracis* can find entry in the body through lungs, skin lesion or gastrointestinal route and germinate to yield vegetative form. In case of cutaneous infections, *B. anthracis* comes into contact with a skin lesion, or cut. In inhalational cases, herbivorous and sometimes humans are infected after inhalation of spores. After inhalation, these spores reach alveoli of lungs through air passages. Generally, herbivores get gastrointestinal anthrax infection during grazing or browsing an anthrax spore infested agricultural field having spiky or rough vegetation. Gastrointestinal tract of animals probably gets wounds due to eating of spiky vegetation which facilitates the entry of spores into tissues and resulting in gastrointestinal anthrax.

The virulence of *B. anthracis* is attributed to a tripartite anthrax toxin and a poly-D-glutamic acid capsule. After entry into the host through ingestion or skin wounds, *B. anthracis* multiply inside the tissues of animal or human host, spread in the lymphatic system and undergo rapid multiplication. This results in production of anthrax

toxin inside the body and causes death of host within a few days or weeks.

Capsule formed by the virulent *B. anthracis* vegetative cells helps the bacterium to evade the host immune system by impeding the ability of macrophages to engulf and destroy the bacteria[7]. Three non-toxic proteins namely PA, LF and EF of anthrax tripartite toxin co-assemble to produce a series of free or cell-bound toxic complexes[8,9,70]. Two of the toxins, LF and EF, are enzymes that modify substrates within the cytosolic compartments of host cells[71]. PA binds on the receptors of host cells and makes a pore for transportation of LF and EF to the cytosol[72]. Thus, anthrax toxin is an A-B type toxin, where PA acts as B subunit and it combines with the LF and EF, which act as A subunits to form the edema toxin and lethal toxin, respectively[10,17].

Anthrax PA is an 83 kDa precursor polypeptide consisting of 735 amino acids which binds to anthrax toxin receptors. There are two distinct toxin cell receptors, ANTXR1 (TEM8, Tumor endothelial marker 8) and ANTXR2 (CMG2, Capillary morphogenesis protein 2) which are widely expressed in cells[73,74]. Cleavage of PA by cellular proteases of the furin family, or by serum proteases generates a nicked 20 kDa fragment (PA20) at N-terminal and a 63 kDa fragment (PA63) at C-terminal[75,76]. The 63 kDa fragment self-associates to form a prepore which is a heptameric ring and can bind up to three copies of EF and/or LF molecules[6]. A smaller population of PA octamers (20%-30% of oligomers) is also formed, which binds up to four molecules of EF and/or LF and this structure is more stable than heptamer[77]. These hetero-oligomeric complexes are endocytosed and brought to an acidic environment, where the PA prepore makes a translocase channel after inserting into the membrane[78]. This channel is used for translocation of LF and EF into the cytosol, where by enzymatic activities they disrupt the host cell[79]. Both, LF and EF toxins reach the late endosomal compartment, where EF remains associated with the late endosomal membranes that surrounds the nucleus forming a perinuclear necklace and LF is ejected into the cytoplasm[80,81].

LF is a zinc dependent metalloprotease which inactivates the members of mitogen-activated protein kinase kinase family (MAPKK)[82-84]. Inactivation of three major MEKs *i.e.,* extracellular signal regulated kinases, c-Jun N-terminal kinases and p38 MAPKs results in impairment of various cellular processes like cell division, cell differentiation, cellular response to different types of stress and ultimately apoptosis[17].

Another protein EF is has adenylate cyclase activity. It is produced in an inactive form by the bacterium and needs calcium modulated protein (calmodulin, CaM) for its activity[71]. CaM, which acts as Ca^{2++} sensor has two Ca^{2++} binding sites on each of the C- and N-terminal domain. CaM binds with helical domain of EF using its N-terminal domain. EF is a highly active and its adenylate cyclise activity is almost equal to that of most active known cyclase. Activity of EF is also regulated by intracellular level of Ca^{++} in a biphasic manner. Resting or little high levels of Ca^{++} activate the EF *via* CaM, whereas high levels of Ca^{2++} reduce its activity due to competition between Ca^{++} and Mg^{++} ion in the EF active site[85]. Because EF is associated with the perinuclear later endosomal membrane, therefore, a cAMP gradient decreasing from the nucleus to plasma membrane is generated[80,81,86]. Contrary, endogenous host adenylate cyclises generate a cAMP gradient in opposite orientation (decreasing from plasma membrane to nucleus) because these are localized on plasma membrane[86,87]. In anthrax infection, these two toxins are responsible for immune system failure and ultimate death of host[9].

PATHOGENESIS OF *B. ANTHRACIS*

Human anthrax is mainly of two types, agriculture related anthrax that occurs in a seasonal pattern, and occupation related that can occur at any time. On the basis of route of infection, there are three clinical forms of anthrax *viz.*, cutaneous (skin), gastrointestinal (ingestion) and pulmonary (through inhalation of spores)[88]. Recently, another type of anthrax has been identified among the heroin injecting drug users Europe[89,90]. The term injectional anthrax was then coined to describe this new mode of infection. A few anthrax cases have been reported due to insect bites also, which could probably be due to feeding of insect on an anthrax infected animal[91,92]. Once inside the mammalian host, the high nutrient content of the body triggers germination of spores, although there may be host-specific germination factors as well[93]. Sporulation does not appear to occur inside the host[94]; perhaps because once the available nutrients are depleted in the dead or dying host, the oxygen tension is too low for Sporulation[95] or possibly due to the repression of sporulation by the virulence gene regulator AtxA[96]. Spores infect macrophages at the site of entry, germinate into vegetative cells and proliferate into the tissues and start producing anthrax toxin within 3 h of spore germination[93].

Cutaneous anthrax infection starts with a small itching papule resembling an insect bite at the site of infection on skin. In a day or 2, this papule enlarges and transforms into a painless ulcer with a depressed necrotic centre and a raised and round edge. Generally, such lesions are formed with 2-5 d at the site of spore entry on skin. Finally, after 7-10 d, a black eschar, surrounded by edema is formed and this leaves permanent scar after anthrax cure[97]. Regional lymph nodes draining the infected area may be swollen and enlarged. Cutaneous anthrax infection mostly remains painless and limited to dermis. However, in certain cases it can become systemic when bacteria enter into blood stream causing bacterimia. Hemorrhagic lesions can be developed on any part of body and can be fatal in bacteremic anthrax.

Gastrointestinal (GI) anthrax occurs by eating the food contaminated with anthrax spores (most often contaminated meat). After ingestion, spores germinate

and can cause lesions anywhere in the body. Based on the lesions, GI anthrax is of two types, abdominal and oropharyngeal. In abdominal GI anthrax, lesions are formed mainly in the ileum and cecum. The incubation period is generally 3-7 d. The symptoms of abdominal GI anthrax include nausea, bloody vomiting, diarrhea, abdominal pain, headache, loss of appetite and massive ascites. Another variant of intestinal anthrax is oropharyngeal anthrax where lesions are formed mainly in the oral cavity and resemble the lesions of cutaneous anthrax. Symptoms include throat pain, problem in swallowing and swelling in neck due to edema and cervical lymphadenopathy[97].

Pulmonary or inhalational anthrax occurs by inhalation of spores into lungs. This is the most severe form of anthrax. Alveolar macrophages ingest the spores and transport to lymph nodes in mediastinum. Initially, symptoms of inhalation anthrax are like cold or flu-like with mild chest discomfort, shortness of breath, nausea and finally severe respiratory collapse. Pulmonary anthrax doesn't cause pneumonia, but causes hemorrhagic mediastinitis and pulmonary edema. Historical, mortality was 92%, but, it can be reduced significantly if treated early as only 45% mortality was observed during the 2001 anthrax attack in United States.

Symptoms of anthrax caused by injection remain the same as in cutaneous anthrax, but there may be infection deep under the skin or in the muscle where the drug is injected. Sometimes there is redness at the area of injection. Injectional anthrax is difficult to diagnose because several other common bacteria can cause skin and injection site infections. Therefore, it is hard to treat injectional anthrax as it spreads throughout the body very fast.

There are two basic stages in the systemic anthrax infection, a prodromal and fulminant. The prodromal stage is mainly asymptomatic and generally lasts 2-4 d[98]. In this stage, macrophages engulf the spores and release to lymph nodes near the port of entry. Behaviour of macrophages and phagocytic cells is changed due to action of anthrax toxins resulting in the apoptosis and release and germination of spores into vegetative bacteria. In the fulminant stage, bacteria multiply and are distributed to different organs through bloodstream[99,100]. In human inhalation anthrax, treatment is started after the onset of fulminant stage because prodromal stage is largely asymptomatic. The symptoms at fulminate stage are flu-like and include labored breathing, chest pain, hypotension, headache and disorientation[55,99-102]. Bacteria secrete anthrax toxins which affect functioning of different organs like spleen, lymph nodes, liver, kidney, heart and brain. It becomes very difficult to cure the disease by antibiotic therapy at this stage and action of anthrax toxins ultimately leads to septic shock and death of host in 1-2 d.

LIFE CYCLE OF *B. ANTHRACIS*

B. anthracis is found in two forms, vegetative cells and spores. Adverse environmental conditions induce the sporulation and endospores are released from the mother vegetative cells. The endospores are dormant, well organized and highly resistant to various stress conditions. Therefore, these endospores can remain viable for a prolonged time in the environment and can germinate into vegetative bacteria after getting the suitable environmental and nutritional requirements. During both the processes, *i.e.*, sporulation and germination, a lot of metabolical as well as morphological changes are observed. For spore formation, *B. anthracis* bacterium is divided asymmetrically by a septum into forespore (smaller portion) and mother cells (larger portion). Each portion gets a single copy of DNA. After the asymmetric division, forespore is engulfed by the mother cell with a double-membrane system. The mother cell DNA material is degraded and forespore DNA material is surrounded an inner membrane. Two peptidoglycan layers known as primordial germ cell wall (inner thin layer) and the cortex (outer thick layer) are synthesized between the inner and the outer membrane of forespore[103,104]. The outer membrane of forespore gets deposited by various proteins to form the coat. Thickness of spore coat varies among different species of *Bacillus*. In *B. anthracis* and *B. cereus*, the spore coat is compact whereas it can be distinguished in *B. subtilis*[105,106]. During spore maturation, spore acquires resistance for temperature and UV radiations and becomes dormant. Thus, spore coat imparts important functions to protect cortex and DNA of spore from various adverse conditions like environmental stress, chemicals and peptidoglycan lysing enzymes.

The life cycle of *B. anthracis* has been shown in Figure 1. Animals get infected by uptake of anthrax endospores present in the agriculture fields. Inside the mammalian host, endospores find the favourable conditions like aqueous environment with sufficient nutrients and therefore, start germination[107]. During anthrax pathogenesis, transformation of spore into vegetative cell is a crucial step, because it is the vegetative form of bacterium only which forms the virulent factors, *i.e.,* capsule and tripartite toxin[27]. The poly-γ-D glutamic acid capsule of *B. anthracis* makes a complex surface of the bacterium and is surrounded by peptidoglycan layer and S-layers[108]. The capsule evades the host immune system and thus is a crucial factor for the survival of the bacteria in the host. On death, the capsulated bacteria are released with blood into the environment through natural orifices. On coming into contact with oxygen, the vegetative bacteria convert into spores and thus again infest the agriculture fields for subsequent anthrax infection in grazing animals.

DIAGNOSIS OF ANTHRAX

As various outbreaks are reported time to time from different areas, there is a great need of an early diagnosis of the disease to save human and animal life. Besides, requirement of rapid and reliable detection, identification and diagnosis systems for anthrax has been emphasized

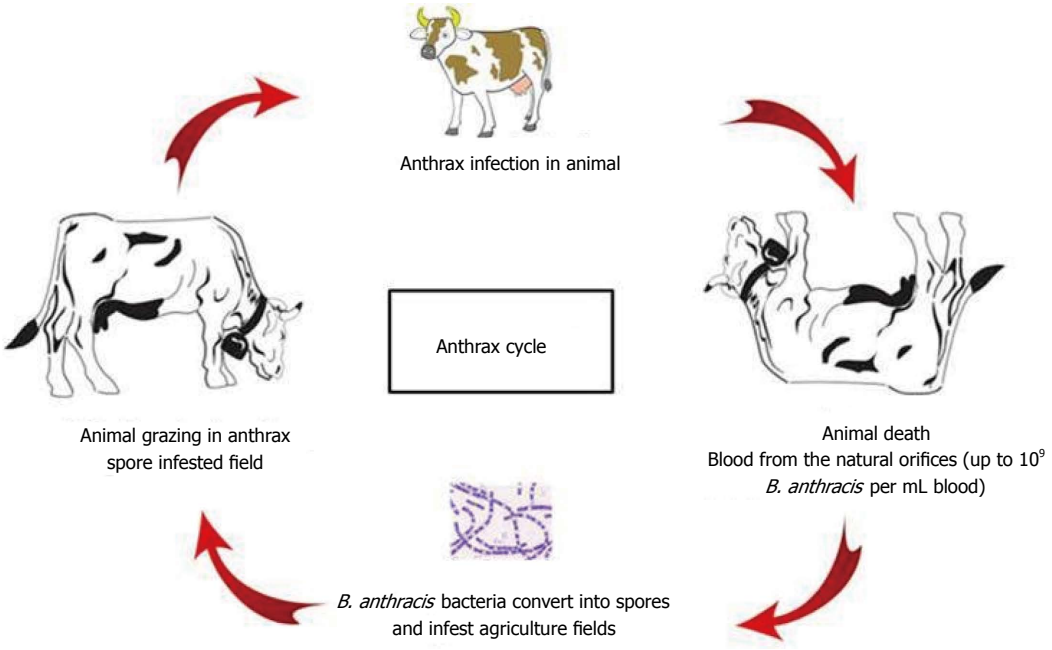

Figure 1 Life cycle of *B. anthracis*. *B. anthracis*: *Bacillus anthracis*.

by recent bioterrorism events. The early monitoring of the disease requires the detection of anthrax spores and infection both at environmental and clinical levels.

Cutaneous anthrax is diagnosed clinically employing traditional microbiological methods like gram-staining, capsule staining from the smear of the lesion or culturing of *B. anthracis*[109,110]. Several methods have been reported for isolation and identification of *B. anthracis*. However, on sheep Blood agar (5%) and other routine culture media, almost all *Bacillus* species grow well[111]. A selective media containing polymyxin-B, lysozyme, EDTA and thallous acetate was used for isolation of *B. anthracis* from contaminated and suspected samples[112]. Another media (bicarbonate agar) is used to induce capsule formation for subsequent identification of *B. anthracis*. However, there is very little utility of these selective growth media because several closely related bacteria of *B. anthracis* like *B. cereus* and *B. subtilis* also grow well on these media. Another undesirable feature is that it takes 18-24 h for *B. anthracis* to grow for characterization by various biochemical tests like catalase, oxidase, nitrate reduction, haemolysis, citrate utilization, urease[113]. Sometimes, microbiological methods like culture and Gram staining of *B. anthracis* do not hold good for patients who have already taken antibiotics before the sample[114]. Immunoflorescence has also been used for direct identification of *B. anthracis* spores[115].

Serodiagnosis is important for surveillance and confirmation of anthrax infection in animals and human. Anthrax toxin consists of PA, LF and EF. Antibodies response against these toxin components is used as a diagnostic tool for determination of past infection or vaccination.

It is well established that PA is the most important protein of anthrax tripartite toxin and it becomes the major component of anthrax vaccines including anthrax vaccine adsorbed. Therefore, antibody (IgG) levels against PA in human and animals are determined to study the host immune response to *B. anthracis* infection and anthrax vaccine[116,117]. In United States, a total of 22 individuals were identified with bioterrorism-related inhalation or cutaneous anthrax, 11 patients for each type from 4th October to 20th November 2001[118]. In 16 of 17 confirmed or suspected clinical anthrax patients, anti-PA IgG antibody could be detected after 11 d of onset of symptoms or probably 15 d after the exposure to *B. anthracis*. Antibodies against PA could be detected up to 8-16 mo in all the cases of inhalation anthrax and 7 out of 11 surviving cutaneous anthrax patients[118]. For serodiagnosis of cutaneous anthrax, an enzyme-linked immunosorbent assay was developed in India for determination of anti-PA IgGs with 99.4% specificity and 100% sensitivity[119]. A field based qualitative visual ELISA for anti-PA IgG was also developed for serodiagnosis of anthrax[120]. Results of sensitivity and specificity of visual ELISA were found compatible with the results obtained from standard ELISA measuring OD values. Likewise, a quantitative ELISA was developed for measurement of the anti-PA IgG level in human serum samples[121]. The minimum detection limits and lower limits of quantification of the assay for anti-PA IgG were 3.2 μg/mL and 4 μg/mL, respectively. The serum samples collected from the anthrax infected patients were found to have anti-PA IgG concentrations of 5.2 to 166 μg/mL[121]. CDC, United States has developed a lateral flow immunochromatographic device using colloidal gold nanoparticles for determination of anti-PA IgG in serum or whole blood[122].

However, animal studies with anthrax vaccine revealed that LF evokes higher IgG response in comparison to PA

in animals[123]. In patients of natural cutaneous anthrax, immune response to LF is higher and faster than the antibody response to EF and PA, which is lower and delayed[124]. Anti-LF IgG antibodies appeared in patients just after 4 d of onset of anthrax symptoms, whereas anti-LF and anti-PA IgG could be detected after 6 d and 13 d, respectively. In a study of human cutaneous anthrax, 11 of the 17 patients had measurable IgGs against one of the three toxin components. Anti-LF IgG was found in 65% patients, while anti-PA and anti-EF response could be found only in 18% and 24% patients. The anti-LF IgG titre in all the infected patients was higher than the titre of anti-PA or anti-EF IgG. After two weeks of infection, the mean anti-LF IgG titre in all infected patients was 69.3 μg/mL, which was twice the tire of anti-EF IgG (37.4 μg/mL) and thrice the titre of anti-PA IgG (22.6 μg/mL)[124]. It was also observed that in anthrax cases, class switching of antibody from IgM to IgG occurs faster. Anti-PA IgG could be detected just after 11 d of onset of symptoms in patients with inhalation anthrax, while no anti-PA IgG response was found till 21-34 d in patients with cutaneous anthrax[117]. Therefore, it is evident that LF evokes a faster and stronger host immune response in comparison to the other two anthrax toxins, *i.e.,* PA or EF. Therefore, detection of anti-LF IgG in human serum can be a good marker for serodiagnosis of anthrax. For detection of anti-LF antibodies, an indirect ELISA was developed for serodiagnosis of cutaneous anthrax in human[125]. The vaccinated and cases of natural anthrax infection can be differentiated by the anti-LF ELISA because PA is the principal component in anthrax vaccine.

Rapid diagnosis of anthrax at an early stage of infection *i.e.,* before the appearance of symptoms can be very useful for proper medical treatment to stop the further spread of infection and accumulation of toxins. For early diagnosis, detection of anthrax toxin in serum or plasma can be a reliable marker of infection[126]. An ultra sensitive immunoassay known as European Nanoparticle Immuno Assay (ENIA) has been developed using European nanoparticle for the detection of PA in sera, which has been found 100 times more sensitive than ELISA[85]. ENIA showed good linearity for detection of PA in the range of 10 pg/mL to 100 pg/mL, whereas range of PA detection in ELISA was 1-100 ng/mL. An engineered sandwich capture ELISA was also reported for the detection of both PA as well as LF[127]. In the sandwich ELISA for PA detection, anti-PA high affinity single chain fragment antibody or receptors for anthrax toxin (ANTXR2) were used for capturing the analyte (PA), and rabbit anti-PA polyclonal serum was used for revealing antibodies. The detection sensitivity of PA by was as low as 1 ng/mL in serum. The detection sensitivity of sandwich ELISA for LF, where PA_{63} was used for capturing of analyte was 20 ng/mL. Surface Plasmon Resonance (SPR) has also been found a very good technique for detection of PA from serum samples of human[128]. The SPR assay could detect 1 pg/mL of the purified PA and 10 pg/mL of PA in human serum[128].

Recently, a new method utilizing genetically modified phages has been developed for detection of pathogenic *B. anthracis* from clinical sources[129]. The reporter phage displays species specificity by its inability, or significantly reduced ability, to detect members of the closely related *B. cereus* group and other common bacterial pathogens.

Nucleic acid based detection methods have also been developed for detection of anthrax. These techniques make use of nucleic acid sequences unique to *B. anthracis*. The technique has gained enormous popularity for its specificity. Polymerase chain reaction (PCR) or real-time PCR amplify the specific chromosomal markers or virulence plasmids present in the *B. anthracis*. Such new rapid detection and diagnostic tests are important for clinicians for early identification of infection.

CONCLUSION

Anthrax, caused by *B. anthracis* is still an important endemic disease of public health importance in several countries of Asia, Africa and Europe. It is re-emerging in some western countries due to political unrest or changing life style (use of intravenous drugs) as evident from the recent outbreaks. In country like India, anthrax is a concern of public health as clandestinely encountering in several states like Andhra Pradesh, Kerala and Karnataka, Orissa and West Bengal. Although anthrax can be cured by prompt antibiotic therapy, yet it is fatal in several cases because of lack of proper diagnosis well in time. Among the three clinical forms of anthrax cutaneous anthrax is most frequent but can be easily cured. The other two forms, gastrointestinal and inhalational anthrax are less common but difficult to cure and have high mortality rate. Recently another form of anthrax, *i.e.,* injectional anthrax is also posing threats for early diagnosis and treatment. However, active surveillance, proper animal immunization and awareness can help to curb the disease. Rapid and accurate diagnosis of cutaneous anthrax is crucial for treatment well in time and making strategies for further spread and control of disease. Although a lot of molecular tests are available for anthrax, yet this is difficult to employ these systems keeping in mind the available resources at far off locations where anthrax is endemic. Therefore, rapid, user friendly, inexpensive serodiagnosis tests can be important tools for surveillance of anthrax and active surveillance can help to minimize the agriculture or occupation related anthrax.

Abstract

Superficial stains and irregularities of the enamel are generally what prompt patients to seek dental intervention to improve their smile. These stains or defects may be due to hypoplasia, amelogenesis imperfecta, mineralized white spots, or fluorosis, for which enamel microabrasion is primarily indicated. Enamel microabrasion involves the use of acidic and abrasive agents, such as with 37% phosphoric acid and pumice or 6% hydrochloric acid and silica, applied to the altered enamel surface with mechanical pressure from a rubber cup coupled to a rotatory mandrel of a low-rotation micromotor. If necessary, this treatment can be safely combined with bleaching for better esthetic results. Recent studies show that microabrasion is a conservative treatment when the enamel wear is minimal and clinically imperceptible. The most important factor contributing to the success of enamel microabrasion is the depth of the defect, as deeper, opaque stains, such as those resulting from hypoplasia, cannot be resolved with microabrasion, and require a restorative approach. Surface enamel alterations that result from microabrasion, such as roughness and microhardness, are easily restored by saliva. Clinical studies support the efficacy and longevity of this safe and minimally invasive treatment. The present article presents the clinical and scientific aspects concerning the microabrasion technique, and discusses the indications for and effects of the treatment, including recent works describing microscopic and clinical evaluations.

Key words: Dental bleaching; Enamel microabrasion; Enamel surface; Esthetic treatment; Fluorosis; Hypoplasia

Core tip: Enamel microabrasion is indicated for the removal of superficial stains and irregularities of the enamel, mainly located in esthetic areas. The technique involves the mechanical rubbing of acidic and abrasive agents on the altered surface. Recent studies show that the technique

is a conservative treatment when the enamel wear is minimal and clinically imperceptible, and is effective and long lasting. The present literature review aims to discuss indications and clinical and scientific aspects of the microabrasion technique, as well as its effects on the enamel surface.

Enamel microabrasion: An overview of clinical and scientific considerations. *World J Clin Cases* 2015; 3(1): 34-41 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/34.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.34

INTRODUCTION

Several treatments have been introduced to the dental market for the restoration of dental appearance to a level that satisfies what patients seek regarding dental esthetics. These techniques are still being evaluated in order to ensure an efficient treatment with minimal chair time and low cost that is safe for professionals and patients. For superficial enamel stains or defects, enamel microabrasion is preferred, as it is considered an esthetic and conservative treatment[1-3]. Since its introduction by Croll *et al*[4] in 1986, there have been numerous reports describing various approaches[5-8], related products, and clinical successes[9-12].

The main indication for enamel microabrasion is intrinsic discoloration or texture alteration due to enamel hypoplasia, amelogenesis imperfecta, or fluorosis[13]. The technique removes the porous surface enamel layer, as well as the entrapped stains, by rubbing a gel that contains an acid and an abrasive compound in a similar way that a dental prophylaxis with pumice and water is performed. The enamel stain or defect is removed by a combination of the erosive and abrasive effects of the recommended mixture containing low acid concentrations and an abrasive agent, applied mechanically using a low-rotation micromotor[13-15]. It should be the first option for the management of teeth with intrinsic stains because it removes opaque, brown stains and smoothens surface irregularities by providing a more regular and lustrous surface[13,16]. As the technique is considered safe and minimally invasive, it can also be combined with tooth bleaching when necessary[1,9,10,13].

The success of enamel microabrasion is directly related to the correct indication of the clinical case and the proper execution of the technique. This review discusses aspects of microabrasion, such as its evolution, indications, advantages, clinical steps, and effects on the enamel structure, in order to address some concerns regarding newer trends presented in the latest research and clinical reports.

EVOLUTION OF THE TECHNIQUE

Enamel microabrasion was initially performed for the removal of fluorotic white spots using 36% hydrochloric acid, as recommended by Kane in 1926[14,17,18]. A heated metallic instrument was used to apply the acid to the altered enamel to increase its penetration[14,18] and hasten the chemical reaction between the acid and the enamel[3]. Concerned about the safety of the technique, Raper *et al*[19] suggested the use of 18% hydrochloric acid applied and rubbed with a wooden spatula wrapped with cotton for a maximum time of 10 min[19]. The authors drew attention to the thickness of the enamel, particularly at the cervical third of the tooth, which is thinner compared to the medium and incisal third. They also recommended the use of sodium bicarbonate to neutralize the effects of the hydrochloric acid.

Mechanical application with a low-rotation micromotor was first indicated in the 1970s, using a mixture of 18% hydrochloric acid, hydrogen peroxide and ether[20]. Combination with an abrasive agent was later indicated by Murrin *et al*[21] in 1982, who added pumice to 36% hydrochloric acid, resulting in a slurry that was applied using a rubber cup coupled to a micromotor[21]. Concerned about the acid concentration, Croll *et al*[4] recommended the use of the same mixture but with 18% hydrochloric acid. Croll later stated that an ideal microabrasive system should include a low acid concentration and abrasive particles in a water-soluble mixture that are applied with a low-rotation handpiece to avoid scattering the compounds, thus making the procedure safer[14]. The author again proposed the use of an extra-fine diamond bur prior to the use of the microabrasive agents to reduce the clinical time needed to perform the procedure[22].

The association of hydrochloric acid to abrasive particles resulted in the development of commercially available products. Prema Compound (Premier Dental Company, Philadelphia, PA, United States), which contains 10% hydrochloric acid, was the first to be introduced to the market. Currently, a lower concentration of hydrochloric acid is used, approximately 6.6%, under the commercial product name of Opalustre (Ultradent Products Inc., South Jordan, UT, United States). Both products use silicon carbide as an abrasive with different granulations (Table 1) dispersed in a water-soluble gel for easy removal[13]. The use of 35% phosphoric acid instead of hydrochloric acid was proposed by Kamp in 1989, and was considered advantageous as it is commonly used in clinical practice for other procedures[3,23].

INDICATIONS FOR ENAMEL MICROABRASION

The proper indications for enamel microabrasion are summarized in Table 2. Dental fluorosis is the most common indication[16], which results from demineralization of enamel caused by excessive fluoride intake. Fluorosis produces opaque white areas or yellow to dark brown discolorations with porosities on the enamel surface, depending on severity[24,25]. Fluoride-induced enamel changes range from thin, white, opaque

Figure 1 Indications for enamel microabrasion. Tooth staining from A: Fluorosis; B: Mineralized white spots.

Table 1 Commercial products used for microabrasion

Material	Manufacturer	Acid	Abrasive	Particle size (mm)
Prema compound	Premier Dental Company (Philadelphia, PA, United States)	10% hydrochloric acid	Silicon carbide/dioxide	30-60
Opalustre	Ultradent Products (South Jordan, UT, United States)	6.6% hydrochloric acid	Silicon carbide	20-160
Pumice	Pumex (Newcastle-under-lyme, Staffordshire, United Kingdom)	-	Pumice	30-50

Table 2 Summary of indications and advantages of the microabrasion technique

Indications	Requirements	Advantages
Stains or defects restricted only to enamel	Shallow alterations just in the enamel surface	Safe and conservative treatment
Dental fluorosis	Use of rubber dam	Minimal loss of enamel
Mineralized white stains	After completion of orthodontic treatment, if necessary	Leaves enamel surface lustrous, shiny and glass-like
Correction of surface irregularities	Supplemented with bleaching, if necessary	Roughness and microhardness alterations easily resolved by saliva
Localized enamel hypoplasia		Reduced bacterial colonization on enamel surface
Polishing of enamel and auxiliary removal of composite resin residues after orthodontic therapy		Lasting and stable esthetic results

lines corresponding to perikymata running across the tooth surface, to an entirely chalky white surface[24]. They are characterized by the presence of bilateral, diffuse, and horizontal striations[25] observed on all teeth that mineralize at the same time (Figure 1A). Enamel microabrasion usually improves esthetic appearance in cases of mild and moderate fluorosis (Thylstrup-Fejerskov Index 1-7)[16,26,27], and should always be considered the first option in the management of these cases[13,16]. Even in situations with yellow or brown discolorations, enamel microabrasion can improve the esthetic appearance of the teeth[28]. As these stains are formed by the discoloration of demineralized surfaces and from external sources, the depth of the stain is likely associated with the penetration of the staining agents[16].

Microabrasion treatment may be indicated for correction of surface irregularities on dental enamel, which may be caused by imperfect enamel formation or acquired after the removal of orthodontic appliances[13], such as the removal of residual resin composite from brackets with diamond burs, and resulting in a smooth and polished enamel surface[29]. Microabrasion is also indicated for opaque, white areas or discolorations, even with porosities, from the demineralization/remineralization process common in the enamel region adjacent to orthodontic bands or brackets (Figure 1B), or from disturbances in the mineralization process, such as hypocalcification[7,13,30]. The white spots caused by orthodontics should first be treated with mineralizing agents, such as sodium fluoride[12,31], or with an infiltration technique[29]. Infiltration of the enamel by resin was recently developed as a way to obstruct the diffusion pathways for acids and dissolved minerals[32]. The resins used have low viscosity, high surface tension, and low contact angle with the enamel, as well as a refraction index similar to enamel[33]. The infiltration technique may also be used in cases of mineralized lesions[29,34]. The technique requires pre-conditioning of the surface with 15% hydrochloric acid, which removes approximately 40 μm of enamel surface, to ensure resin penetration[32]. In

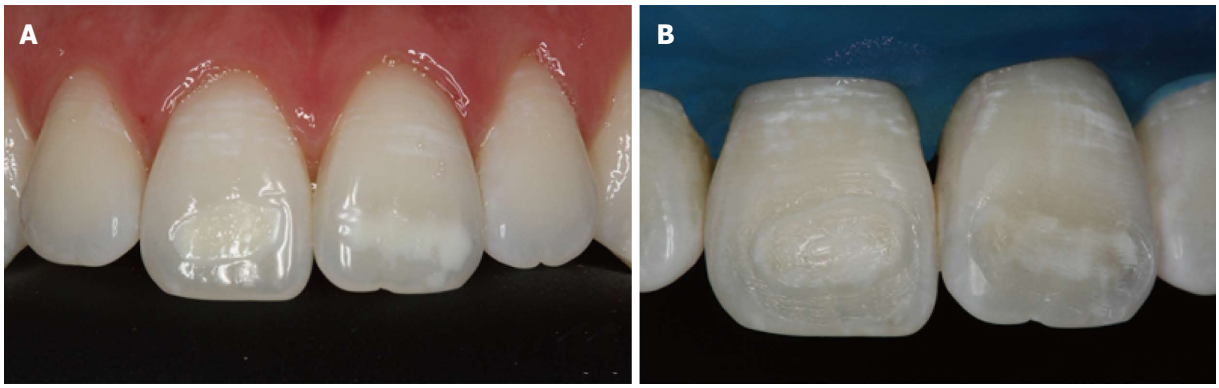

Figure 2 Deep enamel staining due to hypoplasia. A: Hypoplasia; B: Ineffective microabrasion treatment of the right central incisor.

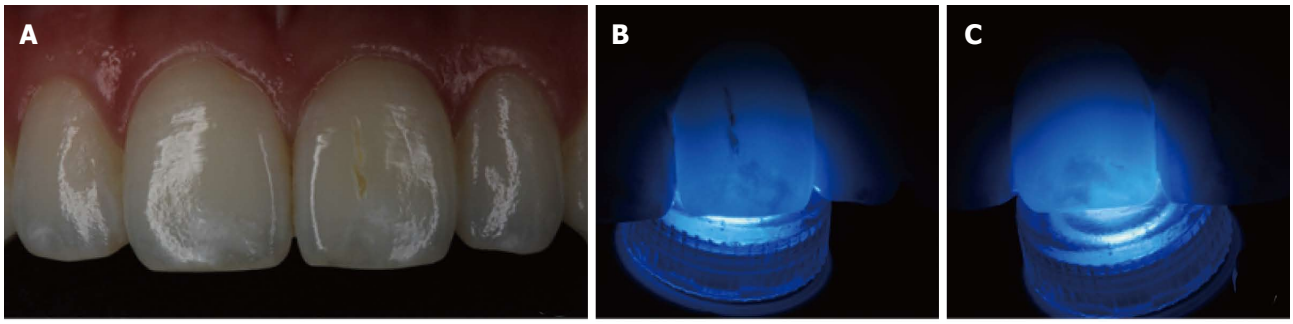

Figure 3 Transillumination to determine staining depth. A: Enamel hypoplasia in both central incisors; B, C:: Transillumination to evaluate the staining.

this way, the thickness of the enamel removed for resin infiltration is similar to microabrasion. However, there are no clinical trials evaluating the staining, abrasion wear or bacterial colonization of resin-infiltrated surfaces.

Microabrasion may be utilized in cases of localized or idiopathic enamel hypoplasia that is limited to the outer enamel layer[15,35]. Although this condition can sometimes require a restorative approach with composite resin or laminate veneer[36] (Figure 2), microabrasion should be considered as the first treatment option[16,36]. In addition to improving esthetics, it may reduce the need for enamel wear for a restorative approach, which is mainly important in young patients[36]. Otherwise, the infiltration technique may be used in cases with deeper stains not resolved by microabrasion, and may be an alternative for the invasive restorative approach[37,38]. Even if all whitish parts of a lesion do not completely disappear, the infiltration technique usually leads to considerable improvement in appearance[37] and masks the enamel stain[34,38].

Enamel microabrasion is not indicated if the patient presents deficient lip sealing, as the teeth are always exposed to air and dehydrate more easily, thus a moistened film is not formed under the enamel. With this condition, the stained appearance of the tooth is more evident, and it may characterize the failure of the microabrasion. Therefore, these patients are encouraged to first seek orthodontic treatment and/or speech therapy[1,13].

The most important factors contributing the success of enamel microabrasion are the location and depth of the enamel stain or defect[8,13,16]. The alteration must be restricted to enamel tissue, without involvement of the dentin[13]. Deeper, opaque stains, such as those resulting from hypoplasia, cannot be resolved with microabrasion, and require a restorative approach[36]. An LED/light curing unit positioned in the palatine or lingual face of the tooth can help the clinician to examine the enamel stain (Figure 3). This can be used to estimate the lesion depth, as a darker color indicates deeper staining[9]. It is also important to perform the diagnosis in wet conditions, as the difference in the refractive index between air and enamel is greater than between water and enamel[12]. Commonly, white spots are more obvious on dry teeth, thus a lesion visible on a wet tooth can be considered deeper than a lesion visible only on dry enamel.

TECHNIQUE

An ideal microabrasion technique should produce insignificant enamel loss, no damage to pulp or periodontal tissues, and satisfactory and permanent results in a short clinical time without discomfort to the patient[4]. The use of a rubber cup coupled to the rotatory mandrel enables precise application of the compound on the enamel surface, which eliminates splattering of the compound and makes the procedure safer, easier, and quicker[13]. For the safety of the patient, a rubber dam should be in place[39], though

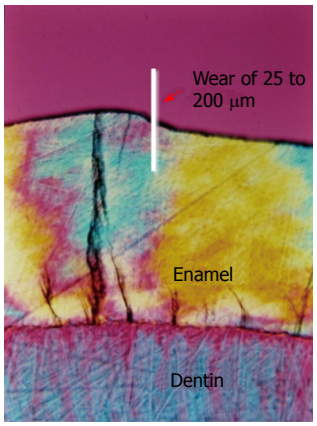

Figure 4 Depth of enamel removal. Polarized light microscopy showing the ground tooth section after enamel microabrasion with Opalustre (reprinted with permission from Sundfeld *et al*[44]).

this may be difficult when the teeth are not completely erupted[13]. It is also important that the patient, clinician, and assistants all wear eye protection during the procedure[1].

The number of applications can vary according to the severity of the enamel staining[1,9,10,12]. To reduce the clinical time, the enamel can first be "regularized" with a tapered fine-diamond bur to lightly abrade the affected area, referred to as enamel macroreduction[1,9,13,30]. With this procedure, the application of microabrasive slurry can be reduced to two or three applications to remove the remaining stains and to smooth the enamel surface ground with the diamond bur[1]. Afterwards, polishing of the microabraded surface with felt discs and polishing[26] or fluoridated[1,9,10,40] pastes is recommended. Application of sodium fluoride gel[1,9,26] is also recommended to promote the remineralization process.

Because enamel microabrasion is a noninvasive technique, it can be supplemented with bleaching procedures[1,9,13,15,41]. Often, this is necessary as microabraded teeth can acquire a darker or yellowish coloration after treatment, and the remaining enamel is thinner and more clearly reveals the dentin. Bleaching is also indicated to reduce the contrast between the remaining white-spotted lesions and the tooth surface[26,42,43]. In either situation, a low concentration of carbamide peroxide is recommended using the home-bleaching technique[1,9,10,13].

CLINICAL AND SCIENTIFIC CONSIDERATIONS

Effects of the technique

Enamel microabrasion has been shown as an effective and conservative treatment[1,9,13,15,43]. According to reports by Sundfeld *et al*[13,43,44], 5 to 10 applications of microabrasive systems (35% phosphoric acid with pumice, Opalustre) can result in the loss of 25 to 200 μm of enamel, which is acceptable for clinical conditions (Figure 4). A recent study showed that 120 s of microabrasive treatment reduces approximately 10% of the enamel thickness[5], suggesting it is a safe and conservative procedure. According to Dalzell *et al*[45], the pressure used during the microabrasion procedure is crucial for total enamel removal, such that the higher the pressure, the greater the quantity of enamel removed. In addition, enamel wear from the microabrasion technique is time-dependent[46].

In addition to the removal of discolored enamel, the microabrasion technique changes the optical characteristics of the enamel surface, called the "abrasion effect"[47,48]. The simultaneous abrasion and acid erosion of enamel prisms may compact mineralized tissue within the organic area, replacing the outer layer of prism-rich enamel with a densely compacted, prism-free region[48]. Microabrasion presents a lustrous, shiny, and glass-like surface of the enamel, which may reflect and refract light differently[13,41]. These optical properties may be able to camouflage any remaining subsurface enamel stains[48]. Tooth hydration by saliva augments these favorable optical properties[47,48]. Schimdlin *et al*[2] found that the luminescence and fluorescence of enamel after microabrasion of demineralized lesions was decreased in comparison with the untreated demineralized enamel.

Several studies have examined the effects of microabrasion on the remaining enamel surface[2,5-8,46,49-51]. The potential erosive and abrasive effects depend on several parameters, including the type, concentration and pH of the acid used, the abrasive medium, time of instrumentation, application mode, force applied, and revolutions per minute[8,50]. The microabrasion technique increases the roughness of the enamel surface, regardless of whether 18% or 35% phosphoric acid or 6.6% hydrochloric acid with abrasive was used[5,7,44,51]. Similarly, enamel microabrasion is also related to reduced enamel microhardness[6,49]. However, both effects can be reversed by the polishing procedure or saliva exposure[5,6,49,51]. Rodrigues *et al*[5] found that unlike that seen with microabrasion, the enamel surface maintained the same roughness through all the evaluated stages when mechanically treated with a silicon polisher; the authors suggested that the chemical features of enamel microabrasion are responsible for the roughness effects. Despite their concentration differences, phosphoric acid and hydrochloric acid have similar erosive effects[5,6,49], such as alterations in the enamel micromorphology with exposition of the interprismatic spaces, similar to the enamel conditioning patterns[7,46]. Although the microabrasive system causes change in the enamel surface, which can be observed by scanning electron microscopy, confocal imaging demonstrates that the subsurface is not altered (Figure 5). The smoother, dense, mineralized enamel layer created by microabrasive systems is also less favorable for bacterial colonization, particularly by *Streptococcus mutans*[52]. Additionally, Hoeppner *et al*[53] reported that the enamel surface was more resistant to demineralization four months after microabrasion with 35% phosphoric acid.

Bertoldo *et al*[49] recently reported that microabrasion with 6.6% hydrochloric acid and silica results in the incorporation of chloride ions and silica into the enamel.

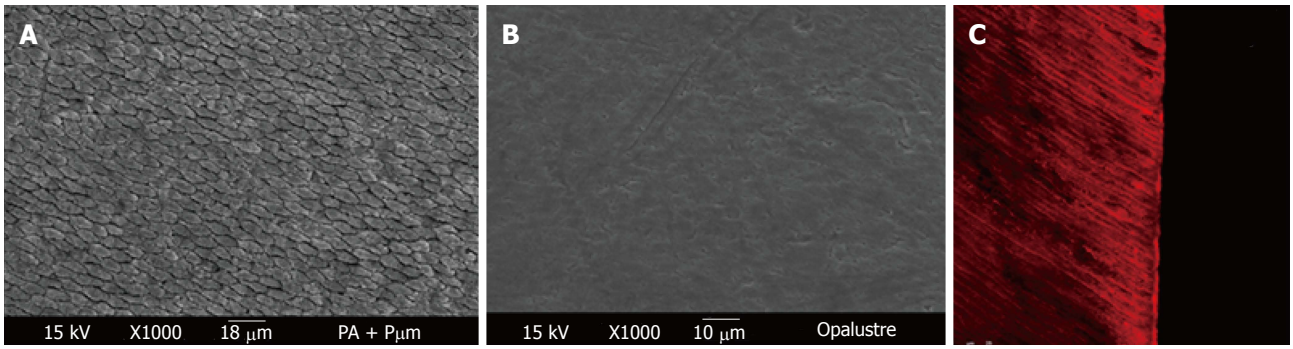

Figure 5 Enamel alterations after microabrasion. Scanning electron microscopy showing the acid conditioning pattern on the enamel surface caused by microabrasion with A: Phosphoric acid and pumice; B: Opalustre; C: Confocal laser scanning microscopy showing the minimal alteration of the enamel surface, but intact subsurface, after microabrasion with Opalustre.

Figure 6 Resolution of fluorosis staining by microabrasion. A: Clinical case of fluorosis before treatment; B: Results after enamel microabrasion (reprinted with permission Machado *et al*[58]).

These, along with results from additional studies concerning the effects of artificial[6,49] and human[51] saliva on microabraded enamel, should encourage clinicians to consider this method. Chloride ions are strongly associated with enamel rehardening, as they account for more than 60% of the ionic strength of saliva[54,55], and the silica compound is used in a bioactive material (Ca_3SiO_5) that efficiently induces a new apatite layer on acid-etched enamel[56]. Some authors believe that these properties should be maximized and, rather than polishing the microabraded enamel, a light polishing with a feltrum disc and fluoridates or diamond toothpaste with low granulation should be applied[1,5,9].

Clinical success

Several case reports demonstrate the lasting and stable esthetic results of the microabrasion technique[1,9,10,12,35,41]. According to clinical results, enamel microabrasion produced permanent color modification of superficial enamel coloration defects because the discolored enamel was removed, rather than altered or masked[57]. Microabraded enamel surfaces achieved a brilliant luster over time[13,57]. An example clinical result of enamel microabrasion is presented in Figure 6[58].

Loguercio *et al*[59] compared two commercially available products for microabrasion for removal of fluorosis stains, and found that treatment with Opalustre was more effective than Prema Compound. This effect was possibly due to the larger size of the silica granules in the Opalustre. However, both products were efficient, and the patients were highly satisfied with the results. Similarly, Sheoran *et al*[57] compared 35% phosphoric and 18% hydrochloric acid with pumice, and found no clinical difference between them, with microabrasive compounds successful in treating enamel opacities.

Enamel microabrasion is considered effective in cases of white, yellow or brown stains located in the outer enamel layer[60]. However, it is important to recognize the severity of enamel stains when facing fluorosis. Celik *et al*[16] performed enamel microabrasion with Opalustre in mild-to-severe fluorosed teeth and found that more applications were needed when lesions were more severe. Mild staining was treated with five applications, whereas moderate to severe staining needed ten applications. Train *et al*[27] also showed that the appearance of mildly fluorosed teeth was moderately improved, but microabrasion only slightly improved the appearance of severely fluorosed teeth. However, enamel microabrasion should still be the first option for patients that seek minimally invasive treatment, even in cases with severe fluorosis. In such cases, removal of opaque white areas or brown stains may increase the success of further treatment, such as bleaching, to achieve a uniform tooth shade[16]. Castro *et al*[26] showed that enamel microabrasion combined with at-home tooth bleaching effectively reduced staining in cases of mild to severe fluorosis, improving the esthetic

appearance of the teeth and the self-perception of the patient, without incidence of side effects such as tooth sensitivity.

CONCLUSION

Accumulating evidence suggests that enamel microabrasion is efficient and effective for producing esthetic improvements. This technique involves minimal enamel loss, leaving a smooth and shiny enamel surface with permanent results. The procedure is considered a safe, conservative, atraumatic method for removing superficial enamel stains and defects. The laboratory and clinical results presented in these articles support the use of enamel microabrasion as a first treatment option for patients who prefer a less-invasive approach.

Abstract

Recent advances in molecular targeted therapies, including targeting human epidermal growth factor receptor 2 (HER2), had a major forward step in the therapy for gastric cancer patients. Application of HER2-targeted therapies, in particular trastuzumab in combination with chemotherapy in metastatic HER2-positive gastric cancers, resulted in improvements in response rates, time to progression and overall survival. Nevertheless, as with breast cancer, many patients with gastric cancer develop resistance to trastuzumab. Several promising therapies are currently being developed in combination with chemotherapy to increase the efficacy and overcome the cancer-resistance. Here we review the current overview of clinical application of agents targeting HER2 in gastric cancer. We also discuss the ongoing trials supporting the use of HER2-targeted agents combined with cytotoxic agents or other monoclonal antibodies.

Key words: Human epidermal growth factor receptor 2; Gastric cancer; Targeting therapy; Trastuzumab

Core tip: This review summarizes the development of diagnostic and therapeutic approach for the patients with human epidermal growth factor receptor 2 (HER2)-overexpressed/amplified gastric cancer. The biology of HER2-dependent signalling is also described. The ToGA trial highlighted the importance of accurate HER2 testing to guide treatment choice of gastric cancer. Future strategies beyond the ToGA trial to address EFGR family, including HER2 pathway are discussed according to current ongoing clinical trials, as well as experimental studies.

INTRODUCTION

Gastric cancer is the fourth most common malignant

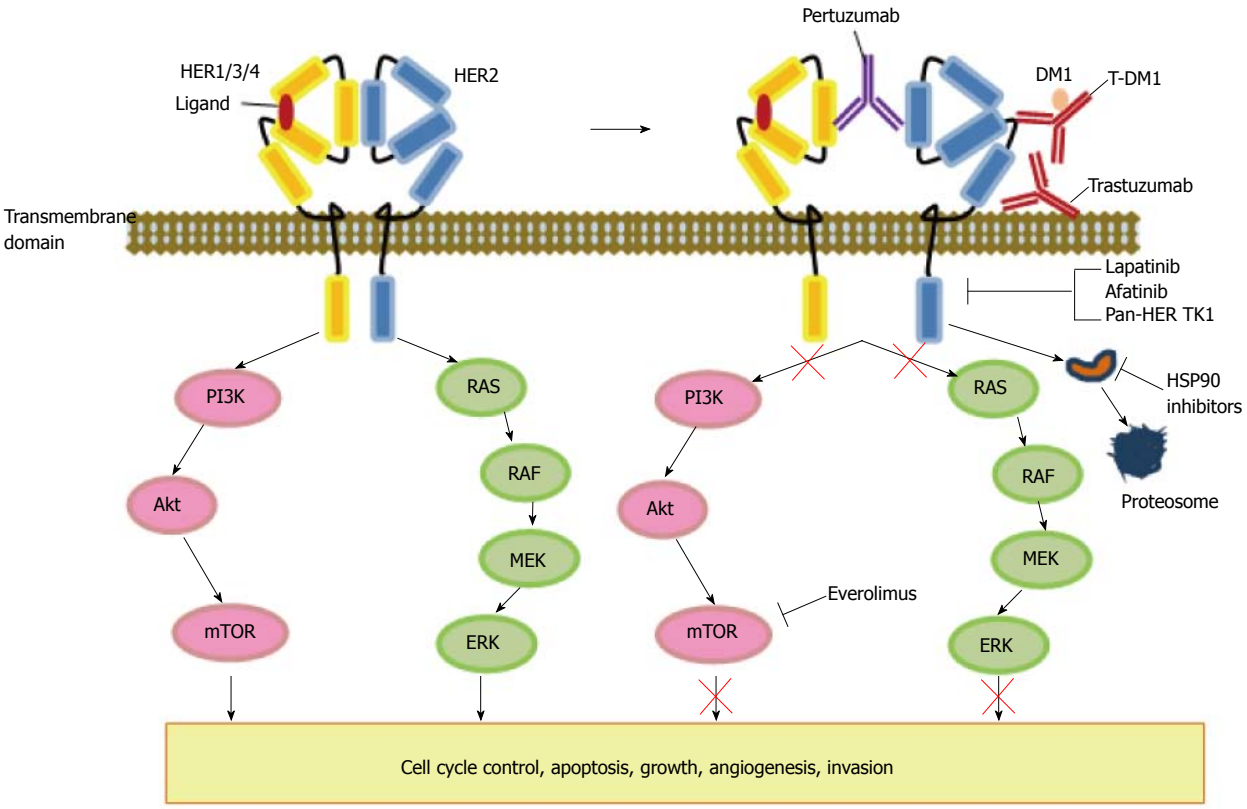

Figure 1 Human epidermal growth factor receptor 2 signaling pathway and interaction with other pathways. This demonstrates schematic representation of the HER-2 family of receptor and their interaction with downstream signalling, along the pathway which are responsible for a variety of biological processes involving cell cycle control, apoptosis, cellular growth, invasion, and angiogenesis. Examples of classes of drugs and corresponding compounds targeting the HER-2 network are also presented. HER1-4 are transmembrane proteins with associated tyrosine kinases. Heterodimerization result in tyrosine kinase activation with the subsequent signaling cascade, and subsequently activates downstream signals, including members of MAPK and PI3K/Akt/mTOR pathways. Trastuzumab and t-DM1 targtets to the extracellular domain IV of HER2. Anti-cancer activity of pertuzumab is interference with HER-receptor dimerization. Lapatinib, afatinib, and tyrosine kinase inhibitors (TKIs) compete for the binding of ATP in the intracellular domain of the receptors. HSP90 suppresses the NH2-terminal ATP binding site which leads to the degradation of client proteins by the ubiquitin proteasome pathway. HER: Human epidermal growth factor receptor; MAPK: Mitogen-activated protein kinase; MEK: Mitogen-activated protein kinase kinase; ERK: Extracellular signal-regulated kinase; PI3K: Phosphatidylinositol 3-kinase; mTOR: Mammalian target of rapamycin.

disease and the second leading cause of cancer-related death worldwide[1]. Despite the current improvements in survival of patients with gastric cancer, it is often diagnosed at an advanced stage and its prognosis is still unsatisfactory due to the high frequency of metastasis[2,3].

Recent studies have shown that several combination chemotherapies have been shown to significantly increase survival for patients with gastric cancer[4]. SPIRITS trial (S1 plus cisplatin *vs* S1 in RCT in the treatment of stomach cancer) showed that combined therapy of S1 with cisplatin significantly prolonged survival as a first-line treatment for advanced gastric cancer. Overall survival (OS) of patients treated with S1 plus cisplatin was 13.0 mo compared 11.0 mo with S1 alone[5]. Additionally, other cytotoxic agents, including docetaxel and irinotecan also prolonged survival[6,7]. Notably, capecitabine and oxaliplatin showed to be non-inferior to fluorouracil and cisplatin[8,9]. However, even with these treatments, most patients with advanced disease have a median overall survival in the range of 6-11 mo[2].

To date, with greater knowledge of the molecular basis of tumor initiation, several kinds of targeted agents have led to a better prognosis for solid tumors. One of the most important targets in human malignancy is the epidermal growth factor receptor (EGFR) family[10]. The human epidermal growth factor receptor-2 (HER2) is a receptor of tyrosine kinase and a member of the EGFR family[11]. HER2 is expressed in a significant proportion of gastric cancer[12]. Trastuzumab, a recombinant humanized monoclonal antibody that targets the extracellular domain Ⅳ of HER2, has recently been noticeably altered the treatment of gastric cancer. Trastuzumab has demonstrated a survival advantage in patients with HER2-overexpressed gastric cancer[13].

In this article, we will outline the issues concerning novel biologic agents for advanced gastric cancer, focusing on anti-HER2 therapies, such as trastuzumab, and other novel agents. We will also discuss the current clinical evidence and ongoing trials supporting the use of HER2-targeted agents combined with cytotoxic agents or other monoclonal antibodies.

MOLECULAR FEATURES OF HER2

HER2, a proto-oncogene encoded by *ERBB2* on chromosome 17, is a cell membrane surface-bound receptor

tyrosine kinase and belongs to EGFR family, including EGFR/HER1, HER2/neu, HER3, and HER4[11]. Each receptor has an extracellular domain, lipophilic transmembrane domain, and intracellular kinase domain (Figure 1). Although HER1, 3, 4 are activated by ligand binding, the specific ligand to HER2 have not been identified yet[14]. Nevertheless, aberrant HER2 activity and activation of the HER2 receptor leads to receptor dimerization (*e.g.*, HER2/HER3), and subsequently activate downstream signals, including members of the Ras/Raf/mitogen-activated protein kinase (MAPK) and phosphatidylinositol-3 kinase/protein kinase-B/mammalian target of rapamycin (PI3K/Akt/mTOR) pathways (Figure 1)[15,16]. Overexpression of HER2 has been found to aggressively promote these signals which are responsible for regulating a variety of tumor biology, such as cancer cell growth, differentiation, invasion and survival[17,18]. Dimerization of HER2 and HER3 is known to be the most active HER signaling dimer. With regard to gastric cancer, HER2 and HER3 are significant predictors of poor survival in multivariate study. HER3 may become another candidate for molecular-targeted therapy in gastric cancer, especially for the diffuse histological type[19,20].

HER2 EXPRESSION AND GASTRIC CANCER

The reported HER2 amplification in patients with gastric cancer ranges from 6% to 23%[13,21,22]. The rates of HER2 amplification or overexpression in gastric cancers are different depending on the primary location of the tumor, which is more frequent in cancers located in the gastroesophageal junction compared with those from elsewhere in the stomach[13,23]. Histological evaluation revealed HER2 overexpression was predominantly seen in the intestinal-type than in diffuse-type cancers (32% *vs* 6%)[22].

HER2 amplification is associated with clinicopathological features, such as age, male gender, tumor size, serosal invasion and lymph node metastasis[24,25]. HER2 expression is a biomarker for the prediction of trastuzumab response[26]. However, the prognostic significance of HER2 overexpression in gastric cancer remains controversial. A number of retrospective studies have demonstrated that HER2 positivity is a prognostic factor associated with increased risk of invasion, metastasis, and worse survival[19,27-29]. HER2 status has been reported as the second poorest prognostic variable following nodal status[30,31]. On the other hand, other studies found no association between HER2 and prognosis in both early and advanced stage cancers[13,32-38].

Several studies have investigated how differences in expression of HER2 between of primary gastric tumor and metastatic lesions. The majority of these reports has described that HER2 expression of primary and secondary sites revealed a high concordance rate, except two studies[35,39]. These data suggest that the evaluation of HER2 expression in the primary cancer is a reliable basis for determing treatment with anti-HER2 agents in patients with metastatic gastric cancer.

HER2 expression is usually determined by immunohistochemistry (IHC) or by the detection of HER2 gene amplification by fluorescence *in situ* hybridization (FISH). The evaluation of HER2 immunostained samples in gastric cancer is carried out as outlined by Hofmann *et al*[40] and optimized by Rüschoff *et al*[41]. HER2 testing is distinct from breast cancer immunohistochemistry testing. The major difference in scoring HER2 IHC staining between gastric cancer and breast cancer is that an incomplete basolateral or lateral staining alone is considered as a positive result, which lead to the frequent incidence of tumor heterogeneity[40]. This heterogeneity may represent the HER2 testing inaccuracy, resulting in the controversy of significance of HER2-expression in gastric cancer. Thus, further studies have been proposed to improve the quality of HER2 testing to make certain that patients receive the best possible therapy for their HER2-positive disease.

A recent study presented the Collaborative Enzyme Enhanced Reactive (CEER) immunoassay may be a useful technique to investigate the HER2 expression[42]. CEER-based assays showed higher sensitivity and specificity as compared to IHC-based assays. Evaluation with this high sensitivity of HER3 resulted in -20% of the IHC/FISH HER2 negative gastric cancers still expressed total HER2 although. Another study presented that the use of a quantitative variable that could be objectively measured, such as the *HER2* gene copy number or the *HER2* amplification ratio, which seems preferable to a subjective classification in accordance with IHC scores that are not regularly consistent[43]. These current development of technology may be useful for elucidating the expression of HER2 more precisely and improving prediction of clinical outcome in gastric cancer patients treated with trastuzumab.

TREATMENT FOR HER2 POSITIVE GASTRIC CANCER

Trastuzumab

Trastuzumab is the first molecular targeted agent approved as standard treatment in gastric cancer[13,44]. This agent induces antibody-dependent cellular cytotoxicity, inhibits HER2-mediated signaling and prevents cleavage of the extracellular domain of HER2 (Figure 1). Trastuzumab for Gastric Cancer (ToGA) study was an open-label phase Ⅲ, randomized controlled trial undertaken in 122 centers among 24 countries[13]. ToGA trial showed that an addition of trastuzumab to conventional cytotoxic chemotherapy demonstrated a clinical benefit compared to chemotherapy alone in terms of tumor response, which suggested that combined chemotherapy with trastuzumab can be cited as a novel accepted option for patients with HER2-positive advanced gastric cancer. Recently, a role of trastuzumab as a second-line chemotherapy got attention because of the usefulness of trastuzumab as a first-line chemotherapy. In

Table 1 Clinical trials of HER2-targeted therapy in gastric cancer (after ToGA study)

Trial	Study design	No. of patients	HER2 status	Regimen duration of treatment	Response rate	Prognosis
LOGiC	Phase Ⅲ/1st Randomized Double Blind	545	HER2 amplification	Lapatinib + XELOX XELOX No description of duration		non-significant prolongation
TyTAN	Phase Ⅲ/2nd Parallel group Randomized	1923	HER2 amplification	Lapatinib +Paclitaxel Paclitaxel 24 mo	27% *vs* 9%	OS: 11.0 mo *vs* 8.9 mo PFS: 5.4 mo *vs* 4.4 mo
HERBIS-1	Phase Ⅱ/1st Non-Randomized	56	IHC 3+ IHC 2+ FISH +	S-1/cisplatin + trastuzumab No description of duration	68%	OS: 16.0 mo PFS: 7.8 mo
PF299804	Phase Ⅱ/2nd Non-Randomized	28 (estimated)	IHC 3+ IHC 2+ FISH +	PF299804 Cycles of 28 d	7.40%	Ongoing
HIROISE (NCT01450646)	Phase Ⅲ/1st Randomized	400 (estimated)		Trastuzumab + cisplatin + capecitabine 33 wk		Ongoing
NCT01472029	Phase Ⅱ/1st Non-Randomized	53		5-FU, leucovorin, docetaxel, oxaliplatin (FLOT), trastuzumab No description of duration		Ongoing
NCT01130337	Phase Ⅱ/ preoperative Non-Randomized	36		Trastuzumab + XELOX 12 mo		Ongoing
NCT01522768	Phase Ⅱ/advanced Non-Randomized	40	IHC 3+ IHC 2+ FISH +	Afatinib + trastuzumab 24 mo		Ongoing
NCT01402401	Phase Ⅱ/2nd Non-Randomized	21	IHC 3+ IHC 2+ FISH +	AUY922 + trastuzumab Every 6 wk		Ongoing
NCT01641939	Phase Ⅱ/Ⅲ/1st Randomized	412 (estimated)	IHC 3+ IHC 2+ FISH +	Trastuzumab emtansine Taxane 12 wk		Ongoing

HER2: Human epidermal growth factor receptor; OS: Overall survival; PFS: Progression-free survival; IHC: Immunohistochemistry; FISH: Fluorescence *in situ* hybridization.

a recent retrospective analysis, gastric cancer patients with HER2 overexpression applied trastuzumab in addition to their first-line chemotherapy with or without trastuzumab maintenance therapy. The median PFS was 14.6 mo and OS was 16.4 mo with an acceptable benefit[45] (Table 1).

On the other hand, the efficacy of HER2-targeted agents have shown to be limited and unsatisfactory than that would be expected[13,46]. These insufficiencies may be overcome by the development of combined therapy with other cytotoxic agents, and strategies against primary or acquired resistance in the patients with gastric cancer. The HERBIS-1 study is the muticenter phase Ⅱ trial undertaken at 22 hospitals in Japan[47]. Patients with HER2-positive advanced gastric cancer received S1 on day 1-14, cisplatin, on 1 d, and trastuzumab on day 1 of a 21-d cycle. The RR based on RECIST was 68% (95%CI: 54%-80%; 80%CI: 58%-76%) and the disease control rate was 94% (95%CI: 84%-99%). Median OS, PFS, and TTF were estimated as 16.0, 7.8, and 5.7 mo, respectively. Trastuzumab combined with SP would be a potential new strategy for patients with HER-2 positive advanced gastric cancer. Another study presented that the level of synergistic effect on combination therapy with trastuzumab and anti-cancer drug was different depending on the expression level of HER-2. The HER-2 expression may be applied to standard for drug selection in combination of trastuzumab with known cytotoxic agents in gastric cancer[48].

Pertuzumab

Pertuzumab, one of the HER2-targeted monoclonal antibody, is distinct and complementary to trastuzumab. Pertuzumab binds the extracellular domain Ⅱ of the HER2 receptor and disrupts HER2 dimerization (Figure 1)[49]. Similar to trastuzumab, pertuzumab activates antibody-dependent cellular cytotoxicity, with equivalent efficacy, leading to cancer cell death[50]. The combination of trastuzumab plus pertuzumab was reported to be synergistic in breast cancer. This combination reduced HER2/EGFR and HER2/HER3 heterodimer formation, leading to in induction of apoptosis *in vitro*[49]. Thus the therapeutic achievement of pertuzumab in metastatic HER2 positive breast cancer provides hope for HER2 positive gastric cancer by using a similar approach. With regard to gastric cancer, a phase Ⅱa study of first-line pertuzumab in combination with trastuzumab, capecitabine and cisplatin in patients with HER2 positive advanced gastric cancer was carried out[51]. Patients were divided into two arms: pertuzumab 840 mg for cycle 1 and trastuzumab 420 mg q3w for cycle 2-6 *vs* pertuzumab 840 mg q3w for six cycles. Partial responses were achieved by 86% and 55% of patients, respectively.

Lapatinib

Lapatinib is a small tyrosine kinase inhibitor of EGFR and HER2 that interferes activation by binding to the intracellular ATP binding site of these kinases (Figure 1).

This agent inhibits HER2 and EGFR dependent activation of PI3K and Ras pathways, leading to downregulation of receptor tyrosine kinase phosphorylation in tumor cells (Figure 1). The synergistic activity was shown by lapatinib in combination with trastuzumab for HER2 positive breast cancer that presented through two lines of trastuzumab related treatments[52]. Regarding to gastric cancer, modest activity was demonstrated with single-agent lapatinib in the Southwest Oncology Group (SWOG) 0413 trial[53]. Subsequently, Tykerb with Taxol in Asian ErbB2 gastric cancer (TyTAN), an open-label randomized phase Ⅲ study comparing paclitaxel with paclitaxel plus lapatinib in patients with HER2 FISH-positive IHC3 + gastric cancer as a second-line therapy was performed. Although the median OS was prolonged by two months with lapatinib, this trial failed to achieve any OS and PFS benefit because statistically significance was not obtained[46]. Moreover, the Lapatinib Optimization study in HER2 positive Gastric Cancer (LOGiC) trial is a phase Ⅲ trial of capecitabine and oxaliplatin with or without lapatinib in first-line advanced HER2 FISH amplified gastric and GEJ cancers suggested not any signs of activity for lapatinib[54]. These negative results of TyTAN and LOGiC trials indicate that there is a presence of drug resistance or an alternative pathways from HER2-targeted therapy. On the other hand, lapatinib may be useful for treating the trastuzumab-resistant HER2-positive gastric cancer. A previous study described that lapatinib showed the antitumor efficacy for trastuzumab-resistant cell lines which was due to both G_1 cell-cycle arrest and apoptosis induction[55].

Trastuzumab-emtansine

Antibody-drug conjugates have been said to transfer cytotoxic drugs directly to tumor cells. Trastuzumab emtansine (TDM-1) is an antibody-drug conjugate of trastuzumab and, a potent microtubule inhibitor, DM1(derivative of maytansine). In preclinical gastric cancer models, TDM-1 has shown more aggressive tumor activity than trastuzumab[56]. A multicenter adaptive phase Ⅱ/Ⅲ of TDM-1 is currently underway with HER2 positive advanced gastric cancer after progression following first line treatment (NIH study trial registration number NCT01641939; ClinicalTrials. gov).

STRATEGIES TO OVERCOME TRASTUZUMAB RESISTANCE IN GASTRIC CANCER

Although HER2 targeting therapy has been advanced, most patients with gastric cancer still develop acquired resistance to trastuzumab[54]. To achieve better benefits for HER2-targeted therapy in patients with HER2-positive gastric cancer, there is an urgent need to clarify the mechanisms underlying the cancer-resistance. Some papers described that intra-tumoral heterogeneity of gastric cancer may play a role in the resistance[57,58]. In this section, we will discuss selected novel agents including those based on proposed mechanisms of resistance to HER2-targeted therapy (Figure 1).

Afatinib

Afatinib (Gilotrif, Boehringer Ingelheim), an irreversible inhibitor of EGFR, HER2, and HER4, has been shown to be effective in the elimination of cancer cells with *HER2* gene mutations[59]. This orally-bioavailable compound binds to its targets and has potential against receptors with acquired mutations that are resistant to first-generation inhibitors. The usefulness of this agent is currently examined in phase Ⅲ study in EGFR-positive non small cell lung cancer, breast cancer, and head and neck squamous cell carcinoma[59]. Phase Ⅱ study in metastatic HER2 positive trastuzumab refractory esophagogastric cancer is underway (NIH study trial registration number NCT01522768; ClinicalTrials.gov).

mTOR inhibitors

One of the most important mechanisms underlying trastuzumab resistance is dysregulation of HER2 downstream signal substrate, including the PI3K/Akt/mTOR pathway. It is well known that *PIK3CA* mutations and phosphate and tensin homolog (PTEN) inactivation result in constitutive activation of the downstream signals. HER2 overexpression is said to be significantly associated with p-Akt expression, suggesting that *PIK3CA* mutation and PTEN inactivation may affect the effectiveness of HER2-targeted therapy[60]. Inhibition of the mTOR/S6K signal by mTOR inhibitor, everolimus, enhanced fluorouracil-induced apoptosis in gastric cancer cells with HER2 amplification. Thus, it is plausible that concomitant therapy between HER2-targeted agents and mTOR inhibitor may provide substantial benefit in patients with HER2-positive gastric cancer.

HSP90 inhibitors

HSP90 is an ATP-dependent, conserved molecular chaperone that is involved in the structural folding and stability of proteins. Suppression at the NH2-terminal ATP binding site results in the degradation of client proteins by the ubiquitin proteasome pathway, which lead to the degradation of HER2 (Figure 1)[61]. Furthermore, p95-HER2, which is amino-terminal truncated form of HER2 and also a major factor of trastuzumab resistance due to the lacks of the trastuzumab binding site, shown to be degraded by HSP90 inhibitors. Several HSP90 inhibitors are undergoing early clinical evaluation. AUY922 is part of the isoxazole HSP90-inhibitor family. HSP90 inhibition by AUY922 leads to decrease the ErbB2 protein level and downstream signaling via PI3K in HER2-positive gastric cancer[62]. A recent study described that a significant synergy exists between AUY922 and trastuzumab in HER2-amplified gastric cancer. The combination of AUY922 and trastuzumab is also synergistic in HER2-amplified trastuzumb-progressed gastric cancer, which may be due to reinforce the rationale behind dual mechanisms of blockade in

HER2-amplified diseases[63]. Clinical trials on the basis of this study are currently underway in gastric cancers (NIH study trial registration number NCT01402401; ClinicalTrials.gov). Thus, the dual inhibition of HSP90 and HER2 may enhance the attenuate effects on downstream signaling, especially in trastuzumab-resistant patients.

Pan-HER TK1

Recent studies have suggested that HER3 plays a pivotal role in tumor resistance to molecular agents targeting HER2[64], and is causing the maintenance of HER2-amplified cell growth. Therefore, it is plausible that a pan-HER TK1, which targets all HER family members, may have more potent activity in HER expressed malignancies. PF00299804 (Decomitib) is an orally bioavailable, second-generation, irreversible pan-HER TKI currently under clinical development[65]. The combination of PF00299804 with chemotherapeutic agents or molecular-targeted agents including trastuzumab produced synergistic effects. These data suggested that PF00299804 may augment the antitumor efficacy of chemotherapy and/or molecular-targeted agents.

Met inhibitors

c-Met is a cell surface receptor for hepatocyte growth factor (HGF), which regulates a variety of cellular processes involved in cell growth, invasion and angiogenesis[66]. A functional crosstalk between Met and HER family members has been shown to acquire an invasive and progressive phenotype, suggesting that Met can be the dimerization partner or crosstalk with HER2[67]. Furthermore, the Met signaling has been implicated as a mediator of resistance to therapies targeting members of the HER family in several solid tumors[68]. These data indicate that HER2 targeted agents combined with Met inhibitor may be useful to facilitate the efficacy and overcome the resistance of HER2 therapy in patients with HER2-positive gastric cancer. Similarly, HGF activation of MET receptors has been described to rescue cells from lapatinib-induced growth inhibition by restimulating the downstream pathways[69]. This effect was abrogated by inhibiting MET with PHA-665752 (a highly specific MET inhibitor), suggesting that lapatinib-induced growth inhibition may be abrogated through the activation of MET. Thus, the dual application of lapatinib and MET inhibitor may be a favorite model to overcome the lapatinib-resistant gastric cancer.

FUTURE PERSPECTIVES

This review has discussed some of a large number of data showing the clinical benefits of trastuzumab for treating HER2-positive gastric cancer. Combination therapy between trastuzumab and conventional chemotherapy is now cited as a standard first-line treatment for HER2 overexpressing gastric cancer in patient with advanced stage. This treatment remains to be under investigation for more potent utilization. Abundant clinical trials are planned or currently underway to evaluate the role of anti-HER2 agents in metastatic disease in combination with cytotoxic chemotherapy as well as with targeted therapy. As previously described, some studies with anti-HER2 combination treatments indicate that the use of more than one HER2-targeted therapy was superior to one of these agents alone in HER2 positive gastric cancer[63,69-71]. With the expansion of utilizing anti-HER2 agents, identifying the right combination of these various novel agents will be urgent to benefit the clinical outcomes in patients with advanced gastric cancer.

There still are several subjects to be discussed and settled for the advancement of HER2-targeted therapy in gastric cancer.

Dose increases of trastuzumab

To date, the clinical relevance of trastuzumab's kinetic variable is not defined. It has been considered that higher dosing may be required in patients with gastric cancer (Roche, Inc. Herceptin package insert. Available at: http://www.medsafe.govt.nz/profs/datasheet/h). Pharmacokinetics data showed in the ToGA study described that the trastuzumab clearance is 0.378 L/d based on the current standard dosing, 70% higher than the rates in trastuzumab-treated patients with breast cancer. The HELOISE study: a study of trastuzumab in combination with chemotherapy in patients with HER2-positive metastatic gastric or gastro-esophageal cancer is currently under investigation (NIH study trial registration number NCT01450696; ClinicalTrials.gov.). In this phase Ⅲ study, patients are randomized to either standard dosing or higher dosing arm (trastuzumab given at 8 mg/kg loading dose followed by 10 mg/kg every 3 wk) in combination with cisplatin based chemotherapy.

Possible candidates as a new biomarker

To date, there are no predictive biomarkers of response to trastuzumab. Thus, identifying a biomarker is one of the most importance in the development of an effective targeted agent. The NeoSphere trial, examining 16 different biomarkers, including HER2 expression, *PI3KCA* mutation, p95HER2, and insulin-like growth factor receptor expression in patients with breast cancer, resulted in failure of predicting response to pertuzumab[72]. In contrast, the presence of HER2 phosphorylation and low HER3 mRNA expression were associated with improved efficacy in patients with ovarian cancer treated with pertuzumab[73]. In some clinical trials, *PIK3CA* mutation or PTEN loss has been evaluated as a possible predictive biomarker. Therefor, to clarify the association between HER2 expression and PI3K/Akt pathway alterations is necessary to develop a new therapeutic strategy.

With regard to gastric cancer, several experimental studies showed the possibility of several factors which may be useful for predicting the efficacy of trastuzumab alone or combined chemotherapy. Trastuzumab resistant cells were noted to express the decreased amount of

p27KIP1 levels and increased CDK2 activity[74]. As a result, p27Kip1 level may be utilized as a marker of trastuzumab response and potential therapeutic target in trastuzumab-resistant gastric cancer. The serum level of HER2-extracellular domain (ECD) has been said to evaluate the HER2 status of patients with gastric cancer. Moreover, the serum HER2-ECD test could enable monitoring of the dynamic changes in HER2 status over the clinical course of the disease. It can be used as an easily accessible real-time biomarker for longitudinal assessments of disease status[75].

Mechanism of resistance

Resistance to trastuzumab is currently emerging in HER2 positive gastric cancers. PI3K pathway may confer resistance to tratuzumab in preclinical studies. Enhanced signaling from HER family receptors, including overexpression of HER3 and formation of high levels of HER2-HER3 heterodimers, and insulin-like growth factor-1 receptor (IGF-1R) are also correlated with PI3K signaling activity and resistance of anti-HER2 agents[76]. Recently, several studies have presented the mechanisms of resistance in patients with gastric cancer. Cancer stem cells may be postulated mediators of the chemoresistance. The c-Met inhibitor may be a promising target molecule for irinotecan-based chemotherapy of gastric cancer[77]. Heregulin 1 can cause resistance to lapatinib in gastric cancers *in vitro* through HER3 and Akt activation[78]. Interestingly, epithelial-mesenchymal transition plays an important role in acquiring resistance to HER2-directed treatment in HER2 positive gastric cancer[79].

CONCLUSION

HER2 signaling lead to receptor dimerization such as HER2/HER3 and positively mediates its downstream signals which lead to a variety of tumor biology. Dimerization of HER2 and HER3 is known to be the most active HER signaling dimer and HER3 may be a subsequent target of therapy in gastric cancer as well as HER2, especially for the diffuse histological type. Current development of technology for identifying HER2 expression is convincing and may result in the improved clinical outcome in trastuzumab applied patients with gastric cancer. There are several molecular HER2-targeted agents applied practically and showing clinical benefits compared to chemotherapy alone in gastric cancer. However, the efficacy of these agents has shown to be modest and unsatisfactory than that would be expected which may be due to the acquisition of resistance or an unmatched combination to known cytotoxic agents. To overcome the trastuzumab resistance, several examinations have elucidated the mechanisms of resistance in gastric cancer. Clinical and experimental studies using several other molecules, which shows synergistic activity by concomitant use with trastuzumab or has potential against receptors with acquired resistance, are under investigation. There still are several subjects to be discussed for the advancement of HER2-targeted therapy in gastric cancer, such as determining the suitable dose of trastuzumab, identifying a predictive biomarker. In conclusion, HER2-targeted therapy is now acceptable for management of patients with gastric cancer and recent studies including resistance-control will provide superior strategies for treating HER2-positive gastric cancer patients. In the meanwhile, considering the low expression (6%-23%) of HER2 and modest effect of ToGA trial (only 2.7 mo prolonged survival) in gastric cancer, the development of a novel molecular targeted therapy which has a more potent activity for gastric cancer might be desirable.

Abstract

Appropriate selection of the implant biomaterial is a key factor for long term success of implants. The biologic environment does not accept completely any material so to optimize biologic performance, implants should be selected to reduce the negative biologic response while maintaining adequate function. Every clinician should always gain a thorough knowledge about the different biomaterials used for the dental implants. This article makes an effort to summarize various dental biomaterials which were used in the past and as well as the latest material used now.

Key words: Biomaterials; Zirconium; Surface roughness; Ceramic; Corrosion

Core tip: This article makes an effort to review and summarize all the biomaterials used for dental implants. Materials in this article are discussed according to the era in which they were used. This review also covers the pros and cons related to these materials. Recent trends in the field of dental implants biomaterials and why these materials are superior over the previous ones. The content of the article are clinically significant and will prove to be helpful for readers to make decision while choosing implant system.

Saini M, Singh Y, Arora P, Arora V, Jain K. Implant biomaterials: A comprehensive review. *World J Clin Cases* 2015; 3(1): 52-57 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/52.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.52

INTRODUCTION

In attempt to replace a missing tooth many materials have been tried as an implant . With all the advancements and developments in the science and technology, the materials available for dental implants also improved[1].

Implants are traceable to early Egyptians and South Central American cultures and with all the developments in material and biological science we have come a long way. Improvements in both the quality and quantity of the implant material have made this treatment modality very promising, budding and highly practiced in today's era. The Earliest dental implants of stone and ivory were

Table 1 Implant materials can be classified based on the type of material used and the biologic response they elicit when implanted[3]

Biodynamic activity	Chemical composition		
	Metals	Ceramics	Polymers
Biotolerant	Gold		Polyethylene
	Co-Cr alloys		Polyamide
	Stainless steel		Polymethylmethacrylate
	Niobium		Polytetrafluroethylene
	Tantalum		Polyurethane
Bio inert	Commercially pure titanium	Al oxide	
	Titanium alloy (Ti-6AL-4U)	Zirconium oxide	
Bioactive		Hydroxyapatite	
		Tricalcium phosphate	
		Bio glass	
		Carbon-silicon	

reported in China and Egypt. Also Gold and Ivory dental implants were reported in the 16th and 17th centuries[2]. Metal Implants of Gold, Lead, Iridium, Tantalum, stainless steel and cobalt alloy were also mentioned in the early 20th century. Between these two periods a variety of polymers, including ultrahigh molecular weight polyurethane, polyamide, polymethylmethacrylate resin, polytetrafluoroethylene, and polyurethane, have been used as dental implant. In the present era, due to the extensive research work and advancements in the field of biomaterials available for dental implants, newer materials came into being such as zirconia, roxolid, surface modified titanium implants. These materials not only fulfill the functional requirements but are also esthetically pleasing. This article makes an effort to review various implant materials, their properties and the various pros and cons associated to those materials. To identify relevant literature an electronic search was performed of Pubmed database using the following keywords, implant biomaterials, implant material biocompatibility, recent trends in implant dentistry. The searches were limited to full text articles in English and those with associated abstracts. All the articles published from 1955 to 2012 are included in this review. All the articles in the language other than English and the articles related to surface coated implants and case reports are excluded.

Materials in this article are divided according to the era they were evolved as an implant material[3-6] (Table 1).

PROPERTIES OF AN IMPLANT BIOMATERIAL

Bulk properties[2,7]

Modulus of elasticity: Implant material with modulus of elasticity comparable to bone (18 GPa) must be selected to ensure more uniform distribution of stress at implant and to minimize the relative movement at implant bone interface.

Tensile, compressive and shear strength: An implant material should have high tensile and compressive strength to prevent fractures and improve functional stability. Improved stress transfer from the implant to bone is reported interfacial shear strength is increased, and lower stresses in the implant.

Yield strength, fatigue strength: An implant material should have high yield strength and fatigue strength to prevent brittle fracture under cyclic loading.

Ductility: According to ADA a minimum ductility of 8% is required for dental implant. Ductility in implant is necessary for contouring and shaping of an implant.

Hardness and Toughness: Increase in hardness decreases the incidence of wear of implant material and increase in toughness prevents fracture of the implants.

Surface properties

Surface tension and surface energy: It determines the wettability of implant by wetting fluid (blood) and cleanliness of implant surface. Osteoblasts show improved adhesion on implant surface. Surface energy also affects adsorption of proteins[2].

Surface roughness: Alterations in the surface roughness of implants influence the response of cells and tissue by increasing the surface area of the implant adjacent to bone and thereby improving cell attachment to the bone.

Implant surfaces have been classified on different criteria, such as roughness, texture and orientation of irregularities[8,9]: (1) Wennerberg and coworkers have divided implant surfaces according to the surface roughness as: Minimally rough (0.5-1 m), Intermediately rough (1-2 m), Rough (2-3 m); (2) The implant surface can also be classified according to their texture as: concave texture (mainly by additive treatments like hydroxyapatite (HA) coating and titanium plasma spraying),convex texture (mainly by subtractive treatment like etching and blasting); and (3) The implant surface can also be classified according to orientation of surface irregularities: Isotropic surfaces: have similar topography independent of measuring direction; Anisotropic surfaces: have clear directionality and vary considerably in roughness.

Biocompatibility

This is property of implant material to show favorable response in given biological environment in a particular function. It depends on the corrosion resistance and cytotoxicity of corrosion products.

Corrosion and corrosion resistance[9-11]: It is the loss of metallic ions from metal surface to the surrounding environment. Following types of corrosion are seen.

Crevice corrosion: It occurs in narrow region like implant screw-bone interface. When metallic ions dissolve, they can create a positively charged local environment in the crevice, which may provide opportunities for crevice corrosion.

Pitting corrosion: Pitting corrosion occurs in an implant with a small surface pit. In this the metal ions dissolve and combine with chloride ions. Pitting corrosion leads to roughening of the surface by formation of pits.

Galvanic corrosion: This occurs because of difference in the electrical gradients. Nickel and chrome ions from artificial prosthesis may pass to peri-implant tissues due to leakage of saliva between implant and superstructure .This may result in bone reabsorption and also affect the stability of the implant and eventually cause failure.

Electrochemical corrosion: In this anodic oxidation and cathodic reduction takes place resulting in metal deterioration as well as charge transfer *via* electrons. This type of corrosion can be prevented by presence of passive oxide layer on metal surface.

Clinical significance of corrosion: Implant bio-material should be corrosion resistant. Corrosion can result in roughening of the surface, weakening of the restoration, release of elements from the metal or alloy, toxic reactions. Adjacent tissues may be discolored and allergic reactions in patients may result due to release of elements.

ANCIENT ERA (through AD 1000)

Implants are traceable to ancient egyptian and south American civilization. There is a skull form pre Columbian era in which artificial tooth is carved with dark stone. Albucasis de condue Arabian surgeon, credited with a written paper of transplants as a means of replacing missing teeth[12].

Foundational period (1800-1910)

This era is the beginning of Endosseous oral implantology. Maggiolo in 1809 used gold in the shape of the tooth root. In 1887 Harris reported the use of teeth made of porcelain into which lead coated platinum posts were fitted. In 1890, Zamenski reported the implantation of teeth made of porcelain, gutta-percha, and rubber and in 1898 R.E payne places silver capsule in the tooth socket. In the early 1900's lambotte fabricated implants of aluminum, silver, brass, red copper, magnesium, gold and soft steel plated with gold and nickel[11,12].

Premodern era (1901-1930)

In 1901 a technique of capsule implantation was reported in dental cosmos which was presented by R.E payne at the clinics of third international dental congress. In 1903, Sholl in Pennsylvania, implanted porcelain tooth which was having a corrugated porcelain root. In 1913, Dr. Edward J. Greenfield introduced into the alveoli the basket of iridium and 24 carat gold. E. J Greenfield also introduced the concept of submerged implant, the healing tissue and dental implant immobility[12].

Dawn of the modern era (1935-1978)

In this era, synthetic polymers, ceramics and metal alloys started replacing the naturally derived materials because they have better performance and more predictable results than the natural ones.

Strock anchored a vitallium screw within bone and immediately mounted it with a porcelain crown. He was the first one to achieve an implant survival for 15 years[12,13].

POLYMERS

The early work with the methyl methacrylate resin implants met mostly with failures[14-18]. However, in 1969, Hodosh reported that polymers were biologically tolerable substances[16,17]. Research on polymethacrylate tooth-replica implants led to the development of the polymer dental implant concept by Milton Hodosh. In replacing a natural tooth, the polymer replica proved to be ideal for the restoration of function and appearance[18].

Polymers were selected for the following reasons[17]: (1) The physical characteristics of the polymers can be altered based on their use as their composition may be changed easily. Polymers can be changed in to more porous or softer form; (2) Polymers can be manipulated easily and allow better reproduction; (3) Polymers do not generate microwaves or electrolytic current as do metals; (4) They show fibrous connective tissue attachment; (5) They can be easily microscopically evaluated than with metals; and (6) They are more esthetically pleasing. There are some disadvantages: (1) inferior mechanical properties; (2) lack of adhesion to living tissues; and (3) adverse immunologic reactions.

Metals and metal alloys

Metals have biomechanical properties which made them suitable as an implant material. Besides these properties metals are also easy to process and have good finish. Metallic implants can be sterilized by the common sterilization procedure which makes them easy to use. But due to advancements with time and low success rates with metals (gold, stainless steel, cobalt-chromium), these materials have now become obsolete and are now replaced by newer ones. Titanium (Ti) and its alloys

(mainly Ti-6Al-4V) have become the metals of choice for dental implants. However, prosthetic components of the implants are still made from gold alloys, stainless steel, and cobalt-chromium and nickel-chromium alloys[3].

Cobalt chromium alloys

They are used in cast or cast and annealed metallurgic conditions. It allows the manufacture of customized implants, such as subperiosteal frames. The elemental composition of this alloy includes cobalt, chromium and molybdenum as the major elements. Cobalt provides continuous phase for basic properties. Chromium provides corrosion resistance through the oxide surface. Molybdenum provides strength and bulk corrosion resistance. Nickels biocorrosive product and carbon must be accurately controlled to enhance mechanical properties, such as ductility[19,20].

Iron-Chromium-Nickel Based Alloys

Stainless steel alloys are used for orthopedic and implant devices. Iron based alloys are used for ramus blade, ramus frame, stabilizer pins and some mucosal insert. The alloy is most prone to pitting corrosion and care must be taken to use and retain the passiviated (oxide) surface condition, as this alloy contains nickel as a major element. Its use in allergic patients must be avoided. They have high galvanic potentials and corrosion resistance.This can result in galvanic coupling and biocorrosion, if titanium, cobalt, zirconium or carbon implant biomaterials are used with it[8].

IMPLANTS IN 21ST CENTURY

Titanium

Titanium has a good record of being used successfully as an implant material and this success with titanium implants is credited to its excellent biocompatibility due to the formation of stable oxide layer on its surface[21,22].

The commercially pure titanium (cpTi) is classified into 4 grades which differ in their oxygen content. Grade 4 is having the most (0.4%) and grade 1 the least (0.18%) oxygen content. The mechanical differences that exist between the different grades of cpTi is primarily because of the contaminants that are present in minute quantities. Iron is added for corrosion resistance and aluminum is added for increased strength and decreased density, while vanadium acts as an aluminum scavenger to prevent corrosion. Hexagonal close-packed crystal lattice of Ti is called the α-Ti (α-phase). On heating it at 883 ℃ phase transformation occurs from hexagonal close packed to body-centered cubic lattice or β- phase. Ti is a reactive as it forms spontaneously a dense oxide film at its surface. Ti is a dimorphic metal i.e. below 882.5 ℃ it exists as α-phase and above this temperature it changes form α- phase to β phase. Because of the high passivity, controlled thickness, rapid formation, ability to repair itself instantaneously if damaged, resistance to chemical attack, catalytic activity for a number of chemical reactions, and modulus of elasticity compatible with that of bone o, Ti is the material of choice for intraosseous applications[3,22-25].

Disadvantage: There is esthetic issue due to gray color of titanium and this is more pronounced when soft tissue situation is not optimal and the dark color shines through the thin mucosa.

Titanium alloys Ti6Al4V

Titanium reacts with several other elements for eg: silver, Al, Ar, Cu, Fe, Ur, Va and Zn to form alloys. Titanium alloys exists in three forms alpha, beta and α-β. These types originate when pure titanium is heated with elements Al, Va in certain concentrations and cooled, these type originate. These added elements play like Phase- condition stabilizers. Aluminum is alpha-phase condition stabilizer and it also increases the strength and decrease the weight of the alloy. Vanadium acts as beta-phase stabilizer. The temperature at which α-to β transformation occurs changes to a range of temperatures as Al or Va is added to Ti. Both α and β forms exist in this range. Temperatures to which the desired form is present can be obtained by quenching alloy at room temperature.To increase the strength, these alloys may be heat treated. The alloys most commonly used for dental implants are of the alpha-beta variety. The most common contains 6% Al and 4% Va. (Ti 6 Al 4V)[3,26].

Ceramics

Ceramics were used for surgical implant devices because of their inert behavior and good strength and physical properties such as minimum thermal and electrical conductivity. Certain properties of ceramics like low ductility and brittleness has limited the use of ceramics[3].

Aluminum, titanium and zirconium oxides

Root form or endosteal plate form, and pin-type dental implants are generally made from High ceramics from aluminum, titanium and zirconium oxides. The compressive, tensile and bending strengths exceed the strength of compact bone by 3 to 5 times. These properties combined with high moduli of elasticity and especially with fatigue and fracture strength have resulted in specialized design requirements for this class of biomaterials[8].

MODERN ERA

Modern Implant dentistry is delineated from the period of mid 1930's to the present. Today's popularity of implants in dentistry is attributed to the developments and the research work which laid the foundation of this field. It is because of all this work in the past that we are seeing the emergence of implant concepts developing into the most refined and popularly utilized systems.

In recent years the treatment options and modalities for achieving optimal functional and aesthetic outcomes with implant restorations have clearly changed. Pure titanium is generally preferred for dental implant because

of its excellent biocompatibilty and mechanical properties. There might be aesthetic problems due to the gray color of titanium. In some situations, there may be a soft tissue recession; in such situations there is an unaesthetic display of the metal components. Therefore, implant research has focused on discovering tooth-colored implant material that improves the aesthetic appearance of dental implants and, at the same time, is highly biocompatible and able to withstand the forces present in the oral cavity and therefore zirconia came into being[27-29].

Zirconia

Zirconia was used for dental prosthetic surgery with endosseous implants in early nineties. Cranin and coworkers published first research work on Zirconia in 1975. Ceramic implants were introduced for osseointegration, less plaque accumulation resulting in improvement of the soft tissue management, and aesthetic consideration as an alternative to titanium implants[30,31].

Monoclinic (M), cubic (C), and tetragonal (T) are the three crystal forms in which polymorphic Zirconia structure is present. Zirconia,on room temperature, acquires a monoclinic structure and changes into tetragonal phase at 1170 ℃, followed by a cubic phase at 2370 ℃. At room temperature these phases are unstable and break into pieces,on cooloing. The C-phase of pure Zirconia can be stabilized by adding CaO, MgO, and Y_2O_3 (Yttrium) resulting in multiphase material called partially stabilized zirconia (PSZ) combining cubic, monoclinic, and tetragonal phases in the order of importance. Tetragonal zirconia polycrystals (TZP), containing tetragonal phase only can be obtained by adding Yttrium at room temperature. Yttria stabilized TZP possesses low porosity, high density, high bending, and compression strength and is suitable for biomedical application[32].

Titanium-zirconium alloy (Straumann Roxolid)

Titanium zirconium alloys with 13%-17% zirconium (TiZr1317) have better mechanical attributes, such as increased elongation and the fatigue strength, than pure titanium. Growth of osteoblasts, that are essential for osseointegration is not prevented by Titanium and Zirconium. Straumann developed Roxolid that fulfills requirements of dental implantologists and is 50% stronger than pure titanium.

Sandblasting and acid-etching on, TiZr1317 with a monophasic a structure results in a topographically identical surface as on pure titanium implants. Because of its superior mechanical properties.Thin implants and implant components that can be subjected to high strains can be produced using TiZr1317 due to its better mechanical properties, provided that the material shows a similar good biocompatibility as pure titanium[33].

CONCLUSION

In evaluating the present and predicting the future, one must also reconsider the past. The implant materials, their composition and properties are not talked about in most of the implant related literature. The literature also lacks the effect of the material properties on success and failure of implants and its effects on the tissues surrounding the implants.

Modern dentistry is beginning to understand, realize, and utilize the benefits of biotechnology in health care. Study of material sciences along with the biomechanical sciences provides optimization of design and material concepts for surgical implants[34].

Implants have been gaining popularity amongst the patients and frequently are being considered as a first treatment option. In the last decade implants have dominated the other treatment modalities and moved into the mainstream of dental practice. "We have come a long way but there is still more to achieve".

Abstract

Vasopressors are routinely used to counteract hypotension after neuraxial anesthesia in Obstetrics. The understanding of the mechanism of hypotension and the choice of vasopressor has evolved over the years to a point where phenylephrine has become the preferred vasopressor. Due to the absence of definitive evidence showing absolute clinical benefit of one over the other, especially in emergency and high-risk Cesarean sections, our choice of phenylephrine over the other vasopressors like mephentermine, metaraminol, and ephedrine is guided by indirect evidence on fetal acid-base status. This review article evaluates the present day evidence on the various vasopressors used in obstetric anesthesia today.

Key words: Vasopressor agents; Obstetrics; Cesarean section; Hypotension; Spinal anesthesia

Core tip: Phenylephrine has emerged as the vasopressor of choice in Obstetrics. However, the present recommendations are essentially based on studies conducted in elective Cesarean sections. Further studies are needed in emergency and high risk Cesarean sections in order to clarify whether there is a benefit of phenylephrine over other vasopressors.

INTRODUCTION

Neuraxial anesthesia remains the preferred choice for Cesarean deliveries across the world. Hypotension is the physiologic consequence of spinal anesthesia and can have a potentially deleterious maternal and fetal impact. Vasopressors, which lead to an increase in systemic vascular resistance and rise in mean arterial pressures[1], have been traditionally used for the prevention and management of hypotension after neuraxial anesthesia. However, the understanding of hypotension after neuraxial anesthesia in obstetrics, and the use of vasopressors to counteract it, continues to evolve over the years. This review article briefly explores the present understanding of the mechanism causing hypotension before discussing the current use of

the various vasopressors in obstetric anesthesia today. The authors discuss the various vasopressors used in obstetric anesthesia and put the recent evidence into perspective to guide our clinical practice today.

HYPOTENSION AFTER NEURAXIAL ANESTHESIA

The sympathectomy resulting from the neuraxial blockade is exaggerated by the physiological changes of pregnancy and puerperium, leading to hypotension in as much as 55%-90% of the mothers receiving spinal anesthesia for Cesarean section[2]. Holmes *et al*[3] and Lees *et al*[4] indicated that the compression of the vena cava by gravid uterus impeded the venous return and caused hypotension. Marx[5] postulated that the subarachnoid block resulted in venous pooling of blood in the lower legs, leading to decreased venous return and reduced cardiac output. Although our present interpretation of the mechanism causing hypotension are still based on these principles, prophylactic therapeutic interventions based upon this understanding do not definitively prevent hypotension after neuraxial anaesthesia in Cesarean sections[6].

Based on studies on pre-eclamptic women, Sharwood-Smith *et al*[6] challenged the understanding that reduced central venous pressure led to decreased cardiac output and arterial pressures. They suggested that "venous capacitance" rather than venous pressure maybe the determinant in causing hypotension after spinal anesthesia in obstetrics. The "endothelium-dependent alteration of vascular smooth muscle function" and increased presence of "vasodilator prostaglandins and nitric oxide" during pregnancy have a vasodilatory effect which is counteracted by the intrinsic sympathetic vascular tone[6]. This intrinsic vascular tone is adversely impacted after spinal anesthesia, leading to exaggerated fall in blood pressure. Studies now show that cardiac output remains nearly unchanged even after sympathetic blockade[7], challenging the concept that in parturients, spinal anesthesia results in decrease in cardiac output[8]. Despite the varied understanding of hypotension following neuraxial anesthesia in pregnancy, vasopressors remain the cornerstone in restoring the arterial pressure and mitigating the possible adverse maternal and fetal impact.

VASOPRESSORS USED IN OBSTETRICS

Vasopressors which have been used in obstetrics primarily include the directly acting selective α_1 receptors agonists, phenylephrine and methoxamine, and both directly and indirectly acting mephentermine, metaraminol and ephedrine.

METHOXAMINE

Methoxamine is an $\alpha 1$ receptor agonist which causes intense vasoconstriction following parenteral administration, raising arterial blood pressure and may result in reflex vagal inhibition of the heart rate[9]. It is devoid of any inotropic or chronotropic effect[9] and has been used to counteract the hypotension caused by spinal anesthesia[10]. Tachyphylaxis has seldom been observed with methoxamine[11]. While the peak vasopressor effect after a single intravenous dose of 2-4 mg has been observed after 0.5-2 min, its duration of action has been reported to be 10-15 min[12]. Intramuscular administration of a 10-40 mg dose has its peak onset of action at 15-20 min and its action lasts for about 1.5 h[12]. Its use in clinical obstetrics has fallen out of favor decades ago owing to concerns regarding decreased uterine blood flow and adverse impact on fetal acid-base status in animal studies[12,13].

MEPHENTERMINE

It has a mixed α and β receptor agonist action with both direct and indirect effect due to release of norepinephrine and epinephrine[14]. Its impact on the heart rate is dependent on the vagal tone. Its use in hypotension after a neuraxial blockade in obstetrics is due to its ability to increase the blood pressures by augmenting the cardiac output[14]. Tachyphylaxis to the pressor action of mephentermine develops rapidly[15]. While there is immediate onset of action peaking at 5 min and lasting 15-30 min after an intravenous dose, an intramuscular dose starts acting after 5-15 min and has a variable duration of action from 1-4 h. It is commonly used as a 3-5 mg intravenous bolus or intravenous infusion of 2-5 mg/min[16], or 25-50 mg intramuscularly[17]. There is scarce literature evidence on the fetal metabolic effect and placental transfer of mephentermine[18]. However, a few studies have shown that mephentermine is as effective as phenylephrine in preventing maternal hypotension after spinal anesthesia and has similar effect on neonatal outcome[19]. It is being widely used in developing countries like India as it is much more economical[19] than phenylephrine. Moreover, unlike phenylephrine which needs multiple dilutions from the single use 10 mg/mL (1 mL) ampoules, mephentermine offers ease of use as it does not necessitates multiple dilutions.

METARAMINOL

Although it has both mixed α and β receptor agonist action, its primary clinical use is to counteract the hypotension after spinal anesthesia in obstetrics. It has significant direct effect on vascular α adrenergic receptors along with its indirect action due to the release of norepinephrine[20,21]. Tachyphylaxis develops due to the displacement of norepinephrine from the sympathetic nerve endings by metaraminol and its action as a false neurotransmitter having inhibited vasopressor effect[17]. While an intravenous bolus dose of 0.5-5 mg has its onset of action in 1-2 min, peak action is at 10 min and duration of action is 20-60 min. An intramuscular dose of 2-10 mg has its onset by 10 min and duration of action of 1-1.5 h[22].

PHENYLEPHRINE

At clinically relevant doses, it is a selective α1 receptor agonist and β agonist action is only seen at much higher doses[20]. It is frequently used in obstetric anesthesia to counteract the hypotension after spinal anesthesia due to marked arterial vasoconstriction caused by its α1 agonist action. Potential negative chronotropic effect is due to reflex bradycardia and decreased cardiac output might not adversely influence the fetus in elective cases[23], but during emergency Cesarean sections with presence of fetal acidosis, any fall in cardiac output may further jeopardize the compromised fetus[23]. However, definitive understanding on the effect of phenylephrine in emergency situations awaits further research[21]. Tachyphylaxis with phenylephrine is possibly caused by the down-regulation of α adrenergic receptors. Its potential to be reversed by hydrocortisone has not been evaluated in an obstetric setting[24].

An intravenous dose of phenylephrine has immediate onset and duration of action of 5-10 min[17]. The optimum regimen for administration of phenylephrine has not yet been defined[25]. Prophylactic administration is associated with a higher incidence of hypertension and bradycardia[26] and treatment after onset of hypotension is associated with higher "incidence and severity of maternal predelivery hypotension"[26]. Despite some studies suggesting that to prevent spinal anesthesia induced hypotension, as an intravenous intermittent bolus dose (ED95) of phenylephrine should be at least 122-147 μg[27,28], 40-100 μg bolus dose remains the common clinical practice[25].

Prophylactic infusions have been advocated in the range of 25-100 μg/min in various studies, but claims have been made that a fixed dose of 50 μg/min minimizes the risk of higher incidence of hypotension at lower doses and reactive hypertension, bradycardia and decreased cardiac output at higher doses[23,25,26].

However, prophylactic fixed dose concept has been challenged[26], necessitating further studies to find the advantages of phenylephrine infusion.

It was even suggested in 2010 that "prophylactic fixed rate infusions may have limited application in clinical practice" and further studies into variable rate of phenylephrine infusion is needed[26]. A recent study by Siddik-Sayyid *et al*[29] has failed to demonstrate any difference in neonatal outcome with a variable rate regimen adjusted in response to changes in arterial blood pressure, as compared to prophylactic fixed rate infusion regimen. However, with respect to limiting maternal symptoms, the variable rate regimen was more effective than relying on rescue phenylephrine[29].

Despite these studies, obstetric anesthesiologists are unable to arrive at a consensus opinion on the ideal regimen for administration of phenylephrine because other studies have demonstrated that with intermittent boluses, the total dose requirement is smaller, blood pressure was better maintained in the 1st 6 min after induction, and indeed, good blood pressure control is achievable by intermittent boluses[30], which is not only simple, but also does not need the setting up of a syringe pump[31].

Although not much literature is available on the efficacy of intramuscular phenylephrine, Ayorinde *et al*[32] reported that 4 mg of intramuscular pre-emptive phenylephrine decreased the severity of hypotension and the need for rescue vasopressors in spinal anesthesia induced hypotension.

EPHEDRINE

It has both direct α and β agonist action, but indirect action is more prominent due to the "release of norepinephrine from sympathetic neurons"[20]. It increases the blood pressure by β1 receptor stimulation with increased heart rate and cardiac contractility, whereas the α agonist action causes peripheral vasoconstriction[21,33]. Prophylactic doses of 30 mg intravenous ephedrine had been suggested by Ngan Kee *et al*[34] to achieve significant reduction in the incidence of hypotension, but it was associated with the risk of reactive hypertension in as much as 45% of the patients. Subsequent studies by Kol *et al*[35] also failed to demonstrate beneficial effect of prophylactic intravenous ephedrine at 0.5 mg/kg. Even for a reduction in the need for rescue boluses of ephedrine, at least 12 mg intravenous prophylactic dose of ephedrine is needed after spinal anesthesia for Cesarean sections[36]. Ephedrine's limited ability to prevent hypotension induced by neuraxial anesthesia is probably related to its slower onset of action[34]. As a rescue vasopressor, 5-15 mg intravenous boluses are most commonly advocated for the treatment of hypotension following neuraxial anesthesia. Its clinical effect is primarily due to its indirect action of releasing norepinephrine from postganglionic nerve endings. The drug not only has delayed onset of action, it also has a longer duration of action of about 60 min. Depletion of presynaptic norepinephrine stores also lead to tachyphylaxis[35]. Due to its delayed onset of action, it should only be repeated after 5-10 min as it was observed that larger doses of ephedrine were required in the first 10 min and often caused overshoot of the desired target systolic pressures after 10 min[37]. Intravenous boluses are therefore preferred to continuous intravenous infusions as the drug exhibits delayed onset of action and tachyphylaxis.

CHOICE OF VASOPRESSOR: THE RECENT EVIDENCE

The ideal vasopressor would be one which is reliable and easy to use, has rapid onset, short duration of action, easily titrable, can potentially be used prophylactically and lack any adverse maternal and fetal impact. A Comparative analysis of the commonly used vasopressors in obstetric anesthesia is illustrated in Table 1.

Table 1 Comparative analysis of vasopressors used in obstetric anesthesia

No.	Drug	Mechanism of Action	Advantage	Disadvantage
1	Methoxamine	α1 receptor agonist	No inotropic or chronotropic effect. Tachyphylaxis has seldom been observed	Reflex bradycardia. Adverse effect on fetal acid-base status
2	Mephentermine	α and β receptor agonist. Both direct and indirectly acting	Economical and does not need multiple dilutions as compared to Phenylephrine	Tachyphylaxis. Little evidence available on placental transfer and its fetal metabolic impact
3	Metaraminol	α and β receptor agonist. Both direct and indirectly acting	No adverse effect on fetal acid-base status as compared to ephedrine	Tachyphylaxis
4	Phenylephrine	Selective α1 receptor agonist at clinical doses	Immediate onset and short duration of action. Ideal for continuous infusion. No adverse effect on fetal acid-base status as compared to ephedrine	Tachyphylaxis. Reflex bradycardia and concerns regarding decreased maternal cardiac output
5	Ephedrine	α and β receptor agonist. Both direct and indirectly acting	Economical and does not need multiple dilutions as compared to Phenylephrine. No bradycardia	Tachyphylaxis. Adverse effect on fetal acid-base status as compared to Phenylephrine

In 2002, Lee *et al*[38] challenged the "traditional idea that ephedrine is the preferred choice". for use as a vasopressor to combat hypotension after spinal anesthesia for Cesarean sections. In a quantitative systemic review they concluded that for elective Cesarean sections, phenylephrine was associated with better fetal acid-base status, although no clinical outcome difference based on the Apgar scores could be established[38].

In patients treated with ephedrine, the cause of decreased pH, base excess and oxygen content in umbilical cord arterial blood is controversial. While earlier studies indicated towards differential action of various vasopressors on uteroplacental circulation[39], studies by Ngan Kee *et al*[40] showed that depressed fetal acid base status was possibly due to ephedrine crossing the placenta and causing depression of fetal pH by its "metabolic effects secondary to stimulation of fetal β-adrenergic receptors". A recent study by Landau *et al*[41] has given a new direction to this debate. They showed that the neonatal homozygosity for Arg16 of *ADRB2* protected from neonatal acidemia in mothers treated with ephedrine[41]. The presence of this genotype in greater that 30% of the Chinese cohort and the fact that their genotype differs considerably from their North Americans indicate that clinicians should be wary of extrapolating studies of one ethnic population group on another[41].

Despite evidence in favor of phenylephrine as a superior choice, there remains widespread variation in the "choice, dosing, and method of administration of vasopressors"[25]. The United Kingdom National Institute for Health and Care Excellence Guidelines state that ephedrine and phenylephrine are equally efficacious as vasopressors in obstetric anesthesia[42]. The American Society of Anesthesiologists Task Force on Obstetric Anesthesia states that while ephedrine and phenylephrine are both acceptable, "phenylephrine may be preferable because of improved fetal acid-base status in uncomplicated pregnancies"[43]. There is much more clarity in the Canadian guidelines which state that there is "general agreement among experts to recommend the use of phenylephrine" as the first line therapy[8]. Belgian guidelines also recommend phenylephrine as the preferred vasopressor in absence of maternal bradycardia (Grade 1, A)[44].

While there is abundant literature evidence claiming superiority of phenylephrine over ephedrine in healthy parturients undergoing elective Cesarean section based on fetal acid-base status, there is dearth of evidence showing benefit in clinical outcome. Meta-analysis of 142 studies comparing phenylephrine and ephedrine failed to show the superiority of one over the other while comparing the Apgar scores[45]. However recent systematic review and meta-analysis do show that fetal acidosis defined as pH < 7.20 was associated with four- and two-fold increase in mortality and morbidity, respectively[46].

Due to a dearth of studies on the vasopressor of choice during non-elective Cesarean sections[47], it is suggested that further research is needed in high-risk pregnancies, intra uterine growth retardation, placental insufficiency, pre-eclampsia[25] and in emergency Caesareans due to fetal distress.

In one study in 2008 by Ngan Kee *et al*[48] in non-elective Cesarean sections, there was "no differences in fetal acid-base status or clinical neonatal outcome" between 100 μg phenylephrine and 10 mg ephedrine boluses to manage spinal anesthesia induced hypotension. Similarly, a retrospective study by Cooper *et al*[49] on the choice of vasopressor between phenylephrine and ephedrine in high-risk Cesarean sections, there was no statistically significant difference in the umbilical artery pH between the two groups.

There is also scarce literature available on the other vasopressors[50]. Kansal *et al*[16] concluded that mephentermine can be used as safely as ephedrine in the management of spinal anesthesia-induced hypotension in Cesarean sections. Similarly, Mohta *et al*[19] concluded that phenylephrine and mephentermine are equally effective in preventing hypotension after a spinal anesthesia for Cesarean section. Both the studies compared the Apgar scores and the neonatal acid-base status while evaluating the vasopressors[16,19]. In 2014, studies by de Aragãoa *et al*[50] compared an infusion of metaraminol with phenylephrine and ephedrine and did not find any difference in the incidence of maternal hypotension or

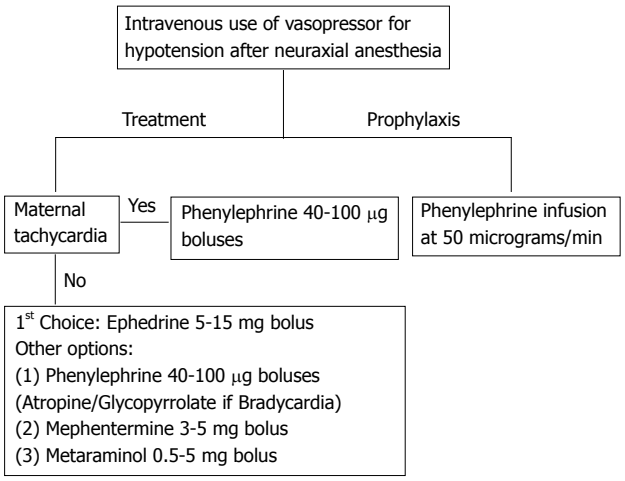

Figure 1 Suggested clinical protocol for intravenous use of vasopressor for Hypotension after Neuraxial Anaesthesia in Obstetrics.

neonatal Apgar scores. Comparison of phenylephrine, metaraminol and ephedrine showed that Ephedrine treated mothers had lower pH and base excess in their newborns[50]. However those treated with metaraminol needed fewer rescue boluses as compared to ephedrine, but not phenylephrine[50].

Combination of phenylephrine and ephedrine infusion has also demonstrated deterioration in fetal acid-base status and maternal hemodynamic control with the proportionate increase in the dose of ephedrine[51-53].

CONCLUSION

Current literature supports the use of phenylephrine as the vasopressors of choice while considering the influence on feto-maternal physiology[25,47]. However, this concept is mostly based on studies conducted in elective Cesarean sections. Therefore, this same principle cannot be extrapolated in emergency Cesarean sections and high-risk pregnancies.

Due to its potential for possible adverse impact on placental perfusion[25] when it causes bradycardia and decreased cardiac output, further studies on phenylephrine are needed, especially in presence of pre-existing fetal compromise.

Certain clinical protocols support the use of phenylephrine in the presence of maternal tachycardia (heart rate > 110/min) and ephedrine at lower heart rates (< 80/min)[54]. A suggested clinical protocol for intravenous use of vasopressor for hypotension after neuraxial anaesthesia in obstetrics is given in Figure 1.

Today, in obstetric anesthesia, both phenylephrine and ephedrine continue to be used in the "absence of relevant evidence, rather than any evidence of the absence of an effect"[55]. The same appears to be true for mephentermine and metaraminol also. Larger trials, especially in non-elective Cesarean sections, would be needed to give further direction to the obstetric anesthesiologists in choosing their preferred vasopressor.

Abstract

AIM: To discuss important characteristics of the use of dental implants in posterior quadrants and the rehabilitation planning.

METHODS: An electronic search of English articles was conducted on MEDLINE (PubMed) from 1990 up to the period of March 2014. The key terms were dental implants and posterior jaws, dental implants/treatment planning and posterior maxilla, and dental implants/treatment planning and posterior mandible. No exclusion criteria were used for the initial search. Clinical trials, randomized and non randomized studies, classical and comparative studies, multicenter studies, *in vitro* and *in vivo* studies, case reports, longitudinal studies and reviews of the literature were included in this review.

RESULTS: One hundred and fifty-two articles met the inclusion criteria of treatment planning of dental implants in posterior jaw and were read in their entirety. The selected articles were categorized with respect to their context on space for restoration, anatomic considerations (bone quantity and density), radiographic techniques, implant selection (number, position, diameter and surface), tilted and pterygoid implants, short implants, occlusal considerations, and success rates of implants placed in the posterior region. The results derived from the review process were described under several different topic headings to give readers a clear overview of the literature. In general, it was observed that the use of dental implants in posterior region requires a careful treatment plan. It is important that the practitioner has knowledge about the theme to evaluate the treatment parameters.

CONCLUSION: The use of implants to restore the posterior arch presents many challenges and requires a detailed treatment planning.

Key words: Dental implants; Mandible; Maxilla; Edentulous jaw; Treatment

Core tip: The treatment plan for rehabilitation with dental implants in posterior quadrants of edentulous jaws must be meticulous. The professional must cautiously evaluate the treatment parameters to guarantee predictable and long-term restorations. The treatment plan includes detailed analysis of space for restoration, bone quantity and density, radiographic techniques, selection of number, diameter, and length of the implants, and occlusion.

Monteiro DR, Silva EVF, Pellizzer EP, Magro Filho O, Goiato MC. Posterior partially edentulous jaws, planning a rehabilitation with dental implants. *World J Clin Cases* 2015; 3(1): 65-76 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/65.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.65

INTRODUCTION

Implant-borne rehabilitation is a good option of treatment for patients with partial edentulism[1-3]. The validity of osseointegrated dental implants for the rehabilitation of posterior partially edentulous jaw had been related in the literature by several studies[4-7]. These rehabilitations offers substantial benefits when compared with removable partial dentures: improved occlusion and support, simplification of the prosthesis, less invasive restorative procedures, bone maintenance and, improvement in oral health[8,9].

However, to obtain excellent results in rehabilitations with dental implants meticulous attention must be paid to details[10]. In addition, the posterior quadrants of the mouth are challenging for rehabilitation with dental implants[6,11,12] due to their anatomical and occlusal features[6,9]. Thus, this article aimed to discuss important characteristics of the use of dental implants in posterior quadrants and the rehabilitation planning.

MATERIALS AND METHODS

An electronic search of English articles was conducted on MEDLINE (PubMed) from 1990 up to the period of March 2014. The Key terms were dental implants and posterior jaws, dental implants/treatment planning and posterior maxilla, and dental implants/treatment planning and posterior mandible. No exclusion criteria were used for the initial search. Titles and abstracts of the screened articles were reviewed and the full text was assessed for an appropriate analysis. Then, the articles were analyzed through inclusion and exclusion criteria. Clinical trials, randomized and non randomized studies, classical and comparative studies, multicenter studies, *in vitro* and *in vivo* studies, case reports, longitudinal studies and reviews of the literature were included in this review. Additionally, current and previous issues of the most relevant papers were inspected, intending to obtain other articles associated to the theme. Articles that were not related to the purpose of this study were excluded from further evaluation. Finally, one textbook was included for the review.

RESULTS

One hundred and fifty-two articles met the inclusion criteria of treatment planning of dental implants in posterior jaw and were read in their entirety. The selected articles were categorized with respect to their context on space for restoration, anatomic considerations, radiographic techniques, implant selection, tilted and pterygoid implants, short implants, occlusal considerations, and success rates. The results derived from the review process were described under several different topic headings to give readers a clear overview of the literature.

DISCUSSION

Space for restoration

The discussion about the space requirements for placing an implant is very important. The mesiodistal space required is related to the type and number of teeth that will be replaced[8]. According to Misch[13], the selection of implant size is influenced by the mesiodistal distance available for implant placement. These authors indicated a guideline for this selection: (1) a distance of at least 1.5 mm must be respected between the implant and the adjacent teeth; (2) a distance of at least 3.0 mm between the implant and an adjacent implant; and (3) for the replacement of a molar teeth, a implant with a wider diameter is indicated.

If the implant-supported proshtesis is positioned with a large distance from the adjacent tooth, critical contours and cantilever forces are generated on the implant. Since the mesiodistal dimension of molar teeth is greater when compared to other teeth, a distance of at least 2.5 mm between the implant and the adjacent implant has to be respected to assure a restoration proper contours[8].

According to Gastaldo *et al*[14], a distance of 3 mm between the bone crest adjacent implants and the proximal contact point is essential, and the implant should be placed 3-5 mm away from the tooth in order to guarantee a healthy interproximal papilla.

Simşek *et al*[15] evaluated, through finite element analysis (FEA), different distances between implants that retained three unit partial prosthesis and their effects on bone stress distribution in the posterior lower jaw. Axial, horizontal and oblique forces were applied and tensile and compressive bone stresses were evaluated. The authors observed that a space of 1.0 cm was the greatest distance between the inserted two implants.

Both the mesiodistal and the buccolingual dimensions from the crestal level to the apical part of the implant site should be evaluated[16]. At least, a 6 mm of bone buccolingual extension is necessary to insert a 4 mm-wide dental implant. For diameters higher than 5 mm, a 7 mm extension is required[8]. Additionally, the intermaxillary

space is an important source. A distance of 10 mm between the residual ridge and the antagonistic arch must be respected when substituting posterior teeth[8,17].

A multidisciplinary approach is considered when planning a dental implant treatment and involves orthodontics, surgery, and restorative, so that the function and aesthetics of those patients are improved[10,16,18-20]. Generally, over-eruption of opposite teeth occurs after a long period of tooth absence, which affects the restorative space. Therefore several treatment options to creat a sufficient space for restoration are available such as enameloplasty, minimal restorative therapy, orthodontic intrusion, tooth realignment, endodontic treatment and full crown preparation, segmental osteotomy for dentoalveolar extrusion and extraction[8,10,16,18,19].

Anatomic considerations: Bone quantity and density

The low-density and quantity of bone and the presence of sinus pneumatization in maxilla are relevant anatomic characteristics in the posterior region, since they can limit the implant height[21-31]. On the other hand, the mandibular canal is an important structure that could limit the installation of dental implants in lower jaws[21,32,33]. According to Jivraj *et al*[8] and Vazquez *et al*[34], a distance of at least 2 mm between the most apical part of the implant and vascular and neurologic structures must be respect.

Additionally, the mental foramen is an important mandibular structure when placing implants in the foraminal region. The mental foramen is either oval or round and is usually placed in the apical area of the second mandibular premolar or between apices of the premolars[35,36]. Nevertheless, its location may vary from the mandibular canine to the first molar[35,37].

Guidelines to evaluate the mental foramen position and the presence of mental nerve deviations have been proposed aiming to preserve the nerve, during surgeries in the foraminal area. Previously to implant insertion, a careful observation of mental nerve and foramen, through panoramic and periapical X-rays, is essential. In case of deficiency of this technique to observe the position of the nerve, the computadorized tomography scans are necessary. After the confirmation of the secure bone height, the professional can install the implants mesially or distally placed from the mental foramen or above it[34,35,37].

The lingual mandibular bone concavity is also another important factor since it increases the risks of fenestrations or perforations during implant insertion, in case of deficient buccal-lingual angulation[20,21,38].

Nevertheless, the bone density on the implant placement region affects the primary stability and in turns determines the implant treatment success[11,39,40]. Fuh *et al*[41] determined the density of trabecular bone at potential areas for implant placement. Chinese jawbones were evaluated through computed tomography (CT) in four different regions: anterior and posterior areas of maxilla and mandible. The bone densities differed between each region, being lower in the posterior area - maxilla (332 + 136 HU) and mandible (359 + 150 HU) - and higher in the anterior area -maxilla (516 + 132 HU) and mandible (530 + 161 HU). These results were similar to those of Sogo *et al*[42], who found that the bone in the posterior maxilla was classified as type Ⅲ (350-850 HU) and type Ⅳ bone (150-350 HU). These findings illustrated the necessity of choosing a specific implant design and surface treatment for the different bone density types owing to improvement of the bone-implant contact area[21]. Furthermore, cutting torque[40,43] and the resonance frequency[40,44] can be used to determine the bone quality and implant stability, respectively, and have a major effect on the osseointegration success.

Sakka *et al*[40], in a literature review, affirmed that to classify the bone quality it is important to evaluate bone morphology and characteristics of the constitutive cells. The cortical and trabecular bone ratio, and bone quantity and density have a great effect on the implant treatment longevity. Cells associated to bone quality, as macrophages, monocytes, fibroblasts, mesenchymal progenitors, osteoclasts, and cells related with angiogenesis, could influence the osseointegration of dental implants.

The implant placement is influenced by the form and contour of the edentulous alveolar ridge[21]. Infections, trauma during dental extraction, remodeling of alveolar bone after tooth extraction create localized defects on the bone[21,25,36,37,45], affecting its height and width, and consequently, influence the dental implant placement[21,28]. Some methods have been used to overcome these complications as guided bone regeneration with resorbable and nonresorbable barriers to enhance localized ridge deformities, the utilization of short-length implants, inclined implants, zygomatic or pterygoid implants, bone grafting surgeries and sinus lifting operations[21,46-52].

Del Fabbro *et al*[46] performed a systematic review of 39 selected studies in which 2046 patients underwent sinus grafting and received 6913 implants. After an accompaniment of 12 up to 75 mo, the reported survival rate was 92.5% (range, 61.2% to 100%). Results were also divided according to type of grafting materials. Overall, the survival rate of implants was 87.7% with autogenous bone, 94.9% when autogenous bone was mixed with other grafting materials, and 95.9% with nonautogenous grafting materials. Results were also reported according to type of implant surface. Overall, the survival rate was 85.6% for implants with smooth/machined surfaces, and 95.9% for implants with rough surfaces.

Radiographic techniques

Prior to implant insertion, intraoral and panoramic radiographies should be considered. But, since those techniques just provide information in a 2-dimensional view, the bucco-lingual bone width is missed[25,34,38,45,53-57].

The localization of the mandibular canal, the submandibular fossa, and the maxillary sinuses, in addition to the angulation of the alveolar crest and the bone volume are of primary importance during implant

treatment planning in the posterior jaw area[22,31,32,34,36,57-60]. Therefore, the use of CT in all sliced images is suggested to indicate the most convenient dimensions of the implant and its optimal position and inclination[25,38,42,45,54-57,61]. Spiral/helical CT scanners provide images with higher quality, with tridimensional view, associated with lower radiation exposure, than conventional computerized tomography[54,62]. Nevertheless, the CT scan is kind of expensive and requires large equipment. The radiation dose is relatively high[63].

In general, the conventional CT liberates a higher dose of radiation than another option of image scan, the cone-beam computed tomography (CBCT), which offers realistically tridimensional sliced images[31,54,57,58]. Therefore, this method is useful during implant treatment planning for partial edentulous patient[57,58,64,65].

Implant selection: Number, position, diameter, and surface

The selection of the ideal number of implants is related to the bone volume and density. Since the posterior region of upper jaw presents a soft bone tissue, it is recommended to insert 3 implants to replace 3 missing teeth[8,65]. In case of one implant failure, the previous prosthesis may still be used. And when the anterior or posterior implant fails, a cantilevered prosthesis could be fabricated[8].

The use of either two or three implants relies on the prosthesis biomechanical function and is influenced by load application during chewing[8]. In cases when it is possible to install three implants, a different configuration with a tripod effect of their distribution can be realized[8,66], which provides greater bone support versus linear placement[66]. Additionally, when possible, multiple implants in posterior quadrants should be splinted. Guichet *et al*[67] observed that splinted implant restorations exhibited optimal stress distribution than non-splinted prosthesis. However, Clelland *et al*[68] and Vigolo *et al*[69] observed that splinted prosthesis did not differ significantly from individual restorations, regarding strain distribution data and peri-implant marginal bone loss, respectively.

Regarding the implant diameter, implants with small (from 3.0 up to 3.5 mm) or regular (from 3.75 up to 4.5 mm) diameters should be used for pre-molar teeth and are not indicated in molar region due to the high occlusion force transmission[21,70]. Prosthesis that does not respect the long axis of the implant tends to develop inappropriate biomechanical forces on the restoration/implant assembly[71,72]. In this case, screw loosening and implant or abutment fatigue may occur[71,73]. Moreover, the cantilever force may induce peri-implant stress and bone resorption[74,75].

Increased mechanical stability and bone-implant contact are achieved using implants with a large diameter (from 5.0 up to 6.0 mm)[21,76-78]. In addition, their use provide an effective counter acting occlusal force of the magnitude that may be observed in molar areas[21,79-81]. Finally, the wide-diameter implants mimic the emergence profile of the molar tooth[8,81].

Nonetheless, due to the presence of a soft bone tissue at posterior jaw, two implants can be indicated in the first molar area[82,83]. Two implants placed very close simulate an anatomical condition of the roots, which increase in two folds the anchorage surface area. Additionally, it eliminates antero-posterior cantilevers, decreases rotational forces and screw loosening. Nevertheless, the routine oral hygiene may be more difficult and insufficient mesiodistal space limits the placement of two implants[8,21].

According to Carvalho *et al*[21], different factors can influence when making a decision between one implant with a large diameter (5 mm) or two implants with a small or regular diameter. These factors are: bone volume and density, bone height between the residual rigde and important structures such as sinus and neurovascular canals and, the availableness of bone in a mesiodistal direction.

In relation to the surface of the implant, the use of rough surface implants has outnumbered machined implants[84-88], and it is supported by evidence of earlier and greater implant stability[84-87,89]. It is also argued that this fact prevents the necessity of a second surgical stage, and even encourages earlier or immediate loading in specific cases[80,90]. But, longitudinal studies comparing the two different surfaces using identical protocols in matched population groups and surgical sites have not been accessed. Therefore, the remaining question rises if the assumed improved longitudinal clinical findings are really the result of better science or the product promotion[89].

Tilted and pterygoid implants

The insertion of tilted implants may be an important alternative to bone grafting, guided bone regeneration, nerve lateralization, short implants, or height deficient atrophic posterior jaw[23,33,50,56,59,75,91-93]. Additionally, it allows for bicortical stabilization of the implants which reduces implant micromotion during osseointegration and enhances the implant success rate[93].

Krekmanov *et al*[94] and Aparicio *et al*[95] evaluated alternatives for implant insertion in severely atrophic maxillas. The authors suggested that a mesiodistal inclination of the implant, associated or not with a bucco-palatal direction, respects the maxillary sinus and are a treatment option for reabsorbed posterior upper jaws. More recently, in a report[93] comprising 196 tilted implants in 64 atrophic posterior mandible edentulous, an absence of osseointegration resulted in failure of only two implants, and the neurovascular structures were intact.

The pterygoid implant was first introduced to be placed in the bone pillar, that is formed by the three structures: pyramidal process of the palatine bone, pterygoid process of the sphenoid bone and maxillary tuberosity[96]. While the first two are formed by dense

cortical bone, the maxillary tuberosity is based on poorer bone quality[22,24,51,96-98]. The surgeon should be aware that the maxillary artery and its branches passess through the posterior and medial regions of the maxillary tuberosity[99]. In case of full-arch implant supported restorations, the use of pterygomaxillary implants gives support and retention for the restorations and eliminate the cantilever's length that may be necessary when just anterior implants are placed[47,51,98,100].

Bahat[101] reported that 7% of the 72 implants inserted with a modified technique in the tuberosity area failed after a follow-up period of 21.4 mo, while Ridell *et al*[99] did not observe failures of any of the 22 implants placed in the same area after an accompaniment of 8 years. Peñarrocha *et al*[47] evaluated 68 pterygoid implants over 1 year of loading and found a success rate of 97.05% and a peri-implant bone loss of 0.71 mm. After that period, the patients were satisfied with the functional and esthetical aspects of the oral rehabilitation.

On the other hand, Balshi *et al*[98] found a cumulative survival rate of 90.8% of 1.608 implants placed into the pterygomaxillary region. These authors compared two-stage freehand, single-stage freehand and single-stage guided protocols. They observed that single-stage protocol exhibited higher cumulative survival rate (96.45%) than two-stage protocol (85.94%) and guided surgery (93.38%). Therefore, immediate loading of those implants is beneficial to treatment.

When implants are inserted into the tuber area, normally it is necessary to tilt the implant, which is unfavorable to the biomechanical point of view, increasing the peri-implant bone resorption and reducing implant success rates. On the other hand, previous studies showed appropriated results with tilted implants *vs* straight ones[33,59,92,95]. Maybe it occurs because the tilted implants can be longer than axial ones[99].

The use of splinted implants has been indicated to reduce the stress on tilted implants[93]. This recommendation has been originated from studies that demonstrated that splinted implants showed better stress distribution when compared to non-splinted prosthesis[67]. On the other hand, Lan *et al*[12] observed, through finite element study, that tilted implants with splinted crowns exhibited greater stress concentration, specially in implants with distal tilting. Nevertheless, additional follow-up and long-term evaluations are warranted.

Short implants

Some authors[91,102-105] have defined short implants as implants no longer than 7 mm. Others[29,106-109] have considered short implants to be implants up to 10 mm long.

The length of implants is limited to the presence of some anatomical structures as the intra-alveolar canal and the maxillary sinus, and bone resorption. In these cases, the use of short implants has been recommended[3,23,29,72,97,104,105,109-112]. From a biomechanical point of view, when an implant is loaded, the peri-implant crestal bone receives the stress from the first few threads of the implant; therefore, once a minimum implant height is osseointegrated, implant diameter is more relevant when compared to an increase in length[23,28,86,108,113-116].

To Grant *et al*[117], short implants are convenient due to: (1) usually, this technique does not require a bone grafting procedure, which results in a faster and less expensive treatment and improves the patient's confort; (2) risks during the surgery, such as nerve damage, osteotomy heat and lesions on the adjacent tooth, are reduced; and (3) there is a surgical ease, in cases of insufficient interarch spaces. However, several controversies still exist to their indication owing to: (1) reduced implant surface; thus leading to less bone-to-implant contact after osseointegration; (2) reduced surface of force distribution after loading; more pressure at the crestal bone; more resorption leading to more threads exposed, decreasing the surface of osseointegrated implant; and (3) compromised crown-to-implant ratio[118].

In case of increased crown-to-implant (C/I) ratio, the crown works as a lever arm, transferring the stress to the crestal bone around the implant[115,119], which can result in peri-implant bone loss[119,120] and problems with components of the prosthesis[66,121].

Blanes[121] found that, when the C/I ratio was higher than 2, the survival rate of the implant-retained prosthesis was 94.1%. Apparently, according to these authors, the C/I ratio did not influence the marginal bone loss. Also, Rokni *et al*[122] observed that the C/I ratio did not interfere on crestal bone loss around dental implants. Similarly, Urdaneta *et al*[73] identified the same results on single-tooth implants. However, these authors noted an increase in prosthetic complications, such as implant abutment and fracture.

Crown/Implant ratios ranging from 0.5 to 1 are important to avoid stress and bone loss at a crestal bone level, which could result in implant loss[116,123,124]. Nevertheless, Tawil *et al*[125] stated that high C/I ratios are not the most relevant agent that affect load distribution and Schneider *et al*[126] added that this increase may be used successfully in implants for single-tooth replacement in posterior jaws, except for smoking patients.

Short implants are feasible solutions in case of insufficient bone height and provide favorable force orientation and distribution[111,125]. In case of full-arch fixed dental prosthesis, short implants can be an alternative in posterior jaws to give support for the cantilever, reducing lever arms and stress loading on implants[72].

Although short implants exhibited greater failure rates that longer ones[127], some studies[3,113,128] demonstrated similar outcomes for both types of implants. Probably, these divergences resulted from other variables, such as implant surface, professional ability, bone characteristics, implant primary stability and prosthodontic protocol, which also affects the implant survival[86].

Atieh *et al*[112] performed a systematic review of 33 selected studies concerning 2573 short implants inserted in posterior upper and /or lower jaws to retain fixed partial

Table 1 Cumulative success rates of short implants placed in posterior region

Ref.	Implant surface	Implant length	N implants	Period of evaluation	Success rate (%)
Bahat[127]	Machined-surface	7 mm	-	5 to 70 mo	90.50
Winkler *et al*[130]	Machined-surface	< 10 mm	181	3 yr	93.40
Friberg *et al*[103]	Machined-surface	< 10 mm	247	8 yr	93.70
Deporter *et al*[84]	Porous-surface	7 or 9 mm	48	8.2 to 50.3 mo	100.00
Tawil *et al*[107]	Machined-surface	⩽ 10 mm	269	12 to 92 mo	95.50
Griffin *et al*[113]	Hydroxyapatite-coated	8 mm	168	Up to 68 mo	100.00
Renouard *et al*[151]	Machined or oxidized surface	6 to 8.5 mm	96	2 yr	94.60
Goené *et al*[110]	Acid-etched surface	7 or 8.5 mm	311	3 yr	95.80
Misch *et al*[85]	Roughened surface	7 or 9 mm	745	6 yr	98.90
Anitua *et al*[86]	Micro-rough acid-etched surface; bioactive surface	7 to 8.5 mm	532	5 yr	99.20
Grant *et al*[117]	-	8 mm	335	up to 2 yr	99.00
Anitua *et al*[114]	-	< 8.5 mm	1.287	1 to 8 yr	99.30
De Santis *et al*[97]	Oxidized surface	< 8.5 mm	107	1 to 3 yr	98.10
Maló *et al*[104]	Oxidized surface	7 mm	217	12 mo	95.00
Pieri *et al*[111]	-	6 mm	61	2 yr	96.80
Perelli *et al*[27]	Porous-surface	5 or 7 mm	110	5 yr	90.00
Jiansheng *et al*[109]	Hydroxyapatite-coated and ankylos	5.7 to 8 mm	162	2 yr	99.40
Slotte *et al*[29]	Acid-etched surface	4 mm	100	2 yr	92.30
Deporter *et al*[88]	Porous-surface	7 or 9 mm	48	10 yr	95.50

prosthesis. A survival rate of 98% was reported, after an accompaniment period of 5 years. When comparing short and long implants, no important differences were observed. The authors affirmed that short implants represents a viable treatment option than longer ones and that the survival rate is not related to implant surface, design or width.

Morand *et al*[118] reported that the one improvement that had the most dramatic effect in improving implant treatments was the evolution of implant surfaces from machined/polished to rough-textured surfaces. Table 1 confirms this information, evidencing higher success rates for rough surfaced implants. The percentage of bone-implant contact can be modified by the surface condition of the implant. This is important because the greater the percentage of bone contact, the lesser stress is applied to the bone-implant interface[86]. Therefore, it is possible to assure that with careful case selection criteria, the longevity of short implants is greater than 90%.

Nevertheless, besides the high success rates, the most important aspect of treatment with short implants is the case selection[23,118]. Facing severe bone resorption associated with poor bone quality and overload, bone grafting techniques could prevent failure in such associations. The success rate of short implants in patients with more favorable conditions is greater which makes it the best treatment option[129].

Occlusal considerations

The excess of loading in posterior jaws associated with the functional activity of the mandible in a buccal-lingual direction and with cusp inclination can create lateral forces onto implants[9,130-132]. Thus, during implant treatment planning, a broad evaluation of the loading is essential, since a bending moment at the peri-implant bone can result in prosthesis components damages and/or crestal bone loss[20,66,115,132,133].

Various factors can overload an implant. Rangert *et al*[134] identified two principal factors that justify this excess of loading: geometric and occlusal load reasons. The first one is related with the implant number and position, and with the prosthesis configuration. The second factor includes lateral occlusal force components and parafunctional habits, which increase the loading onto implant surfaces. If forces are higher than normal, the implant can be overloaded.

Ogawa *et al*[135] affirmed that a decrease in number of supporting implants is to promote an increase in implant loading. The bending moments were higher when prosthesis were supported by three implants than four or five implants. Additionally, concerning the implant position, the smallest implant distribution increased the bending moments.

The prevention of occlusal overload should be the focus of any treatment planning[66,136]. In case of no alternative, the prosthesis should be protected from injuries with an inter-occlusal device[67,93]. Some guidelines were reported aiming to respect physiologic limits for occlusal loading: optimized passive fit, reduction of cantilevers, adequate selection of the dimensions and number of implants, presence of a correct preload in the abutment screw and a proper buccal-lingual dimension and cusp inclination of the crown[66,132,133,137-139].

Furthermore, the principles of implant occlusion are mostly based on the traditional principles of conventional restoration. Anterior guidance should be presented and during lateral excursion, a posterior disclusion is indicated for working and non working sides. Group function disocclusion is indicated when the canine is compromised[8].

Payer *et al*[140] evaluated the outcome of edentulous posterior mandible treated with implant-retained immediate provisional prosthesis. According to these authors, immediately loaded implants exhibited similar results when

Table 2 Cumulative success rates of implants placed in posterior region

Ref.	N implants	Posterior zone	Period of evaluation	Implant systems	Success rate (%)
Jemt *et al*[4]	259	Maxilla and mandible	5 yr	Nobelpharma	97.20
Zarb *et al*[144]	105	Maxilla and mandible	2.6-7.4 yr	Nobelpharma	94.30
Block *et al*[142]	443	Mandible	10 yr		79.30
Becker *et al*[143]	282	Maxilla and mandible	6 yr	Branemark	89.40
Bahat[145]	660	Maxilla	10 yr	Branemark	93.40
Attard *et al*[5]	106	Maxilla and Mandible	10 yr	Nobel biocare	94.00
Attard *et al*[152]	432	Maxilla and Mandible	15 yr	Nobel biocare	91.60
Jebreen *et al*[7]	141	Maxilla and Mandible	12-69 mo	ITI	96.45
Blanes *et al*[6]	192	Maxilla and Mandible	10 yr	ITI	97.90
Huynh-Ba *et al*[153]	273	Maxilla	8 yr	-	94.90
Maló *et al*[70]	247	Maxilla and Mandible	11 yr	Nobel biocare	95.10
Schneider *et al*[126]	100	Maxilla and Mandible	5 yr	Nobel biocare and straumann standard	95.80

compared to conventionally loaded implants. During a follow-up period of 5 years, the survival rate was 95%.

Similarly, Degidi *et al*[136] performed a randomized clinical trial that aimed to evaluate the effect of immediately loaded and immediately restored implants for edentulous posterior lower jaws. The authors found that both procedures are predictable. No differences in marginal bone loss or survival rate were observed.

Nonetheless, concerning the conditions of early-loaded implants in the posterior upper and lower jaws, Kim *et al*[141] observed that, although early loading is a predictable procedure, it is important to be careful with maxillary implants.

Success rates

Table 2 illustrates the success rates of implants inserted in the posterior jaws of patients with partial edentulism. Favorable success rates were observed when edentulous areas were replaced with implants, except for the study of Block *et al*[142], which related lower success rates for implants inserted in posterior inferior jaws (78.5% for first molars and 71.8% for second molars). Some studies showed distinct success rates for those implants placed in the posterior regions of maxilla and mandible, with lower success rates for the posterior maxilla[4,6,7,143]. However, Zarb *et al*[144] obtained a success rate of 97.6% for the 41 implants placed in the upper jaw and, of 92.2% for the 64 implants placed in the lower jaw, after a loading period of 2.6 to 7.4 years.

The non-standardization between and within studies has increased the range in success rates, *e.g.*, 79.3% to 97.9%. The differences in study design may be the driven force toward those results. Factors such as length, number, diameter and surface of the implants, bicortical fixation, and extended healing periods contribute to a good long-term success rate[4,143,145]. When the implants are placed into soft bone tissues or inserted in regions with insufficient bone height that demands grafting procedures such as sinus lifting, lack of osseointegration[11,25,146] and failure after loading[147] are prone to occur. The same problem occurs in case of smoking patients[11,148]. Additionally, the lack of oral hygiene may be another initial factor of implant loss[133,145,149], while bicortical fixation may improve osseointegration and reduce bone resorption[116,145,150].

COMMENTS

Background

The osseointegrated implants allow a functional rehabilitation for patients with partial edentulism, since they improve the occlusion and retention of the prosthesis and the bone maintenance. However, the posterior region of the maxilla and mandible requires special attention due to their anatomical and occlusal characteristics.

Research frontiers

Implant-retained prosthesis is a common procedure for posterior partially edentulous jaw rehabilitations. The knowledge regarding this topic involves maxillofacial anatomy, physiology and radiology, oral implantology, occlusion and prosthodontics, and is directly related with patient's psychological aspects.

Innovations and breakthroughs

This review of the literature presents an accurate description of the main articles that evaluated a rehabilitation with dental implants in the posterior maxilla or mandible. Different topics, such as space for restoration, anatomic considerations, radiographic techniques, selection of number, diameter, position and length of implants, occlusal considerations and success rates, were carefully discussed in this article.

Applications

The study findings suggest that professionals need to minutely evaluate the treatment parameters to guarantee the longevity and success of the rehabilitation.

Terminology

Crown-to-implant (C/I) ratio is a guideline related with the longevity and survival of the prosthesis, since a higher C/I ratio represents a lever arm of the crown over the peri-implant bone area, which can result in bone loss.

Peer review

The work is interesting,and useful to the clinicians.

Abstract

Xanthogranulomas (XG) are benign proliferative disorder of histiocytes, a non-Langerhans cell histiocytosis. Whose etiology is unknown. The nature of these lesions is controversial and could be either reactive or neoplastic; the presence of monoclonal cells does, however, favor the second hypothesis. Xanthogranuloma is frequently found in young adults and children (under 20 years old), mainly in the skin. In about 5%-10% of all Juvenile XG (JXG) cases xanthogranuloma are extracutaneous. Within this group, the site most frequently involved is the eye. Other involved organs are heart, liver, adrenals, oropharynx, lung, spleen, central nervous system and subcutaneous tissue, although involvement of the spine is uncommon. Isolated lesions involving the sacral region are extremely rare. To date, this is the first reported case of a giant JXG arising from S1 with extension into the pelvic region in an adult spine.

Key words: Xanthogranulomas; Non-Langerhans cell histiocytosis; Touton giant cells; Congenital xanthoma; Neurofibromatosis

Core tip: Xanthogranulomas (XG) are benign lesions derived by histiocytes, also called histiocytosis with non-Langerhans cell. Isolated xanthogranuloma involving the sacral region are unique. We report the unique giant Juvenile XG arising from S1 with extension into the pelvic region in an adult spine. Complete surgical removal is the goal of the treatment and usually curative even if there is not a study in the literature with a long follow up able to confirm this. If total resection is not possible, the patients must be followed by strictly clinical examination or should undergo adjuvant radiotherapy.

INTRODUCTION

Xanthogranulomas (XG) are benign proliferative disorder of histiocytes, a non-Langerhans cell histiocytosis[1]. Whose etiology is unknown. The nature of these lesions is controversial and could be either reactive or neoplastic; the presence of monoclonal cells does, however, favor the second hypothesis[2]. Xanthogranuloma is frequently found in the skin of young population, especially under 20 years old. In about 5%-10% of all Juvenile XG (JXG) cases xanthogranuloma is extracutaneous. Within this group, the eye appears to be the site most frequently involved. Other involved organs include the oropharynx, heart, liver, lung, spleen, adrenals, muscles , central nervous system and the subcutaneous tissues, although involvement of the spine is uncommon[1]. Isolated xanthogranuloma of the sacral region are extremely rare[1,3]. To date, this is the first case of a giant JXG arising from S1 with extension into the pelvic region in an adult spine.

CASE REPORT

Anamnestic data and neurologic examination

A 44-year-old man was referred to our hospital with a 9 mo history of pollakiuria, stypsis, and sciatica along the S2 left dermatome, the symptoms appeared slowly worsening. The patient underwent lumbosacral magnetic resonance imaging (MRI) with gadolinium that demonstrated the presence of a presacral, giant, well-circumscribed round formation. The lesion compressed the left S4, S3 and S2 roots and dislocated the urinary bladder, rectum, and iliac artery, and it extended ventrally from the left articular mass of S1 to the pelvic region. The lesion was hypointense on T1 weighted images and isointense on T2 ones with dishomogeneous contrast enhancement after gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA) (Figure 1). The computed tomography (CT) bone scanning showed the erosion of S3-S4 foramen and bone involvement of left sacral wing. On physical examination, the patient had a positive right Lasegue sign. Rectal inspection revealed the presence of a posterior hard-elastic lesion.

Treatment

The patient underwent CT-guided biopsy at the division of general surgery of the Policlinico Umberto I. A juvenile xantogranuloma was diagnosed at the histological examination. The patient was then referred to our attention and underwent surgery performing a posterior approach: the patient was placed in prone position; Intraoperative neurophysiological monitoring has been utilized. A standard electromyography monitoring of L4, L5 and S1 was conducted bilaterally. Moreover the insertion of electrodes in the urethra and anal sphincter during the surgical procedure helps to discriminate between nerve root and tumor. A U shaped skin incision was performed, followed by a complete exposure of the spinal column and partially of the sacro-iliac region with prevalent lateral extension on the left side. A complete laminectomy and partial left sacrectomy (25% of left sacrum removal) was performed. Because of the benign nature of the lesion and the space formed by tumor growth, we performed a less invasive procedure with intralesional posterior tumor removal, obtaining enough space without total sacrectomy that could be destabilizing for spine. We used the posterior approach to easily reach the lesion right after the opening of the subcutaneous layer and because it was easier to reach the origin point of the lesion and to control the S2, S3 and S4 root. Intraoperatively, the lesion appeared xanthochromic, friable, moderately bloody and presented a discontinuous capsule. The consistency was really flabby so that the cranial part of the tumor was easily mobilization and the removal was safe for structures as like as rectum and sacral plexus. The lesion was very adherent to the surrounding tissues. The lesion was macroscopically total removed. Immediately after surgery, the patient had relief of pain and had a progressive resolution of sphincter disturbances, with complete recovery after 15 d from surgery. A complete removal of the tumor was shown in the postoperative spine MRI (Figure 2). The patient was discharged on the tenth postoperative day. Clinical follow-up at 1 year showed the stability of symptoms. Radiological follow up using MRI (3T, T1, T2, STIR, T1 sequences with contrast) at 3, 6 and 12 mo showed no signs of recurrent disease.

Pathology

Gross examination showed a 13 cm × 10 cm × 13 cm round lesion, discontinuously encapsulated and adherent to surrounding tissues. The cut surface was homogeneous, yellow and of gelatinous consistency. Microscopic examination revealed the presence of typical touton giant cells. In general, a finding of such cells is sufficient for a diagnosis of xanthogranuloma. Immunohistochemical studies, in one of Dehner's series, showed an immunopositive response for CD68, factor XIIIa and Vimentin of the tumor cells, and are not reactive for S100 and CD1a (Figure 3)[4].

DISCUSSION

Proliferative disorders of histiocytes were described in 1905 by Adamson[5]. Those diseases comprehend a group of pathologies in which the main hstological patterns are dendritic cells and macrophages. The xanthogranuloma has called a non-Langerhans cell histiocytosis as soon as other entities as: Rosai-Dorfman disease (if associated with lymphadenopathy), benign cephalic histiocytosis, the papular xanthoma, and hemophagocytic histiocytosis. Xanthogranuloma is usually benign and is also known as juvenile because it occurs predominantly in young people under the age of twenty years[1]. Etiology of JXG

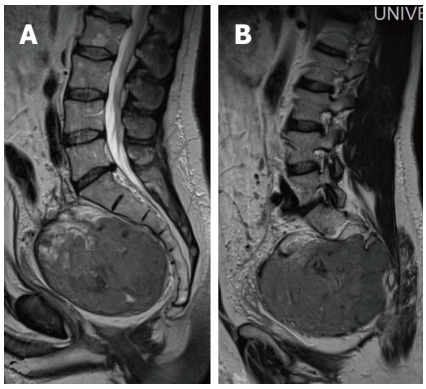

Figure 1 lumbosacral magnetic resonance imaging showing a giant, well-circumscribed round formation hypointense on T1 weighted images and isointense on T2 ones with dishomogeneous contrast enhancement after Gd-DTPA. A: A sagittal T2-wieghted midline image; B: A sagittal T2-weighted lateral image. Gd-DTPA: Gadolinium diethylenetriaminepentaacetic acid.

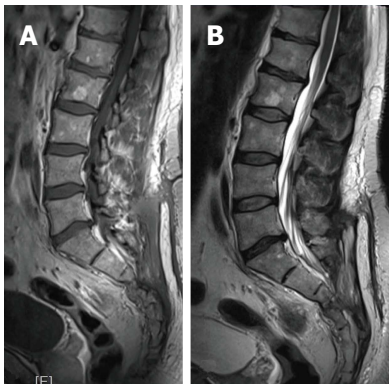

Figure 2 Postoperative spine magnetic resonance imaging showing complete removal of the tumor. A: A sagittal T1-wheighted image after Gd–DTPA; B: A sagittal T2-weighted midline image showing macroscopical total tumor removal. Gd-DTPA: Gadolinium diethylenetriaminepentaacetic acid.

is unknown, but probably is the result of alteration in macrophagic response to an aspecific injury, resulting in a granuloma.

On the other hand, the recent discovery of the monoclonal nature of the cell population of these lesions, has suggested a possible neoplastic origin[2]. The skin of neck and head are the most frequent location of the JXG 67%[3]. It can be multiple or solitary with red-to-yellowish nodules and papules. The involvement of extracutaneous tisuues occurs in about 5%-10% and mainly involves eyes (uvea). Involvement has been reported in other organs including the lung, heart, liver, oropharynx, central nervous system, spleen, adrenals, muscles and subcutaneous tissues, although spinal involvement is extremely rare[3]. The lesions are self-limiting regressing over several years and predominantly occur in childhood. In these cases, conservative treatment and clinical observation is therefore indicated. Adults do not usually experience spontaneous resolution[3] and injuries may present invasive characteristics, meaning that surgical procedures become the treatment of choice. The gold standard radiological examination is MRI, useful

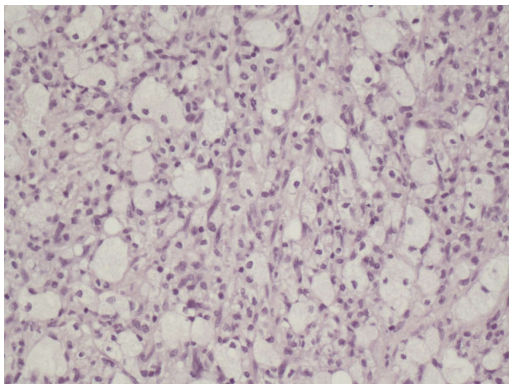

Figure 3 Histological picture: Microscopic examination revealed the presence of typical touton giant cells.

for defining the localization and relation to the other structures. Today a standard treatment for extracutaneous JXG is not defined. However, literature indicates that total removal of the tumor is the treatment of choice and it is important the excision of the origin of the tumor. According to some authors, *en-bloc* excision of the lesion to healthy margins could be a curative treatment option. If total resection is not possible, the patients should be followed under medical observation or be submitted to adjuvant radiotherapy[3]: if the symptoms recur, the patients should be re-operated[1]. On the other hand, radiation treatment, besides not being free from complications, poses the lesion at risk of malignant transformation. To date, this is the first case of giant JXG arising S1 with extension into the pelvic region in an adult spine. All spinal surgeons know and understand the risk of vascular injury because iliac arteries, aorta, and other vascular structures are strictly related to the anterior lumbar spine. We used the posterior approach to reduce the risk of vascular injury, to easily reach the lesion right after the opening of the subcutaneous layer and the origin point of the lesion and to control the S2, S3 and S4 root. Although the depth of the cable and the relationships with the adjacent vascular structures made it particularly difficult to remove the lesion, total removal was achieved by a posterior approach. The placing of neurophysiological electrodes monitor during the surgical procedure in the urethra sphincter and anal sphincter allows surgeons to distinguish between nerve roots and tumor, and to prevent urinary dysfunctions.

The follow-up at one year showed an improvement in reported preoperatively symptoms and confirmed radical removal, without any signs of disease recurrence.

A standard treatment for extracutaneous JXG is not still accepted. However, complete surgical removal is the goal of treatment although the size and the aggressive behavior of the tumor may condition the procedure. Complete surgical removal is usually curative even if there is not a study in the literature with a long follow up able to confirm this. If total resection is not possible, the patients have to be followed under close medical observation or should undergo adjuvant radiotherapy. Important is the

use of neurophysiological monitoring especially of the pelvic region to prevent any neurological dysfunction.

COMMENTS

Case characteristics

Pollakiuria, stypsis, and sciatica along the S2 left dermatome.

Clinical diagnosis

On physical examination, the patient had a positive right Lasegue sign. Rectal inspection revealed a posterior hard-elastic lesion.

Imaging diagnosis

Lumbosacral magnetic resonance imaging with gadolinium demonstrated the presence of a presacral, giant, well-circumscribed round formation. A computed tomography bone scanning showed erosion of the left sacral wing at S3-S4 foramen.

Pathological diagnosis

Microscopic examination revealed the presence of typical touton giant cells. In general, a finding of such cells is sufficient for a diagnosis of xanthogranuloma.

Treatment

Surgical treatment.

Related reports

The recent discovery of the monoclonal nature of the cell population of these lesions, has suggested a possible neoplastic origin. The lesions are self-limiting and predominantly occur in infancy and childhood, and typically regress over several years. In these cases, conservative treatment and clinical observation is therefore indicated. Adults do not usually experience spontaneous resolution and injuries may present invasive characteristics, meaning that surgical procedures become the treatment of choice.

Term explanation

Xanthogranuloma, a proliferative histiocytic disorders.

Experiences and lessons

Complete surgical removal is the gold standard for the treatment of this pathology.

Peer review

The paper describes a rare (probably unique) case of symptomatic giant xanthogranulomas of the pelvis in a 40 years old male. Authors explain clearly why they decided to manage surgically the lesion. Excision was successfully performed trough a posterior route to avoid damages to the surrounding neurovascular structures. Symptoms relief was immediate and preserved one year after surgery. The paper is really interesting.

Abstract

We report the case of a cervical pregnancy successfully treated with intramuscular injection of methotrexate (MTX) and intramniotic administration of potassium chloride. A 41-year-old woman was admitted to our Department with the suspicion of ectopic pregnancy. Transvaginal ultrasound revealed empty endometrial cavity, gestational sac within the cervical canal and embryonic echo measuring crown rump length 1.5 mm. Serum beta human chorionic gonadotropine (β-HCG) was measured 28590 IU/L. No cardiac activity was detected. The diagnosis of a cervical pregnancy was made. Patient was treated with intramuscular administration of methotrexate (50 mg/m^2) in combination with ultrasound-guided intramniotic injection of KCl (2 meq/mL). Gradual decrease of β-HCG levels as well as ultrasound observation of collapsed gestational sac was observed. No curettage was necessitated. Patient was discharged on day 10th and was set in follow-up on a weekly basis. β-HCG values were measured < 10 IU/L on 56th day after MTX administration. Intramuscular administration of MTX may be effective in treatment of cervical pregnancy without additional interventional measures.

Key words: Cervical pregnancy; Methotrexate; Effectiveness; Conservative treatment; Intramuscular

Core tip: This case of cervical pregnancy is one amongst few treated successfully with intramuscular administration of methotrexate and intramniotic KCl, without demanding additional interventional treatment. Our paper also summarizes the basic conclusions about conservative treatment of cervical pregnancy, a challenging issue in which no consensus still exists.

Conservative management of cervical pregnancy with intramuscular administration of methotrexate and KCl injection: Case report and review of the literature. *World J Clin Cases* 2015; 3(1): 81-84 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/81.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.81

INTRODUCTION

Cervical pregnancy represents < 1% of ectopic gestations with its estimated frequency ranging between 1:1000-1:18000 pregnancies[1]. It consists a rather challenging clinical condition that may even lead to life-threatening complications. Diagnosis is based on ultrasound imaging and may frequently present difficulties; however, it should be made as early as possible in order to avoid the risk of severe vaginal hemorrhage which may even necessitate emergency hysterectomy[2,3].

No consensus has yet been achieved regarding the optimal therapeutic approach of cervical pregnancy. Review of literature demonstrates lack of randomized clinical trials comparing the effectiveness of various therapeutic protocols as the rarity of cases poses reasonable scientific limitations. However, the trend of modern clinical practice is rather destinated to conservative management mainly based on the usage of methotrexate (MTX)[1,3,4]. MTX may be administrated intramuscularly (*i.m.*) or intramniotically (*i.a.*) and may also be combined with other therapeutic means, such as intramniotic administration of potassium chloride, vaginal mifepristone or uterine artery embolization (UAE)[4-11]. In any case, close follow-up is demanded in order to diagnose incompletely treated cases and perform additional interventions such as curettage, hysteroscopy or even hysterectomy[7,12,13].

We present the case of a cervical pregnancy which was successfully treated with intramuscular injection of MTX plus intramniotic administration of potassium chloride, without necessitating further treatment with curettage. Furthermore, a narrative review is also provided regarding the various therapeutic options regarding the optimal treatment of cervical pregnancy.

CASE REPORT

A 41-year-old woman was admitted to our Department with the suspicion of ectopic pregnancy. The woman was followed-up by a private physician, being on her 54th day of amenorrhea, with reported beta human chorionic gonadotropine (β-HCG) ranging within normal values, based on her reported last menstrual cycle. Conception was reported to be spontaneous. The patient had an obstetrical history of three pregnancies, of which the first one was delivered vaginally and the consequent two with caesarean section. Regarding medical-gynecological history, patient reported no severe additional pathology. During her physical and gynecological examination patient was haemodynamically stable. Pelvic examination was normal and cervix itself was closed.

Transvaginal ultrasound imaging at the time of admission revealed empty endometrial cavity, gestational sac within the cervical canal and embryonic echo measuring CRL 1.5 mm (Figure 1). Cardiac activity was detected at the time of diagnosis. Serum β-HCG was measured 28590 IU/L, while no other remarkable findings were observed from her blood test examination. The diagnosis of a cervical pregnancy was therefore made and patient was hospitalized for further treatment.

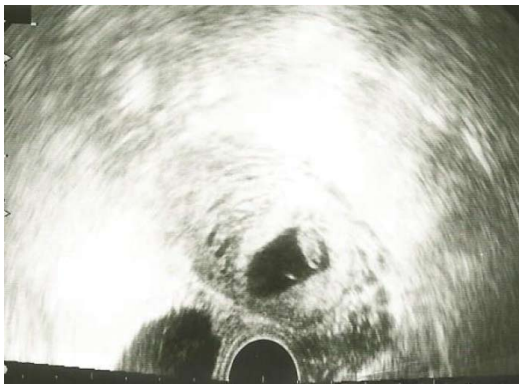

Figure 1 Ultrasound imaging of cervical pregnancy at the time of admission.

Because of patient's stable clinical condition, without signs of vaginal bleeding or pain, patient was decided to be treated with intramuscular administration of methotrexate (50 mg/m^2) in combination with ultrasound-guided intramniotic injection of KCl (2 meq/mL). Injection of KCL was well tolerated by patient without need for anesthesia administration, despite the presence of anesthesiologist during the whole procedure.

Considering that the day of medication was day 1, β-HCG was measured 25.100 IU/L on day 4, 8400 IU/L on day 7 and 1351 IU/L on day 10. Gradual decrease of β-HCG levels was also combined with ultrasound observation of collapsed gestational sac (Figure 2). No additional intervention such as curettage was decided to be performed. During hospitalization period, patient reported only minimal vaginal spotting, without reporting pain or other suspicious signs or symptoms and was therefore discharged on day 10th with the recommendation of follow-up on a weekly basis until β-HCG values are measured lower than 10 IU/L. She was also advised to use contraceptive methods of choice for the next 6 mo in order to avoid conception. Her follow-up period was totally uncomplicated, β-HCG values getting < 10 IU/L on 56th day after MTX administration. Patient was also reexamined 3 mo after cervical pregnancy diagnosis, the gynaecological examination revealing absence of residual pregnancy.

DISCUSSION

We described the case of a cervical pregnancy treated successfully with intramuscular administration of methotrexate and intramniotic injection of KCl, without necessitating additional interventional treatment.

MTX administration has been reported as an effective therapeutic option for the treatment of cervical pregnancy. However, there have been several therapeutic patterns proposed, without consensus regarding their comparative effectiveness. Ben Hamouda *et al*[14] as well as Api *et al*[15] have reported that exclusively single-dose intramuscular administration of MTX may be effective on treating cervical pregnancy without additional need for curettage[14,15]. Intramuscular MTX may also be combined

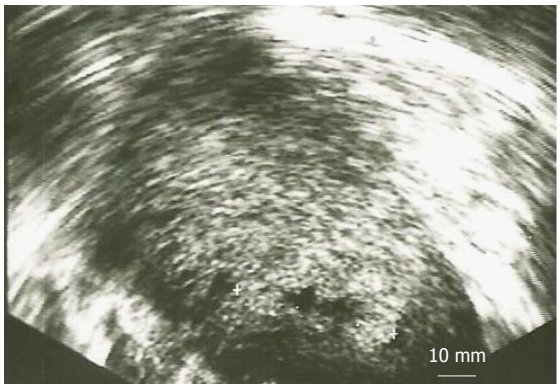

Figure 2 Ultrasound imaging of collapsed gestational sac after methotrexate treatment.

effectively with intramniotic injection of KCl[4,16], while oral mifepristone may also be co-administered effectively as reported by Shresthra *et al*[10]. Kochi *et al*[17], in another case series including 4 cervical pregnancies, have also discussed the alternative of UAE with methotrexate, a method that has been reported to be effective either as monotherapy or in combination with other medication[17]. Furthermore, apart from intramuscular injection and UAE, there is still the option of intramniotic (*i.a.*) administration of methotrexate either as mono-therapy or in combination with intramniotic injection of KCl, as characteristically described by Júnior *et al*[5] in a series of 8 successfully treated cervical pregnancies[5,18-20]. In our case, the choice of intramuscular administration of MTX was based on clinician's relative experience on this certain method of administration, given the fact of the non consensus of optimal method of treatment.

A basic endpoint of the present case report may be the fact that conservative management including *i.m.* MTX and *i.a.* KCl may be effective in treatment of cervical pregnancy without need for performing curettage. Indeed, effectiveness of exclusive administration of MTX has been reported to be as high as 81.3%, while the percentage is increased to 90% when MTX is combined with additional conservative methods[2]. However, conservative treatment with MTX may not definitely exclude the possibility of incomplete treatment, with the underlying possibility of hemorrhage still being potential[21]. Song *et al*[8], in a retrospective study including 50 cases, report that out of 30 cases being treated with *i.m.* MTX, there were only 9 cases that did not necessitate further treatment with curettage[8]. Cipullo *et al*[22], in a case series including 5 cervical pregnancies treated with im MTX + UAE reported that, because of late diagnosis, emergency hysterectomy could not be avoided in a case[22]. Furthermore, there are also reports of unsuccessful intramniotic MTX administration, such as that of Mangino *et al*[11], in which hysteroscopy was finally performed in order to effectively treat cervical pregnancy[11]. Pereira *et al*[7] have also reported the case of a residual pregnancy 3 mo after *i.m.* MTX + *i.a.* injection of KCl + UAE, therefore demonstrating that close follow-up is demanded in order to confirm definite treatment[7]. Thus, conservative treatment with MTX should definitely be combined with close follow-up, including measure of serum β-HCG levels every 3 d after the initial i.m. administration and the possibility of additional 2nd or 3rd dose or even interventional treatment should always be re-evaluated in order to avoid risk of severe hemorrhage. Besides, non-conservative treatment has also been proposed as the basic therapeutic approach by other researchers with satisfying results[23].

The most crucial point, however, regarding treatment of cervical pregnancy with MTX may be to identify patients eligible to be treated conservatively. MTX administration should be preferred in case of haemodynamically stable patients with unruptured ectopic pregnancy, without severe complaint for pelvic pain or vaginal bleeding and mainly in case the size of ectopic mass does not exceed 3-3.5 cm[24,25]. Serum β-HCG levels should always been taken into consideration as there have been implications of improved correspondence in case β-HCG levels are lower than 5000 IU/L. Compliance of patient with close follow-up is also demanded while all potential risks and side-effects should also be explained to the patient[26].

In conclusion, conservative treatment of MTX seems to be the most reasonable therapeutic approach in cases of early diagnosed cervical pregnancies. Intramuscular administration of MTX in combination with intramniotic KCL injection may be effective in the treatment of cervical pregnancy However, further multi-center observational or even randomized studies should be performed in order to assess comparative effectiveness of various therapeutic protocols. Besides, the issue of cost-effectiveness of invasive *vs* conservative management, especially taking into consideration the follow-up necessitated after MTX administration, has to be further elucidated in order to achieve definite conclusions regarding a clinical entity that still poses severe diagnostic and mainly therapeutic challenges.

COMMENTS

Case characteristics

A 41-years-old woman on her 8th gestational week with the suspicion of cervical pregnancy.

Clinical diagnosis

No specific signs or symptoms during typical gynecological examination. Cervix closed.

Differential diagnosis

Other kinds of ectopic pregnancies.

Laboratory diagnosis

Beta human chorionic gonadotropine levels measured 28590 IU/L.

Imaging diagnosis

Empty endometrial cavity, gestational sac within the cervical canal and embryonic echo measuring CRL 1.5 mm.

Treatment

The patient was treated with intramuscular administration of methotrexate and intramniotic injection of KCl. No additional interventional treatment was performed.

Related reports

Successful conservative treatment of cervical pregnancy has been reported by only a few other studies. No consensus has yet been made regarding the various therapeutic options' comparative effectiveness.

Term explanation

Cervical pregnancy accounts for < 1% of ectopic pregnancies with frequency

between 1:1000-1:18000.

Experiences and lessons

Early diagnosis and close follow-up may permit successful conservative treatment with methotrexate, potentially avoiding curettage. However, the risk of severe hemorrhage should always been taken into consideration.

Peer review

This is an interesting study. The case report is well and clearly described and the discussion is concise.

Abstract

The anatomical knowledge of arterial variations of lower limb is of utmost significance for the present day surgeons and interventional radiologists for minimizing complications during vascular reconstructive procedures, catheterization procedures and surgical intervention for embolism. Lateral Circumflex Femoral Artery (LCFA) is an important branch of Profunda Femoris artery and precise knowledge of its variations can be of great relevance during surgical and radiological procedures in femoral region. The present study reports a unique case of anomalous route taken by LCFA posterior to femoral nerve associated with a prominent muscular branch from Femoral artery mimicking the course of LCFA. Documentation of such variations is highly significant. It may serve as guideline for surgeons in reducing the incidence of postoperative complications where LCFA is used as a long vascular pedicle in anterolateral perforator thigh flap and in breast reconstruction after mastectomy. Ignorance of such variations can lead to fatal intraoperative haemorrhage and incapacitating sensory and motor deficit due to injury to femoral nerve branches which are closely related to these vessels.

Key words: Lateral circumflex femoral artery; Femoral nerve; Femoral artery; Angiography; Reconstructive surgical procedures; Surgical flaps

Core tip: The knowledge of variations in site of origin and course of the Profunda femoris artery and its circumflex branches is of utmost clinical significance during diagnostic imaging procedures and surgeries performed in the femoral triangle. The present study highlights an abnormal course of the lateral circumflex femoral artery (LCFA) posterior to the femoral nerve associated with a significant muscular branch of femoral artery which mimicked the course of LCFA. Knowledge of such variations maybe of great help to surgeons, interventional radiologists and physicians in reducing the chances of intraoperative secondary haemorrhage and postoperative complications.

Goel S, Arora J, Mehta V, Sharma M, Suri RK, Rath G. Unusual disposition of lateral circumflex femoral artery: Anatomical

description and clinical implications. *World J Clin Cases* 2015; 3(1): 85-88 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i1/85.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i1.85

INTRODUCTION

Arterial variations of lower limb have always been of utmost importance due to their involvement in vascular reconstructive surgeries, catheterization procedures and in raising myocutaneous flaps with vascular pedicles. The recent use of lateral circumflex femoral artery (LCFA) in coronary artery bypass grafting as well as anterolateral thigh cutaneous flaps for oral and oropharyngeal reconstructions has further enhanced the relevance of normal and variant anatomy of LCFA. In view of anatomical variations, preoperative angiographic evaluation of femoral arterial system becomes mandatory in surgical procedures involving the LCFA. Literature reports several variations in origin of LCFA[1,2]. However reports of variant course of LCFA as described in the present study are few.

CASE REPORT

In a unique case, during cadaveric dissection, variant course of LCFA was detected in the right lower extremity of a 53 years old adult Indian male cadaver.

The Profunda Femoris Artery (PFA) took origin as usual from the Femoral Artery (FA), at a distance of 5 cm from the mid inguinal point. At a distance of 7 cm from the same anatomical landmark, LCFA was seen to arise from PFA (Figure 1). LCFA traversed deep to the posterior division of femoral nerve unlike its usual course anterior to the latter. Coursing for 2 cm, the LCFA divided into ascending, transverse and descending branches each of which also traversed behind the posterior division of femoral nerve (Figure 2). The trifurcation of LCFA was immediately posterior to the site where the posterior division of Femoral Nerve (FN) divided into multiple muscular branches.

A prominent muscular branch was given off from FA, 3 cm distal to origin of PFA and 1.5 cm distal to LCFA. This branch traversed parallel to LCFA, mimicked the usual course of latter and passed laterally between the branches of posterior division of Femoral Nerve. The proximal part of the muscular branch was deep to the posterior division of femoral nerve while the terminal branches coursed between the saphenous nerve (SN) and never to vastus lateralis (NVL). Interestingly, this muscular branch arising from FA, appeared to take the course normally taken by LCFA, between divisions of femoral nerve before it terminated by supplying the Vastus Lateralis muscle (Figures 1 and 2).

DISCUSSION

Anatomical knowledge of LCFA including its variations has gained significant importance with the involvement of LCFA in anterolateral thigh free flap[3], aortopopliteal bypass[4] and extracranial intracranial bypass surgery[5]. With the advent of novel harvesting and reconstructive techniques, precise anatomical knowledge of LCFA becomes further important.

The LCFA, commonly a branch of PFA, traverses between divisions of FN, posterior to Sartorius and Rectus Femoris muscles. Coursing behind these structures it divides into ascending, transverse and descending branches. The LCFA contributes blood supply to head and neck of femur, greater trochanter, vastus lateralis and knee joint[6].

Literature reports the use of descending branch of LCFA as a collateral[7] and use of ascending branch in vascularised iliac transplantation[8]. Variations in the origin of LCFA have been reported in cadaveric[9] as well as angiographic studies[10]. However our study is unique as it reports an unusual route taken by LCFA, posterior to the posterior division of femoral nerve and additional presence of a prominent muscular branch of FA which mimics the normal route of LCFA, coursing between the branches of femoral nerve to terminate in vastus lateralis.

Anomalous route of LCFA is of utmost importance to surgeons while raising free rectus femoris muscle flaps with a branch of posterior division of FN, for one stage reconstruction of facial paralysis[11]. Awareness of such anatomical variations as reported in our case may prevent inadvertent injury to LCFA while handling the branches of femoral nerve.

Preoperative anatomical assessment of LCFA through arteriographic study is also essential. The LCFA is frequently explored for its use as new arterial graft for coronary artery bypass grafting[12]. During such surgical procedures, an atypical course of LCFA may lead to an unfortunate sequel of injury to branches of femoral nerve traversing in front of LCFA.

The femoral nerve block is routinely given at a site just above the origin of PFA during knee replacement surgery. Ignorance of the presence of LCFA behind the posterior division of femoral nerve may lead to misinterpretation of absence of LCFA behind the latter and hence consequential accidental injury to LCFA. Exploration of femoral nerve for anaesthetic procedures, therefore, requires awareness of variant course of LCFA in relation to femoral nerve.

Racial differences in direct origin of LCFA from FA have been reported[13]. Studies also report anatomic pattern and calibre of both LCFA and perforators nourishing the anterolateral thigh flap[1]. However, variations in course of LCFA are few. Knowledge of arterial variations is extremely important as these may be the source of intraoperative iatrogenic haemorrhage or post operative complications. Arterial variations of lower extremity as reported in the present case are also important because of their close association with repair of femoral hernias.

Literature reports cadaveric and angiographic studies involving LCFA. Angiographic studies are of utmost importance although difficulties may be encountered

while defining route and branches of LCFA on angiography. Our study describes variant course of LCFA associated with a prominent muscular branch from FA mimicking the usual route of LCFA. Reports of such cases may be of great importance in bridging the gap between cadaveric and angiographic studies of LCFA.

In aortoiliac occlusive diseases, bypass to the PFA or FA has emerged as a suitable mode of treatment. But in patients with total occlusion of femoral artery as well as profunda femoris artery, bypass to the LCFA was found to be successful[14]. Hence, knowledge of course and branching pattern of LCFA, as reported in our case is extremely important in management of patients with multilevel occlusive diseases of iliac and femoral arteries.

Anatomical knowledge of branches of LCFA is also important while using sharp ended version guidewires during hip fracture surgery[15]. Such surgical procedures, involving exploration of branches of LCFA, may lead to iatrogenic injury to the ascending branch of LCFA because of its variant course behind the femoral nerve.

In the present case, the main trunk of LCFA, as well as its ascending, transverse and descending branches coursed behind the posterior division of femoral nerve. At the same time a prominent muscular branch of FA was seen mimicking the usual course of LCFA, by coursing between the branches of posterior division femoral nerve. Knowledge of such variations is important in surgical transplantation procedures where the branches of LCFA are of utmost use. It may simplify the procedure of flap dissection involving LCFA, especially when anterolateral thigh flap is the easiest and has the least morbidity[16].

Developmental arrests at different stages may lead to anatomical variations related to branches of femoral artery. Vasculature development in the lower limb is preceded by morphological and molecular changes that occur in the limb mesenchyme, therefore variations in vascular pattern are often recorded[17].

With increasing challenges in the field of surgery and occurrence of uncommon anatomic variations, it becomes imperative for the present day surgeons, interventional radiologists and anatomists to be aware of anatomical variations of LCFA - its variant course and muscular branches mimicking the normal course of LCFA. Ignorance of such variations can not only lead to fatal intraoperative haemorrhage but also injury to the branches of femoral nerve which are in close relation to these vessels. Such avoidable femoral nerve lesions can lead to incapacitating sensory and motor deficit. Our study is a sincere effort in this field for minimizing injury to vital structures of lower limb like the femoral nerve and the lateral circumflex femoral artery. We, as anatomists, humbly submit that awareness of vascular variations as encountered in our study is of tremendous significance for successful reconstructive procedures of the region.

COMMENTS

Case characteristics

Anomalous route taken by lateral circumflex femoral artery (LCFA) posterior to femoral nerve and presence of a prominent muscular branch from Femoral artery mimicking the course of LCFA.

Clinical diagnosis

Arterial variants as reported in the present study are of utmost significance in anterolateral thigh flap surgeries, coronary artery bypass grafting and femoral nerve block in knee surgeries.

Differential diagnosis

Anatomical awareness of variant course of LCFA associated with a prominent muscular branch from Femoral Artery (FA) mimicking the course of LCFA is imperative for vascular surgeons and interventional radiologists. The muscular branch of FA can be mistaken for LCFA leading to the accidental ligation of the wrong vessel.

Related reports

Literature reports several variations in origin of LCFA. However reports of variant course of LCFA as described in the present study are few. This vessel as well as its branches are now extensively used in reconstructive and bypass surgeries.

Term explanation

LCFA normally courses in between the branches of Femoral Nerve.

Experiences and lessons

Ignorance of such variations can lead to fatal intraoperative haemorrhage and incapacitating sensory and motor deficit.

Peer review

This article highlights the importance of vascular variations of lower limb encountered in cadaveric studies and its application in surgery, anaesthesiology and interventional radiology.

Abstract

Osteoarthritis (OA) is the most common type of arthritis found in the United States' population and is also the most common disease of joints in adults throughout the world with the knee being the most frequently affected of all joints. As the United States' population ages along with the increasing trends in obesity prevalence in other parts of the world, it is expected that the burden of OA on the population, healthcare system, and overall economy will continue to increase in the future without making major improvements in managing knee OA. Numerous therapies aim to reduce symptoms of knee OA and continued research has helped to further understand the complex pathophysiology of its disease mechanism attempting to uncover new potential targets for the treatment of OA. This review article seeks to evaluate the current practices for managing knee OA and discusses emerging therapies on the horizon. These practices include non-pharmacological treatments such as providing patient education and self-management strategies, advising weight loss, strengthening programs, and addressing biomechanical issues with bracing or foot orthoses. Oral analgesics and anti-inflammatories are pharmacologicals that are commonly used and the literature overall supports that some of these medications can be helpful for managing knee OA in the short-term but are less effective for long-term management. Additionally, more prolonged use significantly increases the risk of serious associated side effects that are not too uncommon. Disease-modifying osteoarthritis drugs are being researched as a treatment modality to potentially halt or slow disease progression but data at this time is limited and continued studies are being conducted to further investigate their effectiveness. Intra-articular injectables are also implemented to manage knee OA ranging from corticosteroids to hyaluronans to more recently platelet-rich plasma and even stem cells while several other injection therapies are presently being studied. The goal of developing new treatment strategies for knee OA is to prolong the need for total knee arthroplasty which should be utilized only if other strategies have failed. High tibial osteotomy and unicompartmental knee arthroplasty are potential alternatives if only a single compartment is involved with more data supporting unicompartmental knee arthroplasty as a good treatment option in this scenario. Arthroscopy has been commonly used for many years to treat knee OA to address degenerative articular cartilage and menisci, however, several high-quality studies have shown that it is not a very effective treatment for the majority of cases and should generally not be considered when managing knee OA. Improving the management of knee OA requires a multi-faceted treatment approach along with continuing to broaden our understanding of this

complex disease so that therapeutic advancements can continue to be developed with the goal of preventing further disease progression and even potentially reversing the degenerative process.

Key words: Disease-modifying osteoarthritis drugs; Knee osteoarthritis; Disease-modifying osteoarthritis drugs; Osteoarthritis management; Non-steroidal anti-inflammatory drugs; Hyaluronic acid; Arthroscopy; Platelet-rich plasma; Corticosteroids; Stem cells

Core tip: The management of knee osteoarthritis is of growing importance in the world and especially in the United States where an aging population and increasing trends in obesity are increasing the prevalence of this disease. Treatment has traditionally focused on symptom control, however, more recently there has been a greater emphasis placed on developing new modalities that aim to slow disease progression or even reverse the process. This review aims to examine the available literature on such modalities ranging from patient education and weight loss to disease-modifying osteoarthritis drugs to platelet-rich plasma, stem cells, and other emerging injectables.

Fibel KH, Hillstrom HJ, Halpern BC. State-of-the-Art management of knee osteoarthritis. *World J Clin Cases* 2015; 3(2): 89-101 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i2/89.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i2.89

INTRODUCTION

Osteoarthritis (OA) is the most common type of arthritis found in the United States population and is also the most common disease of joints in adults throughout the world[1,2]. The knee joint is the most frequently affected of all joints per epidemiological studies with estimates of 37% of United States' adults ⩾ 60 years of age having radiographic evidence of knee OA and 12% having symptoms related to knee OA accompanying radiographic findings[3]. Osteoarthritis risk factors include both genetic and environmental components with multivariable analysis showing significantly higher odds of symptomatic and radiographic knee OA with body mass index ⩾ 30, greater age, non-Hispanic Black race/ethnicity, and among men with manual labor occupations[2,3]. Symptomatic knee OA has also been highly associated with self-reported activity limitations, need for assistive walking devices, and increased use of prescription medications for pain relief[3]. With an aging United States' population and increasing trends in obesity prevalence, it can be expected that the burden of OA on the population, healthcare system, and overall economy will continue to increase in the future without major improvements in management of knee OA. While the synovium, bone, and cartilage are recognized as the main structures being destroyed during disease progression, further research in the field is revealing that OA is not simply a biomechanical process placing excess load on the affected joint but contributions from catabolic cytokine cascades and production of inflammatory mediators also play a significant role and should be targets for intervention[4,5]. In order to take necessary strides towards improving management of knee OA, it is crucial to recognize the complex pathophysiology of its disease mechanism in which a multi-faceted treatment strategy should be employed using both non-pharmacological and pharmacological options, along with understanding the role for surgical intervention. While numerous treatments aim to offer pain relief to better tolerate the symptoms of knee OA, other modalities are attempting to slow the disease progression, halt it, or even reverse it by trying to affect the damaged articular cartilage. Various treatment strategies, both commonly used and newer advances, for the management of knee OA will be reviewed in this present article focusing mainly on non-operative treatments.

NON-OPERATIVE MANAGEMENT

Non-pharmacological

Education and self-management: Multiple societal guidelines and expert panels recognize patient education and self-management strategies as important components of knee OA management[6]. A systematic review and meta-analysis in 2011 evaluated the effectiveness of self-management programs on pain and disability for chronic musculoskeletal pain in which small to moderate effects in improving pain and disability at the long-term level were found using self-management programs[7]. Recent randomized clinical trials have also highlighted benefits from education and self-management, specifically Ravaud *et al*[8] showed that goal-oriented visits focusing on education on OA and treatment management, information on physical exercises, and information on weight loss led to improvement in weight loss and time spent on physical activity[8,9]. These programs can play more significant roles when implemented in conjunction with weight loss and exercise programs by increasing adherence.

Weight loss and strengthening

While genetic and other endogenous risk factors can contribute to knee OA and its progression, it is important to recognize the negative effects that increased stress on the knee joint can have

in the development and progression of OA. Both weight gain and decreased strength of surrounding musculature can increase the load seen by the knee. With the average body weight of the US population increasing across all ages but more significantly in adult population and this being an issue in other parts of the world, weight loss should be addressed as part of the management of knee OA. The Framingham Study by Felson *et al*[10] demonstrated that women with an approximately 5 kg weight loss had a 50% reduction in the risk of development of symptomatic knee OA. Christensen *et al*[11] used a meta-regression analysis of randomized controlled trials to evaluate if there were changes in pain and function when overweight patients with knee OA achieve a weight loss. The study concluded that disability could be significantly improved when weight was reduced > 5.1% over a 20-wk period, or at the rate of > 0.24% reduction per week[11]. Conversely, Riddle *et al*[12] found there to be a significant dose-response relationship between the extent of percentage change in body weight and the extent of change in Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) physical function and WOMAC pain scores, specifically those who gained ⩾ 10% of body weight had worse WOMAC physical function score. Not only has weight change been shown to affect pain and function, it has also been associated with MRI changes as Teichtahl *et al*[13] showed that obese individuals with OA who lost as little as 1% of their body weight were able to reduce the amount of medial femorotibial cartilage volume loss. The relationship between obesity, muscle strength, activity level, and knee OA is complex and it can be difficult to determine which factor is contributing most to the disease. While some studies have suggested that people engaging in relatively high levels of activity have an increased risk of developing knee OA compared to sedentary people, other studies have shown a protective effect. Regarding those who have already developed knee OA, a 2011 systematic review demonstrated moderate effect of strength training and exercise in reducing pain and improved physical function significantly. Furthermore, a 2013 meta-analysis including 60 trials showed that an approach combining exercises to increase strength, flexibility, and aerobic capacity was the most effective in managing lower limb OA with trials largely of patients with knee OA[14]. However, another systematic review and meta-analysis in 2014 included 48 randomized controlled trials and found similar effects in reducing pain from knee OA with aerobic, resistance, and performance exercise. In contrast to the 2013 meta-analysis, it concluded that optimal exercise programs for knee OA should have one aim and focus on improving aerobic capacity, quadriceps muscle strength, or lower extremity performance rather than combining the exercises. While both of these analyses demonstrate a positive effect of exercises on knee OA, the most beneficial regimen is still debatable[15]. The IDEA Randomized Clinical Trial included 3 groups in which participants either were involved with intensive weight loss (⩾ 10% body weight), exercise (1 h for 3 d/wk), or both. After this 18 mo randomized control trial, WOMAC pain scores were reduced to no or little pain in 20% in the weight loss only group, 22% in the exercise only group, and 40% in the weight loss and exercise group[16]. This further supports the notion that both weight loss and exercise are important in managing knee OA as they are more effective in combination than either one alone.

Biomechanical interventions (knee braces, knee sleeves, foot orthoses)

Using an appropriate specialist, assessment of biomechanics and incorporating corrective devices may be an effective intervention for knee OA. A key concept in understanding potential benefit from foot orthoses and knee bracing is in relation to the knee adduction moment (KAM) during gait in which excessive KAM has been associated with radiographic knee OA severity, radiographic knee OA progression, and pain with knee OA[17-19]. However, Zifchock *et al*[20] contended that medial joint space and peak adduction angle, not peak adduction moment, were the best predictors of knee pain. A systematic analysis on the effectiveness of knee braces and foot orthoses in conservative management of knee OA produced results suggesting that knee brace and foot orthoses are an effective means of decreasing pain, joint stiffness, and use of pain medication with minimal adverse effects[21]. However, the authors recognized that conclusions of this systematic analysis were limited due to poor quality of trials and heterogeneity of interventions. Lateral wedge insoles, also designed to reduce KAM and therefore decrease medial knee joint loading, have shown mixed results in studies with some claiming no benefit and others arguing its use as an alternative to valgus bracing for medial knee OA[22,23]. A benefit was well demonstrated in a retrospective study of 51 older adults with mild-to-severe medial knee OA in which a significant reduction in pain and improvements in function and quality of life were found with the prescription of a custom-made lateral wedge insole with arch support[24]. With regards to knee OA bracing, it is designed to create either valgus or varus force to alter the contact pressures especially with unicompartmental knee OA. A Cochrane review of orthoses for knee OA included 4 trials in which 1 investigated effectiveness of a knee brace while 3 examined foot orthoses[25]. The study on knee bracing compared a medial compartment unloader brace group, a neoprene sleeve group, and to a control

group in those that had varus deformity of the knee. Both the brace and sleeve group demonstrated significant improvement in disease specific quality of life and function compared to the control group with the brace group also demonstrating statistically significant improvement compared to the sleeve group per WOMAC pain scores[26]. The three studies on orthoses in the Cochrane review were able to conclude that there is some, though limited, evidence that a laterally wedged insole decreases non-steroidal anti-inflammatory drug intake compared with a neutral insole, patient compliance is better in the laterally wedged insole compared with a neutral insole, and a strapped insole has more adverse effects than a lateral wedge insole[25]. Haim *et al*[27] evaluated whether a biomechanical training program could effectively reduce knee adduction moments at 3 and 9 mo in which his results showed not only was there a significantly reduced knee adduction moment, there were also reduced pain and improved function in these subjects with bilateral knee OA[27]. While studies suggest the potential benefit from knee braces, knee sleeves, foot orthoses, and biomechanical training programs, they also highlight the need for more high quality studies which are currently lacking and for more effective ways to determine which subset of knee OA patients are likely to benefit from these interventions. Future research can include utilization of video gait analysis and 3D motion analysis using computer software to further assess biomechanics and individualize interventions in correcting abnormalities.

PHARMACOLOGICAL TREATMENT

Oral analgesics/anti-inflammatories

Several oral medications are prescribed for treatment of knee OA, mostly addressing the issue of pain. Many supplements are available in the United States that claim to be effective in the treatment of OA, however, few have been well studied for efficacy. Additionally, supplements are not held to the same product quality standards as FDA approved medication and thus variability in product may exist from company to company further making it difficult to determine if certain supplements are beneficial and if they should be considered in the management of knee OA. Glucosamine/chondroitin is the most extensively studied supplement for the treatment of knee OA. This oral supplement is alleged to be absorbed and incorporated into articular cartilage thus potentially allowing for the halting of disease progression and even reparative process[28]. There have been many conflicting studies showing both efficacy and lack of efficacy of glucosamine and/or chondroitin supplements which may be partially due to the difference in quality of products being such as those that are pharmaceutical grade. Fransen *et al*[29] in a double-blind randomized placebo-controlled trial showed that the combination of glucosamine-chondroitin resulted in a statistically significant reduction in joint space narrowing at 2 years of use. While there was also a reduction in knee pain over the study period, none of the groups reach a reduction of pain that statistically significant compared to placebo[29]. In a review of the available literature, many studies demonstrated OA pain relief with glucosamine and chondroitin sulfate use and given its excellent safety profile that is equal to placebo in most studies, this therapy is suggested as one that should be discussed with patients regarding potential benefits and considered as an initial treatment modality[30]. Acetaminophen has been commonly used for the treatment of knee OA and a Cochrane review in 2006 including fifteen RCTs involving 5986 participants showed acetaminophen was superior to placebo in five of the seven RCTs, however, when compared to NSAIDs the evidence suggested that NSAIDs were superior to acetaminophen for the treatment of knee OA[31]. Additionally, acetaminophen had previously been viewed as a safe medication to use as a short-term analgesic of knee OA based on a 2010 systematic review that found a low-level effect for OA pain, however, both this review and a safety review in 2012 have raised concern of its safety profile and suggest that this medication should be used more conservatively in both dosing and duration[32,33]. Many studies have demonstrated the ability for NSAIDs to provide symptoms relief for knee OA with the American Academy of Orthopaedic Surgeon's (AAOS) "Treatment of Osteoarthritis of the Knee: Evidence-Based Guideline, 2nd Edition" concluding that NSAIDs as a group should be recommended for patients with symptomatic OA of the knee and it received a strong strength of recommendation. This was determined after 19 studies were included for review with 202 favorable outcomes comparing either selective, non-selective, or topical analgesics to placebo. Out of the 202 total outcomes, 171 were statistically significant in favor of the experimental group. Fifteen outcomes were above the MCII threshold and 63 outcomes were possibly clinically significant[34]. While NSAIDs should be recognized as a good short-term treatment to manage symptomatic knee OA, it is important to acknowledge their side effect profile which makes this medication class a poor long-term treatment. A comparative effectiveness review in 2011 indicated that NSAIDs are associated with an increased risk of serious gastrointestinal (GI), cardiovascular (CV), and renal injury when compared to placebo[35]. The review also found that Celecoxib had a lower risk of ulcer complications compared to non-selective NSAIDs but had a moderately higher risk of CV complications highlighting the need to use NSAIDs conservatively by limiting dosage to lowest required to achieve pain relief and avoid prolonged use[35]. For those with a moderate comorbidity risk of GI complications,

a proton-pump inhibitor should be considered for co-prescribing with non-selective NSAIDs or this medication class should be avoided all together if there is a high risk. Topical NSAIDs can also be considered as a safer and better tolerated treatment although they have a higher risk of dermatological adverse effects. Tramadol and opioids have been evaluated as medications that may offer pain relief for symptomatic OA. Although opioids were found to have a small to moderate benefit compared to placebo in a 2009 Cochrane review, these benefits were outweighed by large increases in the risk of adverse events and therefore it was recommended they not be routinely used, even if osteoarthritic pain is severe[36]. Tramadol has been studied due to its increasing use for the treatment of OA since it does not produce GI bleeding or renal injury compared to NSAIDs. However, similarly to opioids, its benefits appear to be small in relation to pain reduction with a number of adverse events that cause participants to stop taking the medication[37]. While there are a variety of medications available to help reduce pain related to knee OA, their safety profiles need to be considered when initiating treatment and these should not be viewed as good long term treatment modalities in the management of knee OA.

Disease-modifying osteoarthritis drugs

Disease-modifying osteoarthritis drugs (DMOADs) are drugs that halt or significantly slow the progression of structural joint degeneration, specifically cartilage destruction. Several drugs have been investigated including the tetracycline antibiotic, doxycycline, as *in vitro* studies have shown that it may possess the ability to inhibit collagen degradation. Brandt *et al*[38] conducted a randomized, placebo-controlled, double-blind trial studying subjects with knee OA and measured if joint space narrowing in the medial femorotibial compartment could be reduced with doxycycline. The treatment group received 30 mo of 100 mg of doxycycline twice a day and after 30 mo, the treatment group had 33% less joint space narrowing on radiographic imaging compared to the placebo group. Doxycycline did not reduce the mean severity of joint pain and did not have any effect on either joint space narrowing or pain in the contralateral knee[38]. Additionally, when Snijders *et al*[39] evaluated doxycycline in the management of knee OA in their triple-blinded, randomized controlled trial, it was not effective in reducing symptoms over a 24-wk study period and was associated with an increased risk of adverse events[39]. Bisphosphonates have been studied after they have shown the ability to slow progression of OA in animal models and have decreased pain in states of high bone turnover[40]. When the Knee OA Structural Arthritis study tested the efficacy of risedronate in providing symptom relief and slowing disease progression in patients with knee OA, risedronate did not improve signs or symptoms of OA and did not alter progression of OA compared to placebo, however, it did show a reduction in the level of a marker of cartilage degradation[40]. Strontium ranelate is another drug that has been studied because it has been shown to be able to inhibit subchondral bone resorption and increase cartilage matrix *in vitro*. The SEKOIA trial was a 3-year randomized, double-blind, placebo-controlled trial that studied patients with moderate knee OA who received strontium ranelate 1 g/d, 2 g/d, or placebo. Treatment with strontium ranelate decreased progression of knee OA with estimates for annual difference in joint space narrowing versus placebo found to be 0.14 mm for 1 g/d and 0.10 mm for 2 g/d, with no difference between strontium ranelate groups and all values reaching statistical significance. Strontium ranelate 2 g/d also improved WOMAC total score and pain subscore with the treatment being well tolerated[41]. The SEKOIA trial has sparked more interest in strontium ranelate and has led to further studies that are currently underway which include evaluating its effect on loss of cartilage volume and bone marrow lesions using quantitative MRI. While these drugs will continue to be studied in order to more clearly understand their potential role in the management of knee OA, they will also stimulate new research into other DMOADs in hopes of providing better options to those suffering from the progressive nature of knee OA.

Intra-articular corticosteroid injections

Intra-articular (IA) corticosteroid injections for knee OA appear to be an effective way to decrease pain in the short-term and should be used when signs of inflammation arise. A 2006 Cochrane review of the current literature found that IA corticosteroids were more effective than the placebo group for pain reduction and patient global assessment at 1 wk post-injection. There was continued effect seen between 2 and 3 wk post-injection but at 4-24 wk, there was a lack of evidence of effect on pain and function. Comparing IA corticosteroids to IA hyaluronic acid injections, there was no statistically significant difference between weeks 1-4, however, between 5-13 wk post-injection, IA hyaluronic acid was more effective than IA corticosteroids for one or more of the following variables: WOMAC OA Index, Lequesne Index, pain, range of motion (flexion), and number of responders. The review concluded that IA corticosteroid injections appear to offer good short-term benefits with less evidence to support long term benefit[42]. Another review by Bannuru *et al*[43] compared the efficacy of IA hyaluronic acid with corticosteroids for knee OA. While there short-term analysis differed slightly from the Cochrane review in that the results from baseline to 4 wk showed that IA corticosteroids appear to be relatively more

effective for pain than IA hyaluronic acid, it similarly found that after 4 wk the IA hyaluronic acid continued to show superiority over IA corticosteroids further supporting the notion that IA corticosteroids should be implemented for reducing acute inflammation and relieving pain in the short-term but it is not a good treatment option for long-term management of knee OA[43].

Hyaluronic acid injections

Hyaluronans are also known as sodium hyaluronate or hyaluronic acid. Hyaluronic acid is a natural complex sugar of the glycosaminoglycan family and a normal component of synovial fluid and cartilage in the knee. Its viscosity and elasticity allow it to act as both a joint lubricant and shock absorber, respectively. Hyaluronic acid injections, often referred to as viscosupplementation, are marketed in the United States as several different formulations with some being produced from rooster comb and some from fermentation of the nonpathogenic bacterium Streptococcus zooepidemicus. The different products also vary by molecular weights, concentration of hyaluronic acid, elasticity, viscosity, and number of injections per treatment course[44]. A systematic review in 2011 showed evidence of a small but significant efficacy of IA hyaluronic acid injections for knee OA pain by week 4 post-injection with a moderate clinical significance at week 8 and continued residual benefit until 24 wk[45]. Another review, already mentioned in the previous section, compared IA corticosteroids to hyaluronic acid injections and demonstrated IA hyaluronic acid's superiority over corticosteroids after 4 wk post-injection[43]. The AAOS' "Treatment of Osteoarthritis of the Knee: Evidence-Based Guideline, 2nd Edition" gave a controversial recommendation in 2013 in which it stated they "cannot recommend" using hyaluronic acid for patients with symptomatic knee OA which was a change from their earlier 2008 recommendation that was "inconclusive" based on the available studies to recommend for or against IA hyaluronic acid injections. This update came from changes in their article selection criteria for analysis that included 14 studies, 3 of which were of high strength and 11 of moderate strength. Despite their negative recommendation, their meta-analyses of WOMAC pain, function, and stiffness subscales scores all found statistically significant treatment effects of IA hyaluronic acid compared to placebo and the WOMAC pain and WOMAC total score each were found to be clinically significant but not all of the improvements met the minimum clinically important improvement thresholds (MCII) established by the AAOS panel[34]. It should be noted that their application of the MCII has been called into question by several organizations including the Arthroscopy Association of North America who criticized the statistical analysis and inappropriate use of MCII[46]. A Cochrane review that included 40 trials comparing IA hyaluronic acid to placebo found that at the 5-13 wk post-injection period there was an improvement from baseline of 28%-54% for pain and 9%-32% for function for those receiving IA hyaluronic acid injections for knee OA. They did not find any of the different available hyaluronic acid products to be superior over another and there were very few adverse events reported in the studies. They concluded that viscosupplementation is an effective treatment for OA of the knee with benefits on pain, function, and patient global assessment. The authors also concluded that this review supports the use of the hyaluronic class of products in the treatment of knee OA and that these products provide not only statistically significant effects but also clinically important ones[47]. Some question the true efficacy of IA hyaluronic acid injections because a large placebo effect has been appreciated in several studies being as high as 30%-40%. However, reasons for this large placebo effect may include patient expectation, the Hawthorne effect of participating in a clinical trial, some "placebo" groups were actually receiving an active treatment of saline and/or arthrocentesis, and studies may not account for rescue analgesia or co-therapy being used simultaneously. The safety profile of hyaluronic acid injections is overall minimal. The most common side effects are joint effusion, arthralgia, joint warmth, and injection site erythema which all occur in less than 2.5% of patients and are clinically manageable with short-term use of ice, NSAIDs and do not have long-term sequelae[48-51]. The hylan G-F 20 product appears to have a unique side effect termed a local pseudoseptic reaction in those receiving more than one course of treatment which is hypothesized to be due to the chemical cross-linking used to increase the molecular weight and may occur in up to 21% of patients[52]. This event is not a contraindication to using other hyaluronic acid products and there is no increased risk of recurrence using other products. It should be emphasized that hyaluronic acid injection's excellent safety profile makes it a more appealing treatment for long-term use compared to NSAIDs which have risk of gastrointestinal, renal, and cardiovascular complications. Hyaluronic acid injections also have no known medication interactions making it a good option for patients on multiple medications. Overall, the body of literature appears to support the use of IA hyaluronic acid injections for the treatment of knee OA and future studies of high-quality will continue to be helpful to determine the most appropriate utilization in clinical practice.

Platelet-rich plasma

The use of platelet-rich plasma (PRP) has expanded over the past several years to not only just include the treatment of tendon and ligament injuries, but

also in the treatment of cartilage injuries such as in knee OA. PRP is derived from centrifuging whole blood in order to obtain a platelet concentration above baseline[53]. Growth factors including platelet-derived growth factor (PDGF), insulin growth factor (IGF), vascular endothelial growth factor, and transforming growth factor beta-1 are believed to be key components of PRP for structural repair. Drengk *et al*[54] showed that PRP has a proliferative effect on autologous chondrocytes and mesenchymal stem cells in an *in vitro* study. When Petrera *et al*[55] compared chondrocytes supplemented with either fetal bovine serum, PRP, or platelet-poor plasma, the presence of PRP in the culture media enhanced the *in vitro* formation of cartilage the most with increased glycosaminoglycan content, greater compressive mechanical properties, and maintained characteristics of hyaline phenotype. A randomized control trial involving dogs with documented symptomatic arthritis in a single joint was conducted by Fahie *et al*[56]. Dogs in the test group received a single injection of PRP in the affected joint and the control group dogs received a saline injection in the affected joint. After 12 wk, comfort and function improved by 55% and weight placed on the affected limb improved by 12% in the PRP group compared to the control group[56]. Further helping to understand ways in which PRP may be helpful in treating knee OA regarding anti-inflammatory effects, van Buul *et al*[57] in the Netherlands showed that PRP reduced several different effects of interleukin (IL)-1β which is involved in the catabolic process of articular cartilage in knee OA. Kon *et al*[58] did a prospective study on 115 knees with OA receiving a series of 3 PRP injections in which statistically significant improvement of all clinical scores was observed at 12 mo with maximum improvements at 6 mo[58]. Several studies have compared PRP to hyaluronic acid with each of them demonstrating positive results for these treatments of knee OA compared to placebo. PRP and hyaluronic acid have shown similar results in older patients with more advanced OA but PRP has shown better results compared with hyaluronic acid in younger patients affected by cartilage lesions or early OA[59-61]. When Cerza *et al*[61] compared PRP to hyaluronic acid, PRP was found to be more effective and there was also no statistically significant difference in the effect of PRP with regards to the severity of the knee OA. These findings counteract the argument that PRP is only helpful for milder cases of knee OA. Patel *et al*[62] compared 1 *vs* 2 PRP injections to treat knee OA and they found a single dose of PRP to be as effective as 2 injections to alleviate symptoms in early knee OA which further questions whether multiple subsequent injections are needed rather than a single injection only. A prospective cohort study following patients 1 year after PRP therapy for knee OA was conducted by Halpern *et al*[63]. Twenty-two patients with a Kellgren grade of 0-Ⅱ with knee pain were treated with PRP for early knee OA which was confirmed with a baseline MRI. Pain scores significantly decreased by 56.2% at 6 mo and 58.9% at 12 mo with 88% of patients showing improvement of at least 25% at 12 mo. Additionally, WOMAC overall score improved by 45.1% at 6 mo and 56.2% at 12 mo. In this same study by Halpern *et al*[63], qualitative MRIs demonstrated no change in the medial knee compartment in 73.3% of cases at 1 year despite the expected typical progression of knee OA and joint space narrowing. A systematic review of 59 articles (26 *in vitro*, 9 *in vivo*, 2 both *in vivo* and *in vitro*, and 22 clinical studies) analyzing the use of PRP for joint degeneration reinforced that the preclinical literature shows an overall support toward PRP with clinical studies displaying positive effects of PRP with a more significant benefit appearing to be in the younger patients with earlier stages of knee OA[64]. Cavallo *et al*[65] demonstrated that a comparison of different PRP formulations induced distinct effects on human articular chondrocytes *in vitro*, likely attributable to the differences in the concentrations of platelets, leukocytes, growth factors, and other bioactive molecules. This study highlights the fact that differences in technique and PRP composition may produce different outcomes when treating knee OA and make it difficult to compare results between various studies. However, it does appear that PRP can be a useful treatment for knee OA and certainly additional studies are needed before conclusions regarding true efficacy can be confirmed. Future studies are also needed to determine the optimal composition of PRP (*i.e.*, platelet concentration, leukocyte-rich or poor).

Stem cells

Mesenchymal stromal cells [mesenchymal stem cells (MSCs)] are multipotent cells that can be isolated from several human tissues. The immunomodulatory, reparative, and anti-inflammatory properties of MSCs have been tested in a variety of animal models and appear to have potential clinical applications which includes tissue repair[66]. One such study used scaffold-free MSCs obtained from bone marrow to directly inject intra-articularly in a rabbit model of OA. OA was induced by transecting the anterior cruciate ligament of the knee joint of rabbits and radiological assessment confirmed the development of OA after 12 wk. The rabbits then received either MSCs or medium without MSCs and at 20 wk post-operatively, the rabbits receiving the MSCs showed a lower degree of cartilage degeneration, osteophyte formation, and subchondral sclerosis compared to the control group[67]. While the exact mechanism by which MSCs are able to regenerate articular cartilage in patients with OA is not exactly clear,

these cells can induce proliferation and differentiation of resident progenitor cells and they have an innate differentiation potential to chondrocytes[68]. Orozco *et al*[69] conducted a pilot study where 12 patients with chronic knee pain unresponsive to conservative treatments and radiologic evidence of OA were treated with autologous expanded bone marrow MSCs by IA injection. They found that the patients exhibited rapid and progressive improvement in function that approached 65% to 78% by 1 year and that quantification of cartilage quality by T2 relaxation measurements demonstrated a highly significant decrease of poor cartilage areas (on average, 27%), with improvement of cartilage quality in 11 of the 12 patients[69]. This study, however, contained a small patient number and there was no control group for comparison. When Filardo *et al*[70] conducted a systematic review of the use of MSCs for the treatment of cartilage lesions, they included 72 preclinical papers and 18 clinical trials. In regards to the clinical trials focusing on cartilage degeneration, there were no randomized trials, 5 comparative studies, 6 case series, and 7 case reports. Of further note, 2 involved the use of adipose-derived MSCs, 5 the use of bone marrow concentrate, and 11 the use of bone marrow-derived MSCs. While multiple studies showed positive effects of MSCs for the treatment of OA or other cartilage defects, the authors acknowledge that these results are preliminary data on this topic due to only having available preclinical studies along with clinical studies that are of low quality due to weak methodology, small number of patients, and short-term follow-up[70]. Safety concerns have also arisen surrounding the use of MSCs which include but not limited to the neoplastic potential of MSCs due to their proliferative capacity and susceptibility to infection given their immunomodulatory effects[71]. In a systematic review by Lalu *et al*[71] to evaluate the safety of MSCs, they did not identify any significant safety issues other than a transient fever and concluded that this review should provide some assurance that MSC therapy appears to be safe. As in PRP, the use of MSCs is a therapy in that it goes beyond simply attempting to treat symptoms and instead offers the potential to stop disease progression and regenerate articular cartilage. While the possibility of such a regenerative treatment for knee OA is intriguing, before this therapy can be recommended confidently for clinical use there needs to be further studies that are of higher quality to better determine the efficacy, safety, and optimal source and preparation of cells for the treatment of knee OA.

Other injectables

Several other emerging injection therapies have been evaluated although the amount of quality studies are lacking or are still in early trial phases making it difficult to provide appropriate judgment on the efficacy of these products for the treatment of knee OA. IA botulinum toxin type A (BoNT-A) is hypothesized to have anti-nociceptive and potentially anti-inflammatory effects. Boon *et al*[72] conducted a pilot study to evaluate IA BoNT-A in painful knee osteoarthritis. Subjects were randomized to receive a single injection of corticosteroid, low-dose BoNT-A (100 units), or high-dose BoNT-A (200 units). The primary end point was pain visual analog scale score at 8 wk, which decreased in each group but only the low-dose BoNT-A group achieved statistical significance. Each of the groups did show statistically significant improvements in WOMAC Index scores (pain, stiffness, function) at 8 wk and there were no serious adverse events were noted in any group. The study overall supported a possible role for BoNT-A as a treatment option for symptomatic knee OA however it was recognized that larger double-blind randomized studies are needed[72]. Bone Morphogenic Protein-7 (BMP-7) has been studied due to its apparent strong anabolic effect on cartilage as it stimulates synthesis of cartilage matrix components, increases proteoglycan and collagen synthesis, while antagonizing catabolic mediators of cartilage such as IL-1[73]. In a rabbit model, Badlani *et al*[73] delivered BMP-7 *via* an osmotic pump to the knee 4 wk after ACL transection and when compared to a control group for the progression of knee OA, the BMP-7 group showed less cartilage degradation than the controls. In a phase I safety and tolerability study of BMP-7 for symptomatic knee OA, results showed that by week 12, all treatment groups with BMP-7 and the placebo group had improvement in pain scores with a trend toward more symptomatic improvement in the BMP-7 treatment groups although statistical significance was not achieved[74]. Fibroblast growth factor-18 (FGF-18) has also been studied for use as an IA injection to treat knee OA. Moore *et al*[75] demonstrated in animal models that there FGF-18 increased chondrogenesis and cartilage repair. Lohmander *et al*[76] conducted a proof-of-concept double-blind placebo-controlled randomized trial to evaluate the efficacy and safety of IA sprifermin, a recombinant human FGF-18, in patients with symptomatic knee OA. Their results found no statistically significant dose-response change in central medial femorotibial compartment cartilage thickness. Sprifermin though was associated with statistically significant dose-dependent reductions in loss of total and lateral femorotibial cartilage thickness and volume and in joint space width narrowing in the lateral femorotibial compartment with no association with any local or systemic safety concerns[76]. Other IA injection being studied for treatment of knee OA include IL-1 inhibitor, PDGF, IGF, amongst several others currently being studied. While trial data and preliminary studies have been

done for many of these therapies, more studies are needed to establish that they are both effective and safe.

OPERATIVE MANAGEMENT

This review has discussed many non-operative treatments that are utilized to prolong the need for total knee arthroplasty (TKA), however, there are other surgical procedures that are sometimes performed as alternatives in hopes of preventing the need for TKA. These surgical procedures include arthroscopy, high tibial osteotomy to correct abnormal alignment, and unicompartmental knee arthroplasty. High tibial osteotomy and unicompartmental knee arthroplasty are potential alternatives if only a single compartment is involved with more data supporting unicompartmental knee arthroplasty as a good treatment option in this scenario. An in depth discussion of these surgical procedures are beyond the scope of this review article, although it is important to note that arthroscopy, in the vast majority of patients, is no longer viewed as an appropriate treatment for knee OA or for meniscal degeneration in the setting of significant knee OA. Moseley *et al*[77] conducted a randomized, placebo-controlled trial in which a total of 180 patients with knee OA were randomly assigned to receive arthroscopic debridement, arthroscopic lavage, or placebo surgery consisting of skin incisions with a simulated debridement without insertion of the arthroscope. Outcomes were assessed at multiple points over a 24-mo period and they were no better after arthroscopic lavage or arthroscopic debridement than after a placebo procedure[77]. Another randomized, controlled trial was conducted by Kirkley *et al*[78] comparing surgical lavage and arthroscopic debridement together with optimized physical and medical therapy to treatment with physical and medical therapy alone. Arthroscopic surgery for knee OA was shown to provide no additional benefit to optimized physical and medical therapy and even analyses of WOMAC scores at interim visits and other secondary outcomes also failed to show superiority of surgery[78]. Arthroscopy has also been commonly used in the setting of knee OA to treat meniscal tears, although it is critical to recognize that in a study of incidental findings on knee MRI, among persons with radiographic evidence of knee OA, the prevalence of a meniscal tear was 63% in those who had knee symptoms and still remained 60% among those without symptoms[79]. When comparing surgical intervention to conservative management for meniscal degeneration in the setting of knee OA, outcomes are no better for those undergoing surgical intervention[80,81]. Based on the current literature comprised of several high-level studies, arthroscopy should not be included in the treatment algorithm for knee OA, especially without evidence of mechanical symptoms such as knee locking, as it is has not been shown to be an effective method to treat changes seen in the setting of knee OA which include degeneration of the articular cartilage and menisci.

CONCLUSION

The management of knee OA is of growing importance in the world and especially in the United States where an aging population and increasing trends in obesity are increasing the prevalence of this disease. Not only is this disease a burden on the individual patient, it is a burden on the healthcare system and overall economy. Treatment has traditionally focused on symptom control with some attention being given to prevention strategies and only more recently has there been a greater emphasis placed on trying to develop new modalities that aim to slow disease progression or even reverse the process. While there are many treatments available for knee OA, this review has attempted to provide evidence from the available literature to help guide management with the understanding that some of these modalities may be better options depending on the individual patients and clinical scenario. It is important to recognize the complex pathophysiology of this disease process and that a multi-faceted treatment approach is necessary to improve pain and function. Based on this review, education and self-management strategies should always be a part of managing knee OA as it can be used in conjunction with other treatments. Weight loss should be encouraged for patients who are overweight along with an beginning an exercise program that may involve a combination of aerobic activity, strengthening, and improving flexibility. While the optimal program regimen may be debatable, the literature demonstrates that they offer benefit to patients with knee OA and that weight loss with exercise is better than either one alone. There are several studies that have looked at the usefulness of biomechanical interventions and many of them have demonstrated potential benefit from knee braces, knee sleeves, foot orthoses, and biomechanical training programs warranting their incorporation into the management of knee OA. However, more studies are needed to better determine which patients specifically will benefit most from these various interventions. Glucosamine/chondroitin is a supplement with conflicting studies which may be partially due to the difference in quality of products being used in the studies, however, with its excellent safety profile and some studies demonstrating its superiority to placebo, it is a therapy that should be discussed with patients for potential use. Acetaminophen and NSAIDs, and to a lesser extent Tramadol and opioids, can be helpful in the short-term management of knee OA, but given their side effect profiles, they should be considered a poor long-term treatment. DMOADs were discussed in this review to

present available literature on oral medications being studied to alter the course of knee OA, however, at this time there is not enough evidence to suggest the common use of these treatments in managing knee OA. Injectables are another category of treatment for knee OA that should be considered beginning with the use of IA corticosteroids that have shown the ability to decrease pain in the short-term and should be used when signs of inflammation arise. The body of literature overall supports the use of IA hyaluronic acid injections for the treatment of knee OA and demonstrates it is a superior option for long-term management of knee OA compared to IA corticosteroids. Additionally, hyaluronic acid has an excellent safety profile making it a more suitable for being used for an extended period of time.

PRP is another injectable that when compared to hyaluronic acid has shown similar results in older patients with more advanced OA and may have better results in younger patients affected by cartilage lesions or early OA. PRP should be considered as a treatment option especially if the patient has used the other injectables mentioned without success, however, additional studies are needed before conclusions regarding true efficacy can be confirmed and these studies are also needed to help determine the optimal composition of PRP (*i.e.,* platelet concentration, leukocyte-rich or poor). The use of stem cells is emerging and while the possibility of such a regenerative treatment for knee OA is intriguing, before this therapy can be recommended confidently for clinical use there needs to be further studies that are of higher quality to better determine the efficacy, safety, and optimal source and preparation of cells for the treatment of knee OA. Several other emerging injection therapies were discussed in this review, but the amount of quality studies are lacking or are still in early trial phases making it difficult to provide appropriate judgment on the efficacy and safety profile of these products for the treatment of knee OA. While surgical interventions for knee OA were beyond the scope of this review, the current literature comprised of several high-level studies provide evidence that arthroscopy should not be included in the treatment algorithm for knee OA as it has not been shown to be an effective method to treat changes seen in the setting of knee OA with degeneration of the articular cartilage and menisci. This review hopes to provide a better understanding of treatment options available and their efficacy but it is important to highlight the need for continued research with regards to the management of knee OA. This research should focus on investigating the efficacy of new drugs such as the DMOADs or injectables as well as better understanding their safety profiles. Rather than develop treatments that target symptoms, the emphasis needs to be on developing advanced therapies that can slow or prevent further disease progression and hopefully even initiate a regenerative process. Additional research should also be directed at determining which subset of patients with knee OA may benefit from certain treatments and who are more likely to have a positive response to a given intervention so that more individualized treatment strategies can be established.

Abstract

A wide variety of symptoms and diseases of the upper aerodigestive tract are associated to gastro-oesophageal reflux disease (GORD). These disorders comprise a large variety of conditions such as asthma, chronic otitis media and sinusitis, chronic cough, and laryngeal disorders including paroxysmal laryngospasm. Laryngo-pharyngeal reflux disease is an extraoesophageal variant of GORD that can affect the larynx and pharynx. Despite numerous research efforts, the diagnosis of laryngopharyngeal reflux often remains elusive, unproven and controversial, and its treatment is then still empiric. Aim of this paper is to review the current literature on upper aerodigestive tract disorders in relation to pathologic gastro-oesophageal reflux, focusing in particular on the pathophysiology base and results of the surgical treatment of GORD.

Key words: Clinical management; Gastro-oesophageal reflux; Extraoesophageal disease; Upper aerodigestive tract disorders; Etiopathogenesis; Therapy

Core tip: Despite a growing number of clinical evidences, the association between gastro-oesophageal reflux disease (GORD) and extraoesophageal manifestations still derives from uncontrolled studies on small groups of patients. The evidences in the literature to support the proton pump inhibitor treatment of respiratory symptoms associated with GORD, in the absence of typical symptoms of reflux (heartburn and regurgitation), are scanty. A specific diagnostic tool, of respiratory symptoms associated with GORD, is missing even if oesophageal 24-h pH monitoring has been recommended. Large and prospective studies to assess the successful outcome of antireflux therapy, as well as surgical therapy, are still missing.

INTRODUCTION

Gastro-oesophageal reflux disease (GORD) is a

recognized cause of oesophageal symptoms (*i.e.,* heartburn, regurgitation, chest pain, and dysphagia) and inflammatory damages such as erosive esophagitis and intestinal metaplasia (*i.e.,* Barrett's oesophagus). The association between upper airways disease and pathologic gastro-oesophageal reflux was firstly made in 1968, when laryngeal contact ulcers and granulomas were noted to occur in patients suffering from GORD[1,2], although the concept that GORD could have an impact on laryngeal and pharyngeal disorders has been fully developed in the last 30 years. The reported extraoesophageal manifestations of GORD include asthma, chronic cough, laryngeal disorders, chronic sinusitis, otitis media, and postnasal drip[1]. Laryngo-pharyngeal reflux disease (LPRD) is the term suggested by some authors to define GORD beyond the oesophagus up to the laryngeal and pharyngeal level, thus causing extraoesophageal damages[2,3]. Despite a growing number of clinical evidences to support the association between GORD and extraoesophageal disorders[1], presently the majority of reports still derive from uncontrolled studies of small groups of patients[1]. Nonetheless, in most of the published series, it is difficult to establish a firm connection between GORD and upper aerodigestive disorders (even within the laryngopharyngeal areas), since the presence of gastric content in supraoesophageal structures has been always difficult to document[1,2,4].

This article reviews the current available evidence on extra-oesophageal manifestation of GORD, devoting special attention on the pathophysiology base and results of the surgical treatment of GORD, particularly in relation to arodigestive tract disorders.

RESEARCH

The PubMed database was searched up to June 2014, for meta-analysis, systematic reviews, randomized controlled trials, and controlled trials. Full text articles were obtained when the title, abstract or keywords suggested that the study could be eligible for this review. The search was carried out independently. The search was restricted to adults, while no language restriction was applied.

The medical subject heading used included "gastroesophageal reflux", "laryngopharyngeal reflux", "gastroesophageal reflux ethiopathogenesis", "extraoesophageal gastroesophageal reflux disease symptoms", "reflux laryngitis", "posterior laryngitis".

EPIDEMIOLOGY

GORD is the most common disease of the oesophagus, possibly the most frequently faced by the gastroenterologist. Surveys in the United States have shown that it affects about 20% of the population, while about half experiences heartburn as a minimum once in a month, and 5% to 7% of the population have symptoms related to GORD every day[2,5,6].

Also because of the many clinical variables, the true prevalence of GORD among patients with suspected upper aerodigestive disorders secondary to pathologic gastro-oesophageal reflux is difficult to determine accurately, and it varies depending on the population analysed. For instance, in a study by Koufman *et al*[7], it has been estimated that about 10% of patients presenting to ears, nose and throat (ENT) clinician may have symptoms and/or findings related to GORD. In another study, it has also been reported that about two-thirds of laryngeal and voice disorders had either pathologic gastro-oesophageal reflux as primary cause or as a significant etiological co-factor[8], and that the prevalence of GORD among patients with laryngeal stenosis is 78%, reflux laryngitis 60%, globus sensation 58%, and chronic cough 52%[9,10]. In another survey, symptomatic reflux was diagnosed by pH monitoring in 30% to 60% of adults affected by asthma and chronic cough and nearly 40% of patients had endoscopic signs of esophagitis[2,11]. More recently, a systematic review has demonstrated typical symptoms of GORD in 59% of 10491 patients with asthma[12]. The proportion of asthma patients with GORD remained as high as 51% when more stringent criteria to prove GORD were adopted (*i.e.,* ambulatory 24-h pH monitoring). The average prevalence of asthma in patients with GORD was 4.6% as compared to 3.9% in controls. The overall odds ratio was 5.5 (95%CI: 1.9-15.8) for studies reporting the prevalence of GORD symptoms in patients with asthma and 2.3 (95%CI: 1.8-2.8) for those studies measuring the prevalence of asthma in patients with GORD. Interestingly, two studies that assessed whether GORD precedes asthma gave inconsistent results. The authors concluded that the analysis indicated a significant association between GORD and asthma, but the direction of causality remained undetermined[12].

PATHOPHYSIOLOGY

Upper aerodigestive tract disorders from pathologic gastro-oesophageal reflux appear to be sustained either directly or secondarily. Direct injury can be due to the result of a direct contact of gastric contents with the mucosa of the extra-oesophageal structures. Alternatively, a neurally mediated vagal reflex can be stimulated by the refluxate in the oesophageal body affecting indirectly the bronchopulmonary system, thus triggering cough, bronchial constriction or laryngospasm[6,13]. However, the evidence confirming the mechanisms of injury in LPRD is still inadequate, and in the literature very few laboratory investigations with animal models have substantiated the noxious effects of the refluxate on these anatomic sites by

both direct and indirect mechanisms[14,15].

Certainly, microaspiration of gastric contents can occur during gastro-oesophageal reflux episodes[16]. Direct contact of the refluxate with the mucosa of the pharynx and larynx could therefore represent the main mechanism of injury in LPRD. Unlike the distal oesophagus, the airways are not protected by anti-reflux clearance mechanisms or intrinsic mucosal properties. Moreover, it has been shown that a low lower oesophageal sphincter pressure as well as ineffective oesophageal motility may frequently be present in patients affected by GORD with associated respiratory disease (chronic cough, asthma, laryngitis)[17,18]. It is possible that just a single reflux episode above the oesophagus can be responsible of pharyngeal, laryngeal, and respiratory disorders.

The triggering of a vagal reflex has also been proposed as a consequence of the direct aspiration of refluxed acid into the pharynx or upper airways, besides the stimulation of the distal oesophageal mucosal receptors by the refluxed gastric content[17]. When stimulated, airway nociceptors activate protective responses such as cough and bronchospasm. It is also interesting to evidence that the pathways of some oesophageal and airway sensory nerve fibres terminate within the same regions of the central nervous system; thus, connections among oesophageal nociceptors and airway sensory nerves can exacerbate cough and the asthma-like disorders associated with GORD[19]. So, given the common vagal innervations of lungs and oesophagus, it is not surprising that many patients with asthma and chronic cough also have GORD, and that reflux often precipitates respiratory symptoms that are clinically indistinguishable from asthma[2,19].

Also the specific reflux agent or agents responsible for producing otolaryngology symptoms and pharyngo-laryngeal injury are currently debated[20]. Potential candidates include gastric contents (*i.e.*, acid and pepsin) as well as duodenal contents, including both bile acids and the pancreatic enzyme trypsin. Several animal studies suggested an injurious potential for both acid gastric contents and pepsin[2,20,21].

CLINICAL AND DIAGNOSTIC FEATURES OF AERODIGESTIVE TRACT DISORDERS RELATED TO GORD

The Montreal evidence-based global consensus, defining GORD and its constituent syndromes, recognized oesophageal syndromes and established an association between GORD and asthma, chronic cough, and laryngitis, while proposed an association with pharyngitis, sinusitis, and otitis media[22]. The Montreal consensus also acknowledged that such extra-oesophageal disorders have a multi-factorial aetiology and pathologic gastro-oesophageal reflux may well be a co-factor rather than a cause. Thus, patients with asthma, chronic cough or laryngitis should firstly be evaluated for causes not related to GORD, considering that extra-oesophageal syndromes rarely occur without concomitant typical symptoms of GORD[22]. However, the diagnosis of GORD as the cause of extra-oesophageal symptoms is very challenging and relies on the following investigations.

PPI TRIAL

Traditionally, otolaryngologists have commonly used an empiric course of double dose of proton pump inhibitors (PPIs) (*i.e.,* PPI trial) to initially diagnose and treat patients with upper aerodigestive tract disorders suspected to be related to GORD, deeming the resolution of symptoms with such a treatment as diagnostic of LPRD[3,5,6,23]. PPIs have been shown to improve asthma outcomes in terms of a significant reduction in the proportion of subjects experiencing respiratory symptoms including dyspnoea, cough, wheeze in randomized controlled trials[24,25], although a recent meta-analysis of 11 randomized trials found only small improvements of the respiratory function in adult patients with asthma, unlikely to provide a real clinical benefit[26]. Another meta-analysis of randomized trials by the Cochrane Collaboration regarding cough control with PPIs in GORD reported that PPIs were not better than placebo to resolve cough in such a patient, although they improved cough scores[27]. Finally, also for suspected GORD-related chronic laryngitis a meta-analysis of randomized trials has demonstrated no advantage of PPIs *vs* placebo[28]. Therefore, the evidence to support the treatment with PPIs in the absence of typical symptoms (*i.e.,* heartburn and regurgitation) or objective pathologic gastro-oesophageal reflux (*i.e.,* esophagitis on upper endoscopy or positive ambulatory pH monitoring) is scant[29].

ENDOSCOPY

The most frequent laryngoscopic findings that have been related to reflux are oedema and erythema: (1) of the arytenoid cartilages mucosa; (2) of the interarytenoid region; and/or (3) of the posterior third of the true vocal folds (*i.e.,* posterior laryngitis). A reflux finding score based on the presence and the severity of at least eight different grades of lesions at laryngoscopy has been proposed by Belafsky *et al*[30] to improve the diagnostic accuracy. However, laryngoscopy has revealed laryngeal irritation in more than 80% of healthy controls prospectively evaluated[31] and the concordance among ENT physicians for signs of reflux laryngitis is low when blindly evaluated[32]. Thus, a causal relationship between GORD and laryngitis should not be posed

relying on laryngoscopy findings alone.

Indeed, upper endoscopy has excellent specificity for the diagnosis of GORD in the presence of erosive esophagitis[33]; however, only one third of patients with symptoms of GORD, and even less following treatment with PPIs, have erosive esophagitis which does not establish *per se* a causal relationship between GORD and aerodigestive tract disorders[34,35].

AMBULATORY PH MONITORING

This is the only test that can objectively demonstrate the presence of abnormal oesophageal acid exposure, characterize the reflux episodes and determine their association with symptoms. The pH monitoring has high sensitivity and specificity in the presence of erosive esophagitis (both up to 100%); but its sensitivity lowers (about 70%) in patients without erosive esophagitis, although may be increased adopting impedance pH monitoring (up to 90%)[36,37].

The use of dual pH monitoring (with a probe at the level of the upper oesophageal sphincter) has been proposed by some authors to investigate for respiratory symptoms associated with GORD[23,38]. However, this procedure is not universally performed due to the significant practical problems performing pH monitoring in the pharynx[23,38].

Certainly, there is a great variability in the prevalence of abnormal pH monitoring reported in patients with asthma, chronic cough, and laryngitis[12,39-41]. However, a negative pH monitoring may address the diagnostic investigations toward aerodigestive disorders non-related to GORD, while a positive pH monitoring establishes a diagnosis of GORD, although it does not imply that the latter is the cause of the respiratory symptoms. The temporal association between reflux episodes and respiratory symptoms may be evaluated by the symptom index (SI, *i.e.,* percentage of symptoms preceded by a drop in oesophageal pH below 4.0 within a 5-min time window divided by the total number of symptoms)[42] and the symptom association probability (SAP, *i.e.,* statistical probability with which symptoms and reflux episodes are associated)[43]. The patient must promptly record the symptoms, while the machine should accurately detect the reflux episodes (*i.e.,* drop in oesophageal pH below 4.0) in order to evaluate precisely the temporal association between symptoms (*i.e.,* asthma attacks or cough events) and acid reflux episodes. A positive symptom association is declared if the SI is greater than or equal to 50% (*i.e.,* at least half of the reported symptoms are preceded within a 5-min time window by an intra-oesophageal pH below 4.0) or if the SAP is greater than 95% (*i.e.,* the probability of this association having occurred by chance is less than 5%). Unfortunately, both sensitivity and specificity of symptom association analysis tools is limited and there are no outcome studies to support treatment of extra-oesophageal GORD based on this parameter alone[29]. Recently, Smith *et al*[39] by using a microphone to record cough concurrently with the pH-impedance recording, to overcome patients not always recording timely their symptoms during pH monitoring, reported 6 to 18 times more coughing than with patient reported cough, and 2 to 3 times more than relying on manometry to suppose when cough possibly occurred. If these data will be confirmed by further studies, the evaluation of the temporal association between reflux episodes and respiratory symptoms will be improved.

ASTHMA

Some authors have reported about the possible relationship between asthma and GORD, since a percentage between 30% to 80% of asthmatic patients, have been found to have GORD and/or esophagitis[43-45]. Nonetheless, a cause effect association between GORD and asthma has not been found yet[43-45]. Most of the reports show that GORD medical therapies such as histamine H2 antagonists or PPIs can be effective on asthma outcome[45,46], even if such medications have not been reported to improve asthma symptoms or pulmonary function[43-45].

Finally, on the contrary, few reports have claimed that inhaled b2 agonists and oral corticosteroids, currently used for asthma therapy, may increase oesophageal acid refluxate[2,45-50].

CHRONIC COUGH

Chronic cough is also believed to be possibly related to GORD as proposed by several studies[51-54]. In fact Harding[44] and Pacheco-Galván *et al*[49] have reported that both, medical and surgical therapy of pathologic reflux, can improve or even resolve chronic cough in up to 51% to 100% of adult patients. Unfortunately, most of the data available in the literature come from uncontrolled studies with small sample sizes of patients, and evidences about the efficacy of therapy are still lacking. Long term follow-up studies with a large number of patients are missing.

LARYNGEAL DISORDERS

GORD is also considered to be a possible cause of laryngeal disease: it has been suggested that the aetiopathogenetic mechanism underlying laryngeal disorders, such as chronic laryngitis, could be caused by the contact of the acid refluxate with the laryngeal mucosa. Therefore, patients affected by chronic laryngitis who lack anomalies at the laryngoscopic evaluation should be addressed to a pH monitoring and gastroesophageal endoscopy in order to reveal signs of reflux[55-57]. Some authors have already

reported that they have successfully treated with PPIs some laryngeal diseases such as chronic laryngitis as well as contact granuloma and acquired subglottic stenosis[58-60]. In the study by El-Serag *et al*[61], patients treated with PPIs showed efficacious resolution of laryngeal symptoms when compared to a placebo group. Nonetheless, the small amount of patients involved, as well as the limited follow-up, represent the main drawbacks of this and of similar studies[2,49,56,61,62].

CHRONIC SINUSITIS

Some reports have advocated GORD to have a possible role in the aetiopathogenesis of chronic sinusitis and that medical anti-reflux therapy may be useful for these patients[63]. It has been speculated that GORD may cause sinonasal congestion and alteration of sinusal drainage with consequent inflammation[2,49,64].

PAROXYSMAL LARYNGOSPASM

Also paroxysmal laryngospasm episodes have been associated by some authors to GORD, and medical anti-reflux therapy with PPIs has been reported to be of benefit for these patients. According to the aetiopatogenetic mechanism indicated by these authors, paroxysmal laryngospasm could be considered as a vagally mediated reflex response of the larynx to acid refluxate, a potentially injurious stimulus[2,49,63,65-67].

OTITIS MEDIA

To date, there are only few reports indicating GORD as a possible cause of persistent middle ear problems (*i.e.,* otitis media with effusion). Unfortunately studies considering this specific issue, in adults and children, still are scant[68-70].

POSSIBLE DIAGNOSTIC ALGORITHM

The diagnosis of LPRD is still very controversial, both in clinical practice and research. Most guidelines and reviews recommend starting the diagnostic work-up and treatment of patients with upper aerodigestive symptoms of GORD with an empiric trial of PPI therapy at a double dose given for at least three months[3,5,6,23]. Traditionally, in clinical practice, otolaryngologists have considered diagnostic of LPRD the resolution of symptoms following such a PPI trial. Failure to respond, on the other hand, would indicate incorrect diagnosis of GORD or inadequate dosing or resistance to the treatment. Nonetheless, in patients who do not respond to the empirical trial, further investigations (*e.g.,* ambulatory 24-h oesophageal pH monitoring) have been recommended[2,3,5,23].

MEDICAL TREATMENT

As stated above, PPIs are the main proposed treatment for LPRD. Caution must be used, however, interpreting the available literature, as it is hampered by studies lacking strict inclusion and diagnostic criteria investigating large populations and, consequently, inconclusive meta-analyses. Nonetheless, partial improvement of both symptoms and laryngoscopic signs of laryngitis has been reported with PPI treatment and behavioural changes. Lifestyle modifications comprise the avoidance of heavy and late meals, alcohol consumption, and smoking. Also, to elevate the head of the bed and to reduce the body weight may be beneficial[6]. Most handbooks and reviews suggest a three-month treatment with PPIs at a double dose as the first step in the diagnosis and treatment of patients with upper aerodigestive symptoms attributed to GORD[3,5,6,23]. Patients who do not respond, however, are indeed particularly challenging. Several factors have been suggested to explain refractory cases, such as inadequate dosing or resistance to PPIs, sensitivity to non-acid refluxate, and incorrect diagnosis of GORD. Thus, the dosages of PPIs as well as the frequency of their administration can be increased and pro-motility agents and histamine receptor antagonists may be added. Finally, in patients with signs and symptoms of LPRD despite PPIs treatment, 24-h ambulatory pH monitoring while the patient is on medication may demonstrate persistent acid refluxate due to the lack of acid control[6].

SURGICAL TREATMENT OF AERODIGESTIVE TRACT DISORDERS RELATED TO GORD

Historical background

In 1956, Rudolph Nissen, a German surgeon, opened the era of modern anti-reflux surgery describing a complete plication of the gastric fundus around the abdominal portion of the esophagus that restored an anti-reflux barrier[71]. The Nissen operation has been modified throughout the years, new valves around the abdominal oesophagus, either complete (360°) or partial (240°-270°) have been described, but the basic principle of the operation remained unchanged: to restore a high pressure zone (HPZ) at the gastro-oesophageal junction[72-80]. In 1991, Dallemagne *et al*[81] reported the first laparoscopic anti-reflux operation. In the following decade the technique has been adopted worldwide becoming the gold standard for surgical management of GORD.

Indications and technical details

The surgical treatment of GORD is focused on restoring a HPZ at the lower oesophageal sphincter (LOS), while medication aim to modify the pH of

the refluxate. Nowadays, this purpose is achieved by a fundoplication performed laparoscopically, which offers excellent results combined with the postoperative advantage of a short hospital stay, minimal discomfort, and fast recovery time as compared to the open (*i.e.,* laparotomic) traditional operation[82-85]. According to the 2010 guidelines of the Society of American Gastrointestinal Endoscopic Surgeons, the surgical operation should be considered in the following situations: (1) failure of medical treatment because of inadequate symptom control, persistent severe regurgitation or disturbing side effects; (2) preference of the surgical treatment despite symptom control on PPIs due to quality of life, refusal of lifelong need for medication or costs of medications; (3) presence of Barrett's oesophagus or peptic stricture; and (4) extra-oesophageal symptoms such as asthma, hoarseness, cough, and chest pain or aspiration[86].

The surgical literature is full of eponyms of anti-reflux operations that quite often do not even correspond to the operation originally described by the authors[87]. Therefore, it seems very reasonable to go beyond such eponyms, and stress the surgical elements, common to most of these operations, that have been shown to guarantee long term control of reflux for the patient, namely: (1) to reduce the hiatal hernia in the abdomen; (2) to mobilize extensively the oesophagus and gastro-oesophageal junction; (3) to reduce the hiatus; (4) to interrupt the gastro-splenic ligament; (5) to construct a partial or complete fundoplication of adequate length and tightness; and (6) to fix with posterior and coronal stiches the wrap[87].

Results of anti-reflux surgery

Anti-reflux surgery (*i.e.,* fundoplication) has been shown in clinical studies to control GORD symptoms in 93% and 89% of patients after 5 years and 10 years, respectively[82]. Surgical fundoplication restores the LOS competence and improves the oesophageal peristalsis[88]. Of note, due to the restoration of a HPZ, the reflux control is equally effective when the patient is supine or upright[83]. Anti-reflux surgery has been shown to be safe and effective also in elderly patients affected by GORD[84]. In a randomized trial at a Veteran Affairs Cooperative comparing medication to anti-reflux surgery for GORD, patients on medication at 10-year follow-up in the medical therapy group as opposed to the surgical group were 92% and 62%, respectively[89]. The surgical treatment of GORD may, however, expose patients to some morbidity and increased risk of mortality. The most common complication related to anti-reflux surgery is the so called gas-bloating syndrome, affecting 15% to 20% of patients. Recently, a meta-analysis concluded that a partial (240°) fundoplication as compared to a complete (360°) wrap was associated to less postoperative dysphagia and inability to belch in patients undergoing surgical treatment of GORD[90]. A Cochrane review including more than 1200 patients from four randomized trials comparing medical to surgical therapy has demonstrated higher improvements in GORD specific quality of life after surgery, although a meta-analysis of such data was not performed[91]. Symptoms of heartburn, regurgitation, and bloating improved more after surgical fundoplication then with medication, even if small proportion of patients had persistent dysphagia after surgery. Nonetheless, the surgical operation is associated with some risk of complications and the decision to perform a surgical fundoplication needs to be thoroughly discussed with the patient.

Results on respiratory symptoms

The control of respiratory symptoms in patients with GORD undergoing anti-reflux surgery is less predictable. In the era of the open (*i.e.,* laparotomic) surgical operation, objective data regarding the ability of a fundoplication to control respiratory symptoms in patients with GORD were scarce[92,93]. For instance, Pellegrini *et al*[93] reported the successful results of a complete fundoplication performed in a small group of patients in whom GORD-induced aspiration had been diagnosed. In the past two decades, due to the advent of laparoscopic anti-reflux surgery, the number of patients undergoing fundoplication for GORD has greatly increased[87,94]. Hunter *et al*[94] reported resolution or improvement of respiratory symptoms in 76 out of 87 patients (87%) undergoing laparoscopic fundoplication. However, outcomes of patients with extra-oesophageal symptoms undergoing anti-reflux surgery are not always predictable. A Veteran Affairs Cooperative study, reported no significant improvement in pulmonary function tests one year after fundoplication, even in those patients presenting abnormal preoperative tests[95]. Analogously, a randomized trial showed that both medical and surgical therapy did not increase significantly the forced expiratory volume in 1 s after 6 mo[96]. Anti-reflux surgery can control extra-oesophageal symptoms in carefully selected patients with GORD, although these patient should be informed that the success rate is lower than in patients with typical symptoms[97]. It is particularly important to carefully evaluate the response of such patients to PPIs, as in patients who do not respond to medications, even in the presence of oesophageal acid exposure demonstrated by pH-monitoring, the results of fundoplication are not effective[98].

CONCLUSION

Upper aerodigestive tract disorders related to pathologic reflux appear to be a common but controversial disease, with conflicting data on pathophysiology, diagnosis, and treatment. Whereas trends are observed and many clinical practices are accepted widely on the basis

of experience, definitive, prospective, and controlled studies are strongly needed[2,6].

Also considering the possible implication of GORD in the development of supra-oesophageal neoplasms, as advocated by several investigators, more efforts are necessary to support the relation between extra-oesophageal disorders and GORD, in terms of prospective randomized trials[2].

A better comprehension of the physiopathological mechanisms of these conditions can help clinicians in the management of such patients. In particular, further large randomized-controlled trials in order to clarify LPRD pathophysiology, as well as to evaluate diagnostic algorithms and treatment approaches could be then particularly useful for the diagnosis and the management these disorders.

Abstract

Inherited retinal diseases are uncommon pathologies and one of the most harmful causes of childhood and adult blindness. Leber congenital amaurosis (LCA) is the most severe kind of these diseases accounting for approximately 5% of the whole retinal dystrophies and 20% of the children that study on blind schools. Clinical ophthalmologic findings including severe vision loss, nystagmus and ERG abnormalities should be suspected through the first year of life in this group of patients. Phenotypic variability is found when LCA patients have a full ophthalmologic examination. However, a correct diagnosis may be carried out; the determination of ophthalmologic clues as light sensibility, night blindness, fundus pigmentation, among other, join with electroretinographics findings, optical coherence tomography, and new technologies as molecular gene testing may help to reach to a precise diagnosis. Several retinal clinical features in LCA may suggest a genetic or gene particular defect; thus genetic-molecular tools could directly corroborate the clinical diagnosis. Currently, approximately 20 genes have been associated to LCA. In this review, historical perspective, clinical ophthalmological findings, new molecular-genetics technologies, possible phenotype-genotypes correlations, and gene therapy for some LCA genes are described.

Key words: Gene therapy; Leber congenital amaurosis; Retinal dystrophies; Childhood blindness

Core tip: Leber congenital amaurosis (LCA) is the most severe retinal dystrophy causing blindness before the age of 1 year. Clinical ophthalmological findings together with electroretinogram study, OCT imaging and retinal molecular-genetic technologies provide a precise diagnosis in these individuals. Gene-specific phenotypic features exist in LCA, and in this way is possible to predict the underlying genetic defect in some patients on the basis of ophthalmological clues. Clinical, molecular-genetics, phenotype-genotype and gene therapy aspects of LCA are described.

org/10.12998/wjcc.v3.i2.112

INTRODUCTION

Photoreceptor and retinal pigment epithelium dystrophies are inherited retinal disorders that result in severe visual impairment in childhood and adult years. They affect more than two million individuals worldwide[1,2] and are sorted according to the inheritance trait (autosomal recessive, autosomal dominant, X-linked or mitochondrial); however, these methods of subdividing retinal disease are unsatisfactory due to the fact that they do not always discern the etio-pathogenesis of retinal degeneration[3]. Over the last decade, new molecular-genetic technologies have classified the pathogenic nucleotide variants (mutations) in a more exact way; thus, at this moment, approximately 221 genes are known to cause these diseases[4]. Retinal degeneration phenotypes have variable expressivity that can range from mild retinal dysfunction (night blindness, color blindness) to poor vision and total blindness[5].

Leber congenital amaurosis (LCA) is the most severe and earliest form of the inherited retinal diseases that causes childhood blindness[6]. This dystrophy is a genetically heterogeneous recessive disease affecting 1 in 30000[7] to 1 in 81000[8] subjects; although in consanguineous populations or isolated communities may be more frequent[9]. LCA represents almost 5% of all retinal dystrophies and 20% of children with visual impaired in special schools[10]. Although LCA have a broad expression variability, some clinical features may be specific to individual genetic abnormalities, providing a useful means of determining which gene may be responsible, thus narrowing the number of genes that may need to be tested and thereby significantly reducing the involved cost[11]. To date, eighteen genes involved in LCA have been identified, which encodes proteins important in several retinal developmental and physiologic pathways[4]. Recently, therapeutic gene replacement trials for a specific form of human LCA have started, and represent the first example for inherited blindness treatment. In the following sections, we will describe the historical perspective, the clinical characteristics, the involved genes and their functions, the genotype-phenotype correlations, and the current gene therapy treatments for LCA.

HISTORICAL CLINICAL PERSPECTIVE

In 1869, Theodor Leber described a blind child with vision loss, wandering nystagmus, amaurotic pupils, and congenital retinitis pigmentosa (RP). These characteristics were present at or close birth. This German ophthalmologist classified the disease as a new group of pigmentary retinal dystrophy, or tapetoretinal degeneration[12].

In 1957, a reduced or non-recordable ERG was identified as an essential component in the LCA diagnosis[13]. In such report, congenital keratoconus/keratoglobus and cataracts were features associated with this dystrophy, which was named LCA[13,14]. At the same year, Alstrom *et al*[15] reported that in a study from Sweden 20% of blind children had LCA (*heredoretinopathia congenitalitis monohybrid recessive autosomalis*), which had predominantly an autosomal recessive inheritance. In 1963, Waardenburg *et al*[16] described intrafamilial expression variability and association with keratoconus and cataracts.

CLINICAL CHARACTERISTICS

An appropriate clinical evaluation and ophthalmological history, as well as the determination of suggestive retinal clues make a correct diagnosis of the early-onset childhood retinal dystrophies. The utilization of newer diagnostic tools as optical coherence tomography (OCT), join to electrophysiological test (ERG) support the diagnosis. However, at present, genetic-molecular testing is necessary to obtain a definitive diagnosis of retinal dystrophies through pathogenic variants identification[10].

LCA is characterized by at least three findings: severe and early visual impairment, sluggish or near-absent pupillary responses, and severely subnormal or non-detectable ERG[12,13,17]. In LCA patients the absent of fixation or oscillations of the eyes may be seen as early as 6 wk of life. Phenotypic variability on the retina can be identified; thus, fundus appearance ranged from normal or mild retinal involvement to macular coloboma or maculopathy, bone-spicule pigment migration, marbleized fundus, among others. Refractive errors as high hypermetropia, photoaversion (photophobia), nyctalopia and the oculodigital sign, are also commonly observed[17,18].

Visual function

Visual function and visual acuity (VA) are broadly variable, generally range from 20/200 to perception of light or inclusive no perception of it[18]; thus, the prognosis in these patients are complicated. The natural history of visual impairment has been divided into three types: a stable development in most of affected subjects, visual progressive decline, and an appreciable improvement in a minority[8]. In this way, VA, fundus appearance, and systemic findings were assessed in 55 patients with LCA. Twenty-two patients were seen for follow-up examinations (5 years). Seventeen (77%) patients were found to have stable VA, four (18%) had deterioration of VA, and one patient (5%) improvement[19]. Another

longitudinal study carried out in 14 patients reported that 50% of them have invariable VA, 29% with VA deterioration, and 21% with visual improvement[20]. In a small series of nine LCA patients was showed VA stability was demonstrated in 55% of patients, while 11% and 33% demonstrated decline and improvement, respectively[21]. In summary, in all studies, 90 patients were examinated: 15%, 75%, and 10% of cases have showed deterioration, stability and improvement, respectively[8]. Patients with mutations in specific LCA genes have demonstrated distinctive VA among the different LCA subtypes. We will return to this point later on.

Ophthalmological features associated to LCA

Refraction defects are variable. Subjects with LCA most commonly are hyperopic[19,22,23]; although, they may also be highly myopic[24]. It has been proposed that an unusual emmetropic development may be caused by severe visual impairment[23]. Some children with LCA children are photophobic[24], whereas others LCA patients can have nyctalopia[25] and these symptoms may be gene-specific as we will soon see[2]. Franceschetti´s oculo digital sign, comprising eye poking, pressing, and rubbing is usual in LCA children; it is not pathognomonic for this retinal dystrophy and it can be found in other diseases[26,27]. Some LCA patients may present keratoconus and cataract, which exacerbate the poor vision of this pathology. Mutations in *AIPL1* and *CRB1* genes may be identified in these patients[28-31].

No ophthalmological features associated in LCA

Mental retardation was the most significant systemic association in LCA patients. It was reported in up to 52% on this disease[15,32-35]. As in most of these reports cerebral imaging studies were not performed, it seems that this figure is overestimated. In more recent studies where the brain was evaluated, numerous cases were found to have cerebral anomalies as cerebellar involvement (Joubert syndrome), thereby excluding LCA diagnosis[18].

Stereotypic movements and behavior (hand and rubbing movements, hair touching, facial grimaces, among others) are particularly marked in LCA[6].

Olfactory dysfunction has been described in some LCA patients (and carriers) due to mutations in the *CEP290* gene[36].

DIFFERENTIAL DIAGNOSIS OF LCA

Some inherited retinal no syndromic diseases share similarities with LCA. Achromatopsia and congenital stationary night blindness may present poor eye fixation and nystagmus, which are similar to LCA, but they show normal retinal fundus. On the other hand, ocular albinism also have nystagmus and poor fixation; however, it has albinotic retinal fundus (absent retinal pigment and choroidal vessels visible) and foveal hypoplasia[8].

Complete achromatopsia or colorblindness is an autosomal recessive pathology that presents marked photophia-photoaversion and blepharospam, decreased VA, and inability to discriminate color. At night, they have a significantly improvement. Incomplete form of achromatopsia or blue-cone monochromacy is a congenital stationary cone dysfunction that presents the same symptoms, although it is less severe. In both subtypes of cone dystrophies ERG recordings have rod photoreceptor normal function, while cone function is absent or subnormal[8,18].

CSNB is a heterogeneous group of nonprogressive retinal pathologies that present reduction of VA, myopia, strabismus, and mainly impaired night vision. ERG report absence of rod function in the complete form of CSNB, while in the incomplete form there is a subnormal rod function response[8,18].

Since the sixth week of age albinism may be confused with LCA; however, several features present in albinism as hypopigmentation of the skin, hair and eyes, and a normal ERG make a differential diagnosis[8,18].

Some syndromic inherited disorders may present similar ocular characteristics to LCA. For this reason it is important search features as mental retardation, deafness, kidney disease (nephronophthisis), skeletal anomalies, cerebral and cerebellar anomalies, among others, which can be associated to retinal photoreceptor degeneration.

Bardet-Biedl syndrome (BBS) is an autosomal recessive disorder with a retinal degeneration that presents a rapid progress, characterized by poor vision and night blindness since the first decade of life and total blindness before the second decade. Nystagmus is extremely infrequent. Different forms of retinal dystrophy have been described, including a cone-rod dystrophy or rod-cone dystrophy, choroidal dystrophy, and so-called global severe retinal dystrophy[37]. Truncal obesity and diabetes mellitus, postaxial polydactyly, hypogonadism in males and genital anomalies in females, renal malformations, developmental delay/behavioral anomalies, ataxia, anosmia, cardiovascular anomalies, among others, can be seen in BBS[38]. Alström syndrome is an autosomal recessive disease similar as BBS that also affects severely vision since early ages; but they do not present polydactyly[39].

The neuronal-ceroid-lipofuscinosis are heterogeneous disorders characterized by intracellular storage of ceroid lipofuscin. Progressive vision loss, retinal degeneration, macular degeneration and optic atrophy cause blindness since the age of two years. Developmental delay/mental retardation, psychomotor degeneration, hypotonia, ataxia, seizures, spatiscity, and death are common characteristics seen in this syndrome. ERG shows early non-recordable res-

ponses[40,41].

Senior-Loken syndrome has 2 major features: cystic kidney known as nephronophthisis and early childhood-onset retinal degeneration (retinitis pigmentosa or LCA). Similar features join to cerebellar hypoplasia may be seen in Jourbert syndrome and Meckel syndrome, both diseases known as cerebello-oculo-renal syndromes. Anomalies in cilia proteins (which are essential for the normal development and function of a wide array of specialized tissues as retina, inner ear, kidney, and brain) have been associated in these entities. Thus, mutations in several genes related to centrosomal and ciliary function (as *CEP290*) can cause phenotypic heterogeneity, ranging from LCA to the syndromes above mentioned[42,43].

Refsum disease, neonatal adrenoleucodystrophy and Zellweger syndrome are peroxisomal disorders that have similar ocular LCA phenotype; however, the systemic cerebral, hepatic, and renal features dominate the phenotype, and the patients almost always suffers an early death[18].

MOLECULAR GENETICS OF LCA

LCA is a highly clinical and genetic heterogeneous disease that is inherited as an autosomal recessive trait in most of the affected. Recent advances in knowledge based in molecular genetics of the retina have allowed the improvement and widen of the clinical diagnosis. In this way, patients with LCA or childhood early retinal dystrophies are sooner identified, and new mutations and LCA genes are being discovered[12,15,44].

Identification of LCA genes

Mutations in least 22 genes (Table 1) have been identified in patients suffering from LCA, nonetheless in 30%-50% of LCA patients no genetic cause is confirmed (Table 1). The advent of new genotyping technologies such as DNA microarrays or next generation sequencing (NGS) offers the opportunity of discovering new LCA loci[4]. Currently, some old methods (linkage analysis and candidate gene approach) or newer methods (homozygosity/autozygosity mapping and NGS) are used for LCA genes identification.

Linkage analysis has identified some LCA genes including *AIPL1*, *GUCY2D* and *RDH12*[45-49]. On the basis of retinal expression other group of genes related to LCA have also been found (*RPE65*, *LRAT*, *CRB1*, *IMPDH1*, *CRX*, and *RPGRIP1*)[50-56].

Recently, microarrays technology is utilized to identify mutations that had already been described in other retinal dystrophy reports. This method has the advantage that is relatively cheap and fast; although it has the disadvantage that new mutations will be missed and will not identified. Thus, at least one pathogenic mutation will be found in approximately 60% of the patients when this technology is used. Another method based in microarray technology named homozygosity mapping is important in autosomal recessive diseases where the same ancestral allele is present in affected patients. Thus, this genetic-method is used for detect homozygous mutations (the same mutation in both alleles). *CEP 290*, *LCA5*, *IQCB1*, and *SPATA* are some genes that have been identified by this microarray technology[57].

New mendelian syndromes, new disease genes discovered and even new mechanism of pathogenicity have been identified[58]. A combination of homozygosity mapping and/or exome sequencing have successfully identified mutations in novel LCA genes including *KCNJ13*[59], *ALMS*[60], *CNGA3*[60], *MYO7A*[60], *BBS4*[61], *NMNAT1*[62,63] and *PRPH2*[64].

Genes, function and genotype-phenotype correlation

LCA exhibits a wide intra-and interfamilial clinical heterogeneity. However, it has been recognized that in some instances the retinal phenotype can suggest the underlying molecular defect. This phenotype-genotype correlation may help to determine rapidly a responsible gene, thus decreasing both the number of genes to be analyzed and the cost of molecular analyses. In the next sections we describe some of the most frequently mutated LCA genes.

***GUCY2D* (LCA1, OMIM #204000):** *GUCY2D* gene encodes a transmembrane protein termed guanylyl cyclase 1 which is specifically expressed in the retina and localized in the outer segment of the photoreceptors[65]. This enzyme is involved in the resynthesis of cGMP, a key step in the phototransduction recovery process. GUCY2D mutations accounts for 6%-21% (Table 1) of recessive LCA and up to 40% of dominant cone dystrophies[4,66]. Most *GUCY2D* mutations produce truncation of the protein and total loss of its function[67].

Patients with GUCY2D mutations had markedly poor vision early in life without an obvious subjective degree of progression and their visual acuity can range from 20/200 to light perception[68,69]. Patients have poor responses to visual stimuli, photophobia, preference for dim lights, hyperopia, nystagmus, and do not report night blindness[70]. Retinal fundus generally remains without abnormal findings throughout life. Patients can develop peripheral mild pigmentary changes, optic disc pallor and vascular attenuation[69]. Non-recordable ERGs are typical while OCT imaging shows a significant retinal thinning in the perifoveal area[69].

***RPE65* (LCA2, OMIM #204100):** *RPE65* encodes a retinal pigment epithelium-specific 65-Kd protein[65], which forms a complex with LRAT to act as the isomerohydrolase in the process of visual

Table 1 Leber congenital amaurosis genes and phenotype-genotype correlations

Locus name	Gene symbol	Chromosomal locus	Protein name	Protein function	% of LCA	LCA phenotype	Other retinal dystrophies	Mutations number
LCA1	GUCY2D	17p13.1	Retinal guanylyl ciclase 1	Hydrolysis cGMP	6-21	Marked poor vision, photophobia, hyperopia, nystagmus. Normal appearing fundus or mild granular pigmentary changes in periphery. OCT with significant thinning perifoveal	dCRD, dCD	155
LCA2	RPE65	1p31.3-p31.2	Retinal pigment epithelium protein 65	Isomerohydrolase in vitamin A visual cycle	3-16	Night blindness, nystagmus, poor vision on the first year, transient vision improvement and later deterioration in their third to fifth decades. OCT: thinner retina in both central and perifoveolar areas	rRP, dRP, RPci	138
LCA3	SPATA7	14q31.3	Spermatogenesis-associated protein 7	Possible vesicular transport	Approximately 3	Transient photophobia on the first year, but at three years old all patients had night blindness. Visual acuity at the end of the first decade remained stable. After, only hand motion and 20/200 can be seen. Fundus with typical appearance of RP rapidly progressive	rRP	18
LCA4	AIPL1	17p13.1	Aryl hydrocarbon interacting protein	Rod PDE chaperone	5-10	Keratoconus, cataract, and hyperopia. Variable night blindness or light sensibility. Poor vision. Fundus with bone spicules pigmentation and variable degree of maculopathy. OCT with reduced macular thickness	dCRD, rRP	52
LCA5	LCA5	6q14	Lebercilin	Ciliary functions	1-2	Severe reduced vision at, or near birth. Nystagmus and high hypermetropia. Visual acuity range between 0.20 to light perception. Extensible peripheral field loss. Fundus examination with widespread atrophy of the retina and RPE. Scattered white dots at RPE. Macula is normal most time, but in few patients may be seen macular coloboma. OCT: macular atrophy, disruption of retinal lamination and presence of hyporeflective well-circumscribed area in the outer nuclear layer, with a hyperreflective border (rossettes). Fundus autofluorescence shows hypofluorescence in the macula	No	35
LCA6	RPGRIP1	14q11	RP GTPase regulator-interacting protein 1	Connecting cilium, disc morphogenesis	4-6	Severe loss of vision early in life. Acuity visual worse than 20/200. At the beggining normal retina is seen, then it progress to pigmentary retinopathy. OCT shows remaining photoreceptor in the fovea	rCRD	82
LCA7	CRX	19q13.3	Cone-rod homeobox	Elongation of photoreceptor outer segment, photoreceptor development, phototransduction	1%-3%	Severe vision impairment is expected early in life. Nystagmus and high hyperopia. Fundus grayish with clumping or dot-pigment deposits and macular coloboma-like defect. OCT shows macular atrophy without noticeable signal of the junction between inner segments and outer segments	dCRD, dRP dLCA and rLCA	58
LCA 8	CRB1	1q 31-32.1	Crumbs homologue	Determining ad maintaining photoreceptor architectura	9-13	Nictalopia, nystagmus, keratoconus, corioretinal atrophy and nanophthalmos. Fundus with numular pigment clump, bone spicules and para-arteriolar preservation. Coloboma-like lesions and Coast like lesions	RPpa, rRP	
LCA9	NMNAT1	1p36.22	Nicotinamide nucleotide adenylyltransferase 1	Rate-limiting enzyme NAD (+) biosynthesis	----	Severe form of retinal hereditary degeneration, mainly atrophic macular lesion. Macular pseudocoloboma. Retina´s remainder with pigmentary changes. Nistagmus and severe loss of vision (only light or hand movements perception)	----	44
LCA 10	CEP290	12q21.32	Centrosomal protein Cep290	Ciliary function	20	Nystagmus, hyperopia, keratoconus and cataract. Photophobia. Light perception or no vision. Atrophic spot (dot-like) in RPE, intraretinal bone spicules in most patients. A striking tapetal reflex (specific intraretinal greyish and white marbled areas). Perifoveal thinning by OCT	Syndromes (Senior-Loken, Joubert, Meckel)	187
LCA 11	IMPDH1	7q32.1	Inosine 5´-monophosphate dehydrogensase 1	De novo synthesis de guanine nucleotide	8	Nystagmus with no fixation to light. Retina showing diffuse RPE mottling. No pigmentary deposits	dRP	18

LCA12	RD3	1q32.3	Protein RD3	Transcription and splicing. Suppress retinal membrane guanylate cyclase activity. Role in retinal maturation	< 1	Night blindness, severe nystagmus. Initial refraction was hypermetropic and changed to myopic in the disease´s course. Severe impaired visual acuity. Attenuated vessels, salt and pepper aspect, and bone spicules are seen on fundus. Macular changes as hammer beaten appearance were note on the third decade of live. OCT reveal disorganization of all retinal layers	----	9
LCA13	RDH12	14q23.3	Retinol dehydrogensase 12	Unusual dual specificity for all-trans-retinol and cis-retinols	4-5	Poor vision. Night blindness. Chorioretinopathy (reticular or fishnet pattern) with dense hyperpigmentation and bone spicules. There is little or no autofluorescence on the macula. SDOCT: severe macular thinning and loss of the foveal laminar architecture	dRP	76
LCA 14	LRAT	4q31.3	Lecithinretinol acyltransferase	Esterification essential in vitamin A visual cycle	< 1	Poor vision, nyctalopia, and visual field constriction since childhood. Peripheral RPE atrophy with little pigment migration into retina. Asteroid hyalosis occurs more frequently than RP (37% *vs* 3%). Reduced AF signal	rRP, EORD	13
LCA 15	TULP1	6p21.3	Tubby-like protein	Protein transport from the photoreceptor inner segment to the outer segment	----	Night blindness, nystagmus, moderately to severely limited visual field. Severely disturbed color vision. Fundoscopic findings are variable; pronounced maculopathy in older patients, pigmentary retinopathy in all patients. Pigmentary spicules also are variable affected	rRP	47
LCA 16	KCNJ13	2q37	Inwardly-rectifying potassium cannel subfamily J members	Maintaining resting membrane potential	----	Poor night vision, nystagmus. Cataract. Fundoscopy reveals considerable levels of pigments at RPE and a different configuration that the one seen on typical RP	dVRD	6
LCA 17	GDF6	8q22.1	Grow differentiation factor 6	Codes for a widely expressed growth factor in the TGF-b pathway specifying the dorsal-ventral retinal axis	----	Ocular and skeletal features. Limited vision to detect hand motions	Klippel Feil syndrome, dominant microphthalmia	15
	CABP4	11q13.1	Calcium binding protein 4	Modulate voltage dependent calcium channel	----	Poor vision, nystagmus, photophobia, poor visual acuity	rCSNB, rCRSD	6
	CNGA3	2q11.2	Cone photoreceptor cGMP-gated cation channel alpha subunit	Important for normal vision and olphatory signaling transduction	----	LCA phenotype is not described	Colour blindness total, achromatopsia, cone dystrophy	82
	ALMS1	2p13.1	ALMS1	ALMS protein	----	LCA phenotype is not described	Alstrom syndrome	129
	IQCB1	3q21.1			----	LCA phenotype is not described	Recessive Senior Loken syndrome	
	MYO7A	11q13.5			----	LCA phenotype is not described	Usher syndrome, congenital deafness without RP	304

dLCA: Dominant Leber congenital amaurosis; rLCA: Recessive Leber congenital amaurosis; dCRD: Dominant cone-rod dystrophy; dCD: Dominant con dystrophy; rRP: Recessive retinitis pigmentosa; dRP: Dominant retinitis pigmentosa; Rpci: Retinitis pigmentosa with choroidal involvement; PDE: Phosphodiesterase; recessive retinitis pigmentosa with para arteriolar preservation (rRPpa); EORD: Early onset retina dystrophies; AF: Autofluorescence; dVRD: Dominant viteroretinal degeneration; rCSNB: Recessive congenital stationary night blindness; CRSD: Recessive cod-rod synaptic disorder.

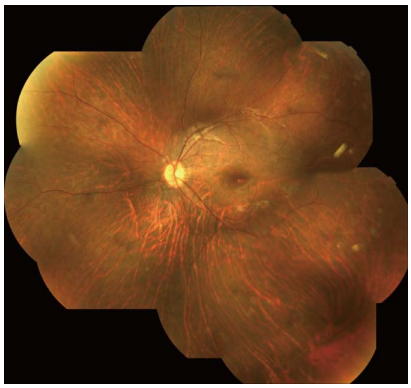

Figure 1 Patient´s fundus with *RPE65* mutations.

pigment regeneration. RPE65 is highly expressed in the RPE cells[71]. High RPE65 concentrations have demonstrated by immunocytochemistry and immunoblotting in the central area of the retina. LCA2 patients show an evident early cone loss, although residual cone preserve structure and function that may be present for many years in humans, supporting the existence of alternative pathways for cone survival[18]. RPE65 mutations account for 6%-16% of LCA cases and for approximately 2% of recessive RP cases[72]. Mutations in the *RPE65* gene are associated to severe visual loss; shortly after birth or in the first few years of life, affected child is noted to be less visually responsive than normal child[72].

In LCA2 patients, night blindness is a common characteristic and for that reason they prefer being in well-illuminated environments. Patients typically have nystagmus and poor vision since the first year of life. Improvement of visual function over the first few years of life can occur and vision may be relatively fair through teenage years, with later deterioration as patients reach their third to fifth decades[2,11]. Myopia and cataract are frequently associated[69]. The fundus appears normal at birth, but several abnormalities can progressively develop. Most patients present optic disc pallor, vascular attenuation and pigmentary retinal changes. Bull's eye maculopathy can be present at early stages while geographic atrophic lesions, diffuse hypopigmentation (dot-like changes) and pigment clumping can be observed at late stages (Figure 1). SD-OCT show 1-3 retinal layer with progressive disorganized lamellar structures. Patients with RPE65 have significantly thinner retinas in both the central and perifoveal areas[69].

***AIPL1* (LCA4, OMIM #604393):** *AIPL1* gene encodes the aryl hydrocarbon receptor protein-like 1, which is involved in nuclear transport or chaperone activity for rod phosphodiesterase (PDE)[4]. This protein is expressed early during human development in the central and peripheral retina, coinciding with rod and cone development; in contrast, *AIPL1* expression is restricted to rod photoreceptors in the adult retina[73]. Mutations in *AIPL1* resulting in blinding diseases can be classified into three categories: Class Ⅰ and class Ⅱ changes (missense and stop mutations) results in LCA (5%-10% of recessive LCA cases), while class Ⅲ mutations (small in-frame deletions) originate dominant forms of cone dystrophy (CORD5) or juvenile retinitis pigmentosa (RP13)[18,74].

The phenotype of LCA patients due to *AIPL1* mutations is relatively severe and is characterized by maculopathy and pigmentary retinopathy since young ages[31,75]. Nystagmus is observed in all patients starting at birth or at early infancy[75]. Keratoconus (26%-30%) and cataract (26%-60%) are commonly associated ocular findings[31,76] while hyperopia is the most common refraction error[2,76]. In addition, light gazing, night blindness, and photophobia can also be present[2,76]. Patients show markedly decreased visual acuities since early ages, ranging from 20/600 to no light perception associated with severe visual fields loss, and extinguished ERGs responses[76]. Fundus examination can vary from normal fundus to a salt-and-pepper retinal dystrophy and no apparent macular involvement in young patients; in contrast, older patients can exhibit typical features of retinitis pigmentosa as mild retinal vessel attenuation, bone spicule pigmentation, nummular pigmentation, and pale optic disc in combination with macular anomalies that can vary from mild foveal atrophy to macular coloboma. Autofluorescence (AF) imaging in AIPL1 young patients demonstrates mild generalized reduction in AF at the posterior pole and a relatively preserved macular AF, which demonstrate some degree of structurally intact photoreceptors and retinal pigment epithelial cells[77]. OCT imaging indicates a reduction in macular thickness in all patients (with salt-and-pepper dystrophy or RP-like lesions) with retinal lamellar structures partially retained, displaying 3 retinal layers with preservation of the outer nuclear layer and photoreceptor inner/outer segment juncture[76].

***CRB1* (LCA8, OMIM #613835):** The *CRB1* gene encodes a transmembrane protein named crumbs homolog 1 that is expressed in brain and retina and plays a central role in determining and maintaining the apico-basal cell polarity and adherens junction in embryonic epithelia[18,66]. CRB1-associated LCA is suggested to be caused by a developmental defect in the retina, since LCA patients with mutations in CRB1 have a thickened retina and lack of distinctive layering, resembling an immature retina[78]. Mutations in this gene cause multiple retinal phenotypes including LCA, retinitis pigmentosa, early onset rod-cone dystrophy, and cone-rod dystrophy[4]. The frequency of LCA8 varies considerably between populations in different geographic regions and

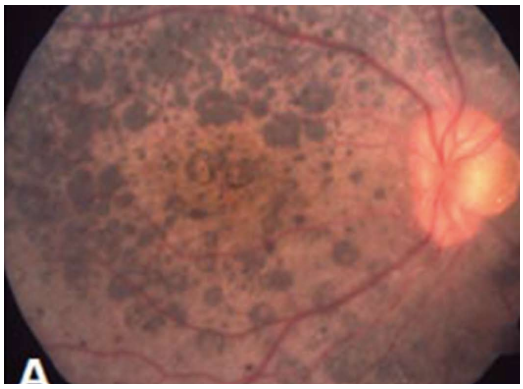

Figure 2 Patient´s fundus with *CRB1* mutations.

ranges from 17% in Spain to 0% in India[79,80].

Nystagmus is a common finding and visual acuities vary widely; thus the majority of patients retain walk-around vision in their first decade, during which median visual acuity is approximately 20/200. Later, visual acuity deteriorates with advancing age[29]. However, some reports have described VA as good as 20/40[2]. Approximately half of patients also have high hypermetropia[2,81]. Night blindness is present in the majority of affected; however, decrease of central vision and photophobia may present in some cases[81]. Keratoconus, occurring in 14%-70% of cases, contributes to visual deficiency in patients with LCA8[80]. Patients carrying CRB1 mutations have shown to be predisposed to chorioretinal atrophy[82] and nanophthalmos[83]. The fundus retinal hallmark of LCA8 is nummular pigment clumps (Figure 2), which are found in more than half of the patients. Although these feature are typical of *CRB1* mutations, it is not pathognomonic and has also been associated with mutations in other retinal dystrophy genes as *NR2E3*[82], *NRL*[84] or *TULP1*[85]. Bujakowska *et al*[81] reported two patterns of fundus pigmentation in their cohort: a typical bone spicule-shaped pigment migration within the peripheral retinal, and clumped pigmentary changes of nummular appearance at the level of the RPE[81]. Preservation of the para-arteriolar retinal pigment epithelium, retinal telangiectasia with exudation (Coat's-like vasculopathy), and macular lesions as coloboma-like lesions in macular or cystoids edema may also be seen[81,84]. SD-OCTs in patients with *CRB1* mutations show increased retinal thickness and loss of the outer limiting membrane[84,85].

***CEP290* (LCA 10, OMIM #611755):** *CEP290* gene encodes the centrosomal protein 290 which is a centrosomal protein with a probable ciliary function and expressed at high levels in the photoreceptor connecting cilium. This protein putatively interacts with the protein retinitis pigmentosa GTPase regulator and also with nephrocystin-S, which is mutated in nephronophthisis type 5[66]. *CEP290* mutations account for 6%-22% of non-syndromic LCA, depending on the population studied[18].

Although there is some inter-intrafamilial variability, patients carrying *CEP290* mutations exhibit a relatively homogeneous distinctive phenotype[86]. Most of the patients present roving eye movements or nystagmus with sluggishly papillary reactions since early childhood. Eye poking, enophthalmos, hyperopia, keratoconus and juvenile cataract are frequently observed[86]. Photophobia is present later in life, and night blindness has sometimes been described. Most patients have severe visual deficiency and visual acuity is either light perception or no vision at all from birth. In some patients visual capability may be equal to or more than hand motion and most of them are able to record progressive deterioration of visual acuity in succeeding years[86]. Fundoscopic findings are variable, from no changes to small (dot-like), well defined, atrophic spot at the level of the RPE to more pronounced RPE atrophy with intraretinal bone spicule-like pigmentation and a preserved macular region. Pasadhika *et al*[69] described LCA 10 patients with various degrees of macular changes, from a blunted foveal reflex to bull's eye maculopathy and optic disc drusen. In several patients, a striking tapetal reflex consisting of intraretinal greyish white marbled areas, more noticeable in the younger patients, is observed[86-88]. The small atrophic spots at the RPE layer and tapetal reflex-like changes seem to be specific of CEP290-associated LCA, since they have not been described in other forms of LCA. A distinct yellow scleral rim and pseudopapillary edema are also suggestive of this specific type of LCA[86]. Retinal SD-OCT analysis of patients with *CEP290* mutations shows segmentation into only three layers. ONL was notably preserved at the central macular area, but was thinner from the perifoveal area to the periphery. Such preservation tended to decline with an increase in the patient's age. Photoreceptor inner/outer segment was poorly defined in the central macula, but was invisible in the periphery. Moreover, cyst-like macular lesions can be identified in up to 43% of LCA 10 patients[69].

***RDH12* (LCA 13, OMIM #612712):** Retinol dehydrogenase 12 (*RDH12*) gene encodes a RDH12 protein that is a photoreceptor-specific enzyme involved in all-trans-and cis-retinol transformation[66]. RDH12 is expressed in the mouse and human photoreceptor inner segments and ONL[18]. Most *RDH12* mutations result in reduced expression and activity of the retinal dehydrogenase 12 enzyme, which in turns disrupts the cycle of synthesis of the visual pigment chromophore, 11-cis-retinal, from 11-trans-retinal[66]. *RDH12* mutations account for 4%-5% of recessive LCA, but may also cause other phenotypes as progressive rod-cone dystrophy, macular atrophy,

Figure 3 Patient´s fundus with *RDH12* mutations.

and early-onset RP[4].

LCA 12 patients exhibit a homogeneous clinical picture characterized by poor visual function in early life, a transition period with visual improvement, and a progressive period of decline in visual function due to rod and cone degeneration[89]. At young ages (4-6 years), patients have visual acuities in the range of 40/100 to 50/100, and visual fields are relatively well preserved; however, an age-related progressive loss of visual acuity is evident, with values from 10/100 to light perception on people at ages above 20 years. In younger subjects, residual rod and cone ERGs responses are recordable, with preferential preservation of cone function documented by use of multifocal ERG recordings; however, both rod and cone ERG are undetectable in patients older than 20 years[90]. Night blindness is the predominant symptom of this type of LCA[2]. This subjective symptom together with visual field constriction may not be frequently reported at time of presentation, but may be commonly recognized later in the disease progression[91]. Most LCA 12 patients have no photophobia while mild posterior subcapsular cataract and mild hyperopia can occur[90]. A marked pigmentary retinopathy, ranging from mild RPE atrophy and mid peripheral hyperpigmentation to severe chorioretinopahty (reticular or fishnet pattern) with dense hyperpigmentation has been associated to this form of the disease[90]. Bone spiculae are almost always present (Figure 3)[90]. There is little or no autofluorescence at macula in severe disease. SD-OCT imaging demonstrates severe macular thinning as well as excavation and loss of the foveal laminar architecture[91].

Gene therapy in LCA

Recent advances in the knowledge of the genes and the pathophysiology associated with mutations in those genes, has opened a new era of mechanism-based molecular therapeutics in ophthalmology. Immune privilege, small organ size, easy access and compartmentalization, as well as contralateral control, make the eye a perfect organ for gene therapy treatment[92,93]. Thus, to date, several independent phase I/II clinical trials for inherited retinal dystrophies including LCA2 (*RPE65*), choroideremia (*CHM*), Usher syndrome 1b (*MYO7A*), Stargardt disease (*ABCA4*), Leber hereditary optic neuropathy (*ND4*), and autosomal recessive retinitis pigmentosa (*MERTK*) are being studied[93].

Human Therapy: *RPE65*: Recently, three independent clinical trials of gene replacement therapy for LCA (specifically by *RPE65* gene) are carrying out to evaluate safety and efficacy[94-96]. Clinical assessment of these LCA2 patients analyzed ERG results, pupillary light reflex, nystagmus, and fundus abnormalities. Patients were treated in the most affected eye with a unique retinal injection of adenovirus vector (AAV2) carrying *RPE65* gene. A safety assessment has not showed the presence of serious adverse event in all trials. The reports of short-term follow-up of these trials have demonstrated an improvement in selected measures of vision, including best-corrected visual acuity, kinetic visual field, nystagmus testing, pupilarry light reflex, microperimetry, dark-adapted perimetry, and dark-adapted full-field sensitivity testing[97]. Soon, the third clinical trial phase of RPE65 replacement in these patients, will start.

Animal models in other LCA genes: Preclinical promise: In several genetic-molecular studies, *GUCY2D* is the most common *LCA* gene affected. A normal retinal fundus evaluation and relatively preserved rod-cone architecture make this group of LCA patients aspirants for gene therapy treatment. GUCYKO mouse containing recombinant AAV-*GUCY2D* gene has restored and preserved cone function during long time[98,99]. A recently study carried out in non-human primate demonstrated a persistent function in both rod and cone cells, mainly in foveal, perifoveal and parafoveal photoreceptors. These results suggested that *GUCYD2* gene therapy replacement could be a good treatment for LCA patients[100].

Other LCA genes considered for gene therapy are *AIPL1* and *CEP290*. Recently, a study developed in hypomorphic and null function mouse model shown long time rescue of rod-cone photoreceptors. Thus, these results showed that CEP290 gene therapy could be applied to patients with partial or complete loss of gene function, mainly when intervention occurs early in life[101]. Another recent study, using self-complementary viral vector has achieved functional vision rescue for this rapid retinal dystrophy[102]. CEP290 mutations may maintain cone cell structure in macular region, mainly in the fovea; in this way, this group of patients are a perfect target for a new gene therapy. Recently, Burnight *et al*[103] built a viral vector containing the *CEP290* gene and they demonstrated in cells culture that some mutated

cells developed cilia after this therapy. Thus, this gene therapy rescued the ciliogenesis anomaly, and could be effective affected subjects[103].

CONCLUSION

Current technology, such as gene testing, OCT or autofluorescence imaging studies together with the knowledge of the ocular-phenotype features of distinct LCA diseases has increased the individual diagnosis of this retinal dystrophy. This will lead to better prognosis and treatment options for LCA patients. Currently, gene therapy for RPE65-LCA2 patients is a fact, and new similar emerging therapies will be soon available. Thus, the knowledge of genotype-phenotype is necessary for a better patient management.

Abstract

Dengue has emerged as an important arboviral disease with significant impact on the disease burden in population residing in tropical countries. Dengue is spread by the bite of Aedes mosquito. The virus seems to have some hepatotoxic effects. Affliction of liver in form of derangements in the liver function tests is common and may include mild elevations in serum bilirubin, elevated transaminases and derangements in serum albumin. Although asymptomatic in most cases, clinical manifestations like jaundice, and acute liver failure (ALF) may occasionally complicate the clinical picture. Indeed, dengue has been implicated as an important cause of ALF in endemic countries. The present review focuses on the hepatic manifestations and the pathogenesis of the liver injury in dengue.

Key words: Dengue; Liver; Viral hepatitis; Acute liver failure; Transaminases; Bilirubin

Core tip: Dengue is an important cause of febrile illness in the tropical countries. It may affect the liver but the hepatic involvement is usually asymptomatic. However it is recognized as an important cause of acute hepatic failure in endemic counties. Dengue must be considered as a differential in the evaluation of acute hepatic failure and as an acute precipitant in patients presenting with acute on chronic liver failure.

Samanta J, Sharma V. Dengue and its effects on liver. *World J Clin Cases* 2015; 3(2): 125-131 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i2/125.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i2.125

INTRODUCTION

Dengue or "break bone fever" has gradually evolved as one of the important causes of febrile illness in the tropical and subtropical region. Second only to malaria, dengue is a common mosquito-transmitted disease, and currently, it is the most common cause of arboviral disease globally. Around 2.5 billion people in 100 endemic countries are believed to be susceptible, so are the equally significant number of travelers to these tropical and subtropical regions[1,2]. Presenting with a wide range of severity, "severe" dengue (Group C) as categorized by World Health Organization (WHO) in 2009 includes the dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS)[3]. Despite the inadequate surveillance of cases from the underdeveloped tropical countries, the average number being reported per year has

increased drastically[1,4]. A host of factors including the relentless urbanization with poor hygiene, dilapidated health systems to increasing international travel fuel the spread of this disease geographically and increase the disease burden of tropics significantly[1,2].

This disease has been found to have profound effect on multiple organ systems, the commonest being the liver. Starting from asymptomatic elevated transaminase levels to acute liver failure (ALF), dengue has all the properties of a hepatic illness. In this paper we review, the pathogenesis, pathology, clinicobiochemical parameters and management of the effects of dengue on liver.

DENGUE VIRUS

Dengue virus (DENV) has 4 serotypes (DEN 1-4) and is a member of the Flaviviridae family and the genus Flavivirus[5]. Though initially DEN1 and DEN2 were found around Central America and Africa, and all 4 serotypes found in Southeast Asia, currently all the serotypes have diffused in all tropical and subtropical regions of the world[1,6]. The serotypes sharing a mere 65% of the genotype among each other produce a uniformly wide array of manifestations, with most of them being asymptomatic[2].

DENVs are transmitted *via* the species Aedes aegypti, and less commonly by Aedes albopictus. The Aedes aegypti mosquito with its anthropophilic nature is well adapted for urban thriving and frequently bites several times before completing oogenesis[3,7].

If during the 5 d period of human viremia, the mosquito feeds, it gets infected and the DENV migrates from insect mid-gut to the salivary glands. After 8-12 d of life cycle of DENV inside the mosquito, with optimum high temperatures, the mosquito becomes infective, and can bite and transmit the virus to another host[1,3]. High concentrations of virus are exhibited in mosquito cell cultures with persistent infection[8].

DENV is an RNA virus with a single-stranded positive-sense RNA acting as the genome. The virus has an envelope and is icosahedral in shape. The structural proteins encoded by the DENV are capsid, precursor membrane, and envelope [E]. The virus also encodes for seven non-structural (NS) proteins one of which (NS1) has found use as a diagnostic antigen in initial phases of the disease. The E glycoprotein plays a crucial role in the biology of the DENV, starting from receptor binding to immune response[1,9].

Endocytosis of virus occurs after binding mediated by various molecules including glycoproteins like heparin sulfates as also dendritic cell-specific intercellular adhesion molecule-3-grabbing non-integrin, and a carbohydrate recognizing mannose receptor[10,11]. Upon internalization, the acidic pH induces change in the classically described "herring-bone" pattern of E glycoprotein. The uncoating and release of the genome occurs once the nucleocapsid is exocytosed into the cytoplasm[12].

CASE DEFINITION

Before going into the various hepatic manifestations of dengue, the evolution of dengue case definition will be briefly discussed. Dengue has been traditionally classified into dengue fever (DF), DHF and DSS (WHO 1997 Classification)[13,14].

DF: Fever and at least two features: ocular pain, headache, muscle or joint pains, cutaneous rash, bleeding manifestations and reduced leukocyte count.

DHF: Fever, thrombocytopenia ($\leqslant 100 \times 10^9$/L), bleeding manifestations and evidence of plasma leakage.

DSS: DHF with tachycardia or low pulse pressure (< 20 mmHg) or hypotension (systolic blood pressure < 90 mmHg).

The modified categorization of WHO in 2009 includes dengue with or without warning signs or severe dengue[3].

Dengue: Fever and two of these: nausea, vomiting, skin rash, bodyache, leukopenia, or any warning sign.

Warning signs include pain in the abdominal or presence of tenderness, persistent vomiting, clinical evidence of fluid accumulation like effusions and ascites, bleeding, lassitude or restiveness, liver enlargement, or rise in hematocrit ($\geqslant$ 20%) with rapid reduction in thrombocyte count (< 50000/mm^3).

Severe dengue: Evidence of severe plasma leakage, bleeding and organ impairment. Organ impairment includes hepatic involvement in form of transaminases elevated beyond 1000 IU/L and central nervous system manifestations like alteration in sensorium or cardiac or other organ involvement.

In spite of the recent categorization, the majority of the studies widely use the more popular DF, DHF and DSS classification for case definition.

DENV INFECTION AND LIVER

With DENV infection, high level of viremia is associated with involvement of different organs (liver, brain) in the severe form of the disease[15]. The liver is the commonest organ to be involved in dengue. Hepatic manifestations are either a result of direct viral toxicity or dysregulated immunologic injury in response to the virus. The spectrum of involvement includes asymptomatic elevation of hepatic transaminases to occurrence of severe manifestation in form of ALF.

PATHOGENESIS OF LIVER INJURY

Hepatic dysfunction is a crucial feature seen in DENV

infection. Hepatocytes and Kupffer cells are prime targets for DENV infection[16-18], as confirmed in biopsies and autopsies of fatal cases[19]. For infecting cells, the major rate limiting step is the viral attachment to the receptors present on surface of host cell. The E protein has a role in the attachment of the virus[20], although the nature of the receptor used is yet to be determined[18]. Heparan Sulphate plays a pivotal role for the intrusion of the DENVs into liver (HepG2) cells[21]. A cell to be infected by a virus requires essentially viral entry and a conducive environment for the invader to grow inside the host cell and this property is influenced by viral serotype, strain and cell type. For example, the G_2 phase cells are more prone to infectivity and enhance virus replication[22]. It has been postulated that the binding of DENVs onto hepatocytes is facilitatory, one binding promotes the binding of successive particles, similar to binding of oxygen on hemoglobin. After binding of the virus, internalization is by either direct fusion or endocytosis. The entry pathway may either be mediated through the presence of receptors or even in their absence[18].

An eventual outcome of hepatocyte infection by DENV is cellular apoptosis, a phenomenon demonstrated both *in vivo* and *in vitro*[23]. After apoptosis, what stays of the cells are the Councilman Bodies[19]. The various pathways involved in this apoptotic process include viral cytopathy, hypoxic mitochondrial dysfunction, the immune response[17] and accelerated endoplasmic reticular stress. Expression of DENV-induced TRAIL[24] and TNF-α and Fas signaling[25] have also been implicated in this process. Activation of the mitochondrial cell death pathway stems from the functional and morphological defects of these mitochondria[26].

Enhancement of immune reaction due to recurrent infections is believed to be responsible for causation of severe dengue disease. DHF and DSS occur as a consequence of several factors interacting, involving the microbial and host features, with antibody-dependent enhancement which explains the phenomena of more severe disease on second infection[27]. Dengue infection induces a cytokine storm and concentrations of cytokines like interleukin (IL)-2, IL-6, tumor necrosis factor (TNF)-α, and interferon (IFN)-γ reach peak levels in the initial 3 d. IL-4, IL-5 and IL-10 contribute to later in the course of disease[28]. Currently, the exact mechanism by which the host immunity damages liver is unknown, albeit a role of T cells entering the liver causing cytopathology cannot be ruled out. Thus, pathogenesis of hepatic injury in dengue is believed to be primarily a T cell mediated process involving interaction between antibodies and the endothelium and a concomitant cytokine storm often labeled as cytokine "Tsunami," and host factors like genetic polymorphisms.

PATHOLOGY

A wide spectrum of hepatic histological changes have been noted in dengue. This comprises fatty change (micro vesicular), hepatocyte necrosis, hyperplasia and destruction of Kupffer cells, Councilman Bodies and mononuclear cell infiltrates at the portal tract[29,30]. Hepatocyte injury including necrotic changes commonly involves the midzonal area followed by the centrilobular area. Probable explanation for such a finding could be that the liver cells in this area are more sensitive to the effects of anoxia or immune response or may be a preferential target zone of the DENVs. A recent autopsy series of dengue patients from Myanmar[31] showed varying degrees of damage in the liver, with majority of subjects having sinusoidal congestion of moderate to severe degree with predominant midzonal and centrilobular area cell death. Diffuse fatty change was noted within the hepatic lobules. The investigators noted no evidence of any significant fibrosis[31].

CLINICOBIOCHEMICAL PROFILE OF HEPATIC INVOLVEMENT

Clinical features suggesting dengue related hepatic involvement are the presence of liver enlargement and elevated transaminases[32].

Among the clinical features of hepatic involvement, patients have abdominal pain (18%-63%), nausea/vomiting (49%-58%) and anorexia[33,34]. Symptoms such as abdominal pain and anorexia have been found to be significantly more common in DF than DHF[35]. Hepatomegaly is present in both DF and DHF but more common in DF[35]. The frequency of hepatomegaly in the adult dengue patients ranges from 4%-52%[34-36]. Clinical jaundice has been detected in 1.7%-17% in various series[33,35,36] and hyperbilirubinemia has been found to be as high as 48%[34].

The commonest abnormality detected has been raised transaminase levels (Table 1). Raised AST levels have been seen in 63%-97% of patients, while raised ALT levels in 45%-96% of patients. In a majority of the studies, elevation in AST is more than ALT, more during the first week of infection, with a tendency to decrease to normal levels within three weeks[37]. The AST released from damaged myocytes could explain the higher levels of AST than those of ALT in patients with dengue fever at an earlier stage[38]. The increased AST/ALT ratio is useful for differential diagnosis from acute hepatitis caused by the hepatitis A, B or C viruses where it is rarely observed.

The average levels of AST ranged from 93.3 U/L[39] to 174 U/L[33], while ALT from 86 U/L[39] to 88.5 U/L[33] in various studies. More than a 10-fold rise

Table 1 Liver function abnormalities in dengue patients

Ref.	Patients	Raised AST	Raised ALT	AST > ALT	Hyper-bilirubinemia	> 10 fold rise (AST, ALT)
Kuo *et al*[37]	270	93.30%	82.20%	+	7.20%	11.1%, 7.4%
Souza *et al*[39]	1585	63.40%	45%	+	-	3.4%, 1.8%
Itha *et al*[41]	45	96%	96%	Equal	30%	-
Wong *et al*[40]	127	90.60%	71.70%	+ in 75.6%	13.4%	10.2%, 9.5%

Saha *et al*[35]	1226				16.9%	

AST: Aspartate transaminase; ALT: Alanine transaminase.

has been seen in 3.8% cases in a large study from Brazil[39], whereas in other studies were between 1.8% and 11.1% of cases[34,40]. Severe hepatitis was present in 15% in one study[33], while in another study it was 1%[41]. The level of increase in hepatic transaminases can easily mimic acute viral hepatitis.

The median Aspartate transaminase (AST) and Alanine transaminase (ALT) values have been found to be higher for severer forms of dengue than for uncomplicated dengue fever[14,35,39,42]. This hints at a possible association between increased transaminase levels with increasing disease severity. Interestingly the values of liver enzymes were noted to be higher in the febrile and the severer phases of dengue vis-à-vis the convalescent phase[14].

AST has various sources including the heart, striated muscle, erythrocytes, *etc*., apart from the liver, whilst ALT primarily is hepatic in origin[14,43]. Acute insult to these non-hepatic tissues by the DENV can result in higher elevations of AST when compared to ALT rise. Therefore, rise in AST might not be a true reflection of hepatic involvement. Moreover, patients with high levels of enzymes may be labeled as severe disease without any effect on the final outcome.

Liver damage has been found to be more common among females in the large study from Brazil[39] (74.6% of females compared to 52.2% of males) with 4.2% of them having acute hepatitis. However, no significant difference could be elicited between males and females as far as the level of transaminase elevation was concerned.

Hypoproteinemia or hypoalbuminemia have been seen in 12.9% in one of the large studies from Kolkata, India[35], while it ranges from 16.5%-76% in various other studies[34,40,41]. The heterogeneity in the population and severity of the disease may be responsible for such a wide range observed in the various studies.

Coagulation abnormalities have been found in multiple studies. International normalized ratio (INR) > 1.5 have been found in 11% of patients in one study[35], while abnormal prothrombin time (PT), partial thromboplastin time noted in 34%-42.5% of the cases in other studies[34,40]. Increasing bleeding episodes have been found with increasing AST/ALT levels[33,37], but only a weak correlation could be demonstrated between PT and transaminase levels during the convalescent period, suggesting that liver synthetic function in terms of coagulation factor production was generally well compensated.

Dengue has a slightly different profile of hepatic involvement among children (Table 2). They have been found to have a higher percentage of liver enlargement as compared to adults.

Various factors which predict liver damage are DHF, secondary infection, thrombocytopenia, high blood concentration, female sex and children[39,40,44].

DENGUE AND LIVER FAILURE

The liver injury in dengue, as already mentioned, ranges from asymptomatic hepatic transaminase elevation to fatal ALF. Dengue related ALF has been well described in the literature, although the majority of reports are amongst children with few case reports in adults[32,49-55]. Although viral hepatitis and drugs are the predominant cause of ALF, infectious diseases such as dengue are being more and more recognized as an etiological agent.

In a study from Thailand, Poovorawan *et al*[56] found dengue to be a major cause of ALF among children, with 12 out of 35 children (34%) aged 1-15 years of age, enrolled between February 2000 to December 2001, having positive dengue serology. In a further extension, the same group enrolled 14 children of ALF from June 2002 to December 2006, in a recent study and found 2 of them to be due to dengue[57]. Jagadishkumar *et al*[46] have reported 5 (18.5%) confirmed dengue cases in a study cohort of 27 children with ALF from Northern India. The presentation can be varied, either classical presentation of dengue with hepatitis and shock syndrome or there may be less classical dengue characteristics[46]

Deepak *et al*[58] in a study from Mumbai, India, have found 5 cases of dengue associated ALF out of a total of 56 cases (8.9%) of ALF, while Tan *et al*[59] from Malaysia showed 8 out of 155 adult ALF cases (5.2%)

Table 2 Liver function abnormalities among children with dengue

Ref.	Patients (*n*)	Raised AST/ALT	Hepatomegaly	Jaundice	Hypoalbuminemia
Pires Neto Rda *et al*[45]	32	96%	37.50%	-	77%
Mohan *et al*[44]	61	87%	74%	25%	-
Jagadishkumar *et al*[46]	110	-	79%	4.50%	66%
Kulkarni *et al*[47]	948	90%	36.70%	0.95%	-
Roy *et al*[48]	120	94%	80.80%	60%	-

AST: Aspartate transaminase; ALT: Alanine transaminase.

to have dengue. Adult dengue patients developed ALF at a median of 7.5 d (5 to 13 d) after the inception of fever. Occasionally, ALF may in patients who seem to be recovering from dengue[59]. Dengue can mimic ALF and needs to be considered in differential diagnosis of acute liver failure and cerebral malaria in endemic areas[60]. Occasionally, dengue has been reported to cause ALF in patients with underlying liver disease including a HBV carrier[61].

After a period of 3-7 d incubation, the natural course runs in form of fever lasting for 2-7 d, and subsequently a critical phase may occur during defervescence starting from 3-7 d of the illness when plasma leakage dominates the clinical picture[59]. Those surviving this phase of plasma leakage would eventually recover[3,62]. More severe disease is associated with higher viral load[63].

ALF due to paracetamol (PCM) overdose may be due to either a single large overdose or cumulative, multiple overdoses. The latter has been increasingly being recognized as an important cause of ALF due to PCM overdose. Mild to moderate hepatitis is well known in dengue. However there have been ample evidences, obtained both *in vitro* and *in vivo*, that the metabolism of PCM is reduced in patients with hepatitis [64,65]. Moreover, WHO guidelines discourages the use of other nonsteroidal antiinflammatory drugs, such as ibuprofen or antipyretics, in DF[3].

Interestingly, dengue has also been implicated as the cause of worsening of chronic liver disease, *i.e.*, being the acute component of acute on chronic liver failure (ACLF)[61,66,67]. Therefore in endemic areas one should be aware of dengue as a possible cause of ACLF.

Dengue pathogenesis as outlined earlier is not fully understood and is multi factorial ranging from direct viral injury, dysregulated immune response to hypoxic/ischemic injury and even secondary to drugs such as PCM used commonly for such symptoms. Mortality data are comparable with other causes of ALF, although adults have been reported to have a slightly better prognosis as compared to children, in whom it is 50%-66%[68].

In the management of patients with dengue with ALF, besides supportive measures specific measures have also been tried with success. There have been reports of use of N-acetyl cysteine (NAC) in various case series; use of NAC by Senanayake *et al*[69] from Sri Lanka on seven children and Lim *et al*[70] from Singapore on a single child showed clinical improvement. Kumarasena *et al*[71] used NAC on 8 adult patients, 5 of which having grade I-II hepatic encephalopathy and recovered completely while the remaining 3 with higher grades of encephalopathy (grades Ⅲ and Ⅳ) died. Use of molecular adsorbent recirculating system (MARS) has also been[51] reported in dengue associated ALF. Liver transplantation becomes a difficult proposition in lieu of hemodynamic compromise, bleeding, and organ impairment seen during dengue infection.

CONCLUSION

Dengue has a wide spectrum of manifestations. The effects on liver are usually asymptomatic but can be atypical and have varied severity. From asymptomatic elevated transaminase levels to fulminant hepatic failure, the variable manifestations are a big challenge to the clinicians treating the condition. Hepatic involvement is more common and more severe in children as compared to adults. Management is primarily supportive and the outcome is usually good. Care must be taken regarding the diagnosis and use of drugs which may worsen the liver damage.

Abstract

The role of third molars in the oral cavity has been extensively studied over the years. Literature includes numerous diagnostic and treatment alternatives regarding the third molars. However, an issue that has not been discussed at the same level is their involvement in orthodontic therapy. The aim of this study is to present a review of the contemporary literature regarding the most broadly discussed aspects of the multifactorial role of third molars in orthodontics and which are of general dental interest too.

Key words: Crowding; Extraction; Eruption; Third molar; Orthodontics; Impaction

Core tip: There are multiple factors associated with the eruption or impaction of third molars. According to the existing literature, orthodontic extraction treatment is not directly associated with the eruption of third molars, but might have a positive effect on their position and angulation. There is currently no reliable research evidence supporting the prophylactic removal of non-pathological impacted third molars for the prevention or relief of mandibular incisor crowding.

INTRODUCTION

The development of third molars and their interaction with the rest of the dentition has been of great concern to general dentists and dental specialists for a long time. Third molar is a tooth characterized by variability in the time of its formation and calcification, its crown and root morphology, its course of eruption and final position, presence or absence in the oral cavity[1,2]. Third molars start appearing on radiographs as early as the age of 5 years and as late as the age of 16 years, usually erupting in the oral cavity between the ages of 18 and 24[3] and they present the highest rate of impaction[4,5].

Although, in the majority of cases, third molars are not directly involved in orthodontic treatment, the fact that, in some cases, they can influence the latter or be influenced it, dictates their direct involvement in treatment planning.

The main issues, concerning the third molars that are related to orthodontic treatment and have been most extensively reported throughout the literature are: the possibility of their eruption or impaction in relation to genetically predetermined factors, the possible repercussion of orthodontic treatment extractions in their position and their influence in orthodontic post-treatment mandibular incisor relapse. These are the topics that are going to be presented and discussed in the herein review.

For the purpose of this study, an extensive online search of PubMed database was conducted. The main focus of the investigation was on original research articles in English. No chronological or other limits were applied.

FACTORS INFLUENCING THE ERUPTION OR IMPACTION OF THIRD MOLARS

The possibility of eruption of third molars is of important consideration in treatment planning and in the long-term maintenance of the dentition and, therefore, of particular interest to dentists and orthodontists[6].

The presence or absence of third molars from the oral cavity has been related to genetically predetermined skeletal and/or dental factors. As early as 1936, Bowdler *et al*[7] suggested that the individual growth pattern is an important factor for the eruption of the third molar. Broadbent[8] believed that the inability of the mandible to achieve its full growth potential may be contributing to the impaction of third molar, whereas, according to Begg[9], the impaction of third molars is attributed to insufficient forward movement of the teeth of modern man due to the lack of interproximal attrition that was observed in ancient skulls.

Björk *et al*[10], in an early study, reported that in 90% of third molar impaction cases the retromolar area space was limited. A few years later, in a longitudinal cephalometric study[11] of 243 cases with the use of implants, he identified two skeletal and two dental factors that were linked with the impaction of mandibular third molars. These factors were: a vertical direction of condylar growth, a reduced mandibular length, a backward-directed eruption of the mandibular dentition and a retarded maturation of the third molars. However, in the same study, it is also stated that, depending on the case, these three factors "may either amplify or neutralize each other".

Ricketts *et al*[12], used longitudinal records in an attempt to predict the amount of mandibular growth and to estimate the amount of space for forward and upward development of the molars. He concluded in that, in order the third molar to have a 50% chance of erupting, 50% of the crown must lie ahead of the external ridge. In a previous study[13], he had also claimed that the direction of tooth eruption plays a critical role in the impaction of third molars.

Kaplan[14] also agreed that cases with impacted third molars exhibit a larger angle of mandibular growth compared with cases with erupted third molars. The distance from Xi cephalometric point to the distal surface of the second permanent molar, was used by Schulhof[15], in an attempt for a computerized prediction of third molar impaction. When this length decreased below 25 mm impaction became more likely and, conversely, less likely as the length increased towards 30 mm. However, this method of prediction presupposes impaction being solely related to available space.

Richardson[16], in a longitudinal study of a group of 95 subjects observed that skeletal Class Ⅱ cases, with a shorter in length, narrower in width and more acute angled mandible, were more prone in third molar impaction. There was also a reduced amount of mandibular growth in cases with impacted third molars, which also had a tendency, although non-significant, to be relatively larger in size. The developmental initial mesial angulation of third molars in relation to the mandibular plane was also increased in subjects with impacted third molars. Ades *et al*[17], after studying the data from cephalometric radiographs and study models from 97 patients, found no significant differences in mandibular growth between those who had impacted or fully erupted mandibular third molars.

Capelli[18], using a sample of 60 patients who had received orthodontic treatment, including the extraction of four premolars, stated that, according to his results, the impaction of third molars is associated with a vertical component of mandibular growth, high mesial inclination of the lower third molar crown in the ascending ramus and reduced mandibular length. Hattab[19], in a radiographic follow-up study of 36 students with an average age of 19.7 years, discovered that a significant proportion of mesially impacted mandibular third molars changed their angulation and became fully erupted by the time the individuals reached 24 years of age. Therefore, he concluded that the positional changes and the eruption of impacted mandibular third molars are two unpredictable phenomena.

Erdem *et al*[20] examined the data from lateral cephalograms, orthopantomograms, periapical radiographs and study models of 27 patients and came to the conclusion that impaction of lower third molar is an unpredictable event. However, they also stated as a conclusion that the chances of eruption for mandibular third molars are more increased in patients with a more vertical growth pattern in general and a vertical direction of condylar growth, with anterior rotation of the mandible. In addition, a greater mesial inclination of the impacted lower molars was also mentioned as a possibly contributing

factor in their occurrence of impaction.

Artun *et al*[21], in an attempt to identify risk factors for maxillary third molar impaction, examined the radiographs of 132 adolescent patients. According to the results of their analyses, the most predictive parameters of impaction were a mesial angulation and a distal angulation of more than 30 degrees of the maxillary third molars relative to the occlusal plane, a reduced retromolar space and a small mandibular plane/Sella-Nasion plane (MP/SN) angle. In a study published in the same year, Artun *et al*[22] retrospectively investigated the lateral cephalograms, panoramic and/or periapical radiographs and study models of 389 patients who had received orthodontic treatment with or without extractions. They concluded that mandibular third molars angulated more than 40 degrees mesially relative to the occlusal plane at the end of treatment may also be at increased risk of impaction.

Behbehani *et al*[23], in a retrospective radiographic study of 134 patients, concluded that increased mesial angulation of the third-molar buds and signs of pronounced forward mandibular growth rotation increase the risk of impaction. Eruption space and mandibular growth rotation were also indicated as the most predictive parameters of impaction. Breik *et al*[24], in the contrary, reported that subjects with horizontal facial growth pattern demonstrated two times lower incidence of third-molar impaction than subjects with vertical growth pattern. Legović *et al*[25], on the other hand, in the same year, had not found any significant differences between the position of lower third molars and type of facial growth.

Finally, Hassan[26], in a retrospective cephalometric study of 121 Saudi patients, concluded that third molar impaction is more likely to occur when the retromolar space is inadequate. The latter was attributed to different skeletal and dental features, including an increased width of the mandibular ramus and a backward rotation of the posterior teeth.

EFFECT OF PERMANENT TEETH EXTRACTIONS ON THIRD MOLARS

Orthodontic treatment, especially during the period of active growth, may significantly influence the development of the dentition. Third molars too, according to the existing literature, are affected by orthodontic therapy in various ways. One of them is the orthodontic extraction treatment, the effect of which on third molars has been broadly investigated. The teeth that are usually removed for orthodontic reasons are the premolars, the first and the second permanent molars, either bilaterally of unilaterally, depending on the individual treatment requirements.

When it comes to extraction therapy, Kaplan[14] was one of the first authors to suggest that premolar extractions increase the probability of third molar eruption. According to the same author, when eruption does not occur in extraction cases, an insignificant resorption of the anterior border of the ramus is probably responsible, which is associated with vertical growth type.

Williams *et al*[27], in a study examining the effect of different extraction sites on orthodontic incisor retraction in 260 cases of patients of the same age at (mean age 13 years), treated with the Begg technique, also investigated on the influence of extractions on third molar eruption. According to their results, the change in the rate of third molar eruption following premolar extractions was indifferent, in contrast with first molar extractions or a combination of first premolar and first molar extractions, which had a significantly positive impact.

Rindler[28], in his investigation, examined the data from the casts and lateral oblique radiographs of 78 patients between 10 and 15 years of age, with a Class II initial malocclusion and crowding in the lower arch. The patients were treated with different techniques and had both their second mandibular molars extracted at the same time with the initiation of root development of the third molars. In 21 cases no additional orthodontic treatment was involved and, in the rest of the cases, lower first molars were moved distally with the use of activators (9 cases) and fixed appliances (48 cases). As they reported in the summary of their study, the third molars successfully replaced the second molars in most cases (77%).

Haavikko *et al*[29], after the analysis of a set of 110 longitudinal orthopantomograms of patients with a mean age of 13.5 years at the start of treatment, 50 of which had had two lower premolar extractions, concluded that the possibility of lower third molar eruption increased only occasionally and that extraction treatment seamed to merely accelerate and not promote eruption. Gaumond[30] used a relatively smaller study group of 11 patients, with different types of malocclusion, which were treated with germectomy of their second molar buds, as soon as the germ of a respective third molar was visible on a radiograph. As he reported, 19 of the 22 third molars that were followed-up achieved "satisfactory of very satisfactory" positions with acceptable final angulations. Based on the outcomes of this study, the author's belief was that every case with mild or moderate mandibular crowding should be treated in this way, rather than with four premolar extractions.

Cavanaugh[31], in a clinical and radiographic evaluation of third molars after second molar extractions in 25 patients, all of which, except for 2, had had some kind of orthodontic treatment, suggested that third molars usually successfully erupt into the space provided by the removed second molars. Richardson[32] conducted a retrospective investigation

of the records (casts and sixty-degree cephalometric radiographs) of a group of 48 subjects that had had unilateral or bilateral mandibular first premolars extractions and of a control group with no mandibular extractions. She concluded that there was a significantly increased space for third molar eruption in the group of the extraction cases. She could still, though, not explain the fact that a number of third molars had become impacted in extraction cases.

Gooris *et al*[33] conducted a study using 95 sets of panoramic radiographs of patients, within an age range of 9 to 19 years, who had received orthodontic treatment involving second molar extractions and first molar distalization. Their measurements indicated that almost all erupted third molars presented with a mesial inclination. Staggers *et al*[34], in a retrospective study of panoramic radiographs from 78 orthodontically treated subjects, 33 of which had been treated with four premolar extractions, concluded that there was no relative considerable impact of the extractions on third molar angulation. All the patients used in the study had Class I skeletal and dental relationships, they were treated with straight-wire appliances and the age range was roughly 11-26 years for the extraction group and 11-17 for the non-extraction group.

Richardson *et al*[35] cooperated in a retrospective study regarding the evolution of third molars after second permanent molar extractions. In total, 63 sets of records (lateral cephalographs and study models) were selected, from patients that had bilateral or unilateral (8/63) second molar extractions. Twenty-three/sixty-three patients had acceptable initial occlusion and had not received additional orthodontic treatment. Based on the results of this study, the authors suggested that there was a tendency of mandibular third molars to autocorrect their bucco-lingual inclination subsequent to second molar extraction and that the earlier the developmental stage of a third molar is at the time of extraction the higher are the chances for their eruption.

Moffitt[36] evaluated a subgroup of 56 patients, 28 of which had unilateral maxillary second permanent molar extractions, clinically, radiographically and *via* their study models, regarding the effect of extractions in the third molar eruption and function. The results showed that after second molar extractions maxillary third molars erupted in most cases in acceptable positions and that their eruption was also accelerated in variable degrees. Orton-Gibbs *et al*[37] aimed to assess with their study the final position of third molars after the extraction of second molars, in a retrospective radiographic analysis of the records of 63 patients, with a mean age of 13 years and 3 mo and different initial types of malocclusion. According to the results of this study, both maxillary and mandibular third molars in most cases erupted in "good or acceptable" positions, based on "Richardson's score system"[35]. They also noted that the angulation of mandibular third molars improves further after the end of active treatment.

Elsey *et al*[3] conducted their own study with the objective to evaluate the influence of the extraction of mandibular premolars and subsequent orthodontic closure of the extraction spaces on the third molar development. A set of 30 consecutive patients' records with bilaterally impacted lower third molars and a history of lower premolar extraction treatment. A control group with lower premolar and third molar extractions was also used. Measurements were made on panoramic radiographs. Retrospective analysis of the collected data indicated a positive influence of lower premolar extraction on the position and inclination of impacted third molars.

Kim *et al*[38], in a retrospective study of the diagnostic records of 157 patients, 105 of which had four premolar extraction-treatment during their active growing stage of development, suggested that there was a clinically significant reduction in the impaction rate of both maxillary and mandibular third molars in these patients in comparison to the non-extraction group.

Janson *et al*[39], comparing the records of two groups of 55 patients in total, in their late adolescence, with and without maxillary premolar extractions, concluded that the number of erupted maxillary third molars was greater in the extraction group. He also claimed that the mesio-distal angulations of the un-erupted molars appeared relatively decreased and, therefore, more favorable to eruption.

De-la-Rosa-Gay *et al*[40] conducted a retrospective study based on data from panoramic radiographs, with the aim not only to assess third molar eruption after second molar extraction orthodontic treatment, but to identify the risk factors of unsuccessful eruptions too. Their sample included 48 patients, treated with fixed appliances (Ricketts or straight-wire techniques), with a median age of 14.8 years. The analysis of their results indicated that maxillary and most mandibular third molars successfully erupted and eventually obtained upright positions. Both late developmental stage of third molars and increased mesial inclination or lack of proximal contact in the beginning of treatment were identified as risk factors for an unsuccessful eruption.

Salehi *et al*[41], assessing the effect of first premolar extractions on third molar eruption, evaluated the clinical records of three groups of subjects: a group with first premolar extractions, a group with no extractions that had received orthodontic treatment and a control group with neither extractions nor orthodontic treatment. According to their results, there was a significant difference in the third molar eruption rates in the extraction (42%), non-extraction (12%) and control (20%) groups. These

findings indicate that first premolar extractions may increase the possibility of third molar eruption.

Jain *et al*[42], in a retrospective study that they conducted with the use of panoramic radiographs also investigated on the effect of first premolar extraction treatment. Their study sample consisted of 50 dental Class Ⅰ patients, between the ages of 11 and 19, half of which had received four first premolar extractions. In addition, no more than the 2/3 of the third molars had been formed in the initial radiographs and extraction spaces had been eliminated in the end of orthodontic treatment. The analysis of the collected data indicated a positive influence of first premolar extractions on the angulation of third molars.

Bayram *et al*[43] investigated the influence of orthodontic treatment involving four first molar extractions on the third molars. It was a retrospective study on panoramic radiographs from 41 patients, with a mean age of 16.6 years of age, 21 of which were treated with extraction of all four first permanent molars. No extraoral forces were used for the treatment of the above patients. According to their conclusions, first molar extractions may considerably increase the eruption space of third molars, whereas they normally have a more favorable effect on the angulation of the maxillary than of mandibular third molars. The main conclusion of this study was that the extraction of first permanent molars considerably reduces the frequency of third molar impactions.

Livas *et al*[44] used for their study lateral cephalometric radiographs from a group of 91 subjects, with a mean age of 13.2 years of age, treated with the orthodontic Begg technique and an initial Class Ⅱ Division 1 malocclusion. The subjects were divided in a group with first molar extractions and a control group with no extractions, which consisted of Class Ⅰ and Class Ⅱ cases. The findings of this study suggest that the position of third molars was significantly improved during orthodontic treatment involving the extraction of first molars.

Gohilot *et al*[45], almost two years ago, published an investigation regarding the impact of first premolar orthodontic extraction treatment on third molars. The study sample included 60 Indian patients, between 14-19 years of age, 30 of which had all first premolars extracted and the rest serving as a control non-extraction group. The root development of third molar roots did not exceed the 2/3 of its full length at the initial radiographs, all patients had been initially diagnosed with a skeletal and dental Class I malocclusion, which meant that they all had been high-anchorage cases during treatment and there were no extraction spaces in the end of treatment. Based on their results, they concluded that premolar extractions had a positive effect on maxillary third molar angulations, whereas they did not notice any difference in mandibular third molars' positions. They also suggest that borderline extraction cases with favorable third molar angulations could benefit by premolar extractions.

Türköz *et al*[46], comparing two groups of 22 non-growing patients, with and without first premolar extractions in a retrospective study, also revealed a positive influence of premolar extraction therapy in the size of retromolar space and a significantly lower impaction rate of third molars in the corresponding extraction group. Mihai *et al*[47] evaluated the panoramic radiographs of 20 initially Class I patients, who had received orthodontic treatment, with and without premolar extractions and the crowns of their third molars had already been formed in the beginning of treatment. The results of this study indicated the third molars with the most favorable positions, were the ones in the mandibles of the extraction group.

Al Kuwari *et al*[48] conducted a cross-sectional radiographic study, using 40 sets of patient records from a university clinic. Half of these patients were orthodontically treated with first premolar extractions. According to their results, orthodontic treatment premolars extraction treatment seems to have improved the angulation of impacted third molars in most cases. Finally, Halicioglu *et al*[49] recently published a large retrospective study of the panoramic radiographs of 294 patients, aged from 13 to 20 years, with at least one permanent first molar extraction. Among other conclusions, they report that the development of the third molars was significantly accelerated on the extraction sites of these patients.

THIRD MOLARS AND MANDIBULAR INCISOR CROWDING

The effect of third molar position and eruption stage on the rest of the dentition has also been the subject of many investigations and is also of great concern to the orthodontists. Especially the role of third molars in the development of a secondary mandibular incisor crowding has been an object of debate for many years.

As early as 1917 Dewey[50], examining the role of third molars in malocclusion, suggested that, in some cases, the mandibular third molars need to create space in the dental arch in order to erupt, causing crowding of the anterior teeth. Since then, numerous investigations have been conducted in an attempt to objectively identify a possible correlation between third molars and mandibular incisor crowding. Bergström *et al*[51] studied 60 subjects with unilateral molar agenesis and noted that there was greater crowding in the quadrants in where third molars were still present, than in those in which third molars they were absent. Vego[52] also found a greater percentage of dental crowding in subjects with erupting third molars in comparison to subjects with congenitally missing third molars.

Sheneman[53], in an investigation of 49 patients for a mean period of 66 mo, concluded that patients with congenitally missing third molars showed comparatively greater dental stability.

Woodside[54], on the other hand, suggested that in cases where mandibular third molars were not present, a more distal settling of the lower dentition occurred in response to growth and soft tissue pressure, implying a passive role for the third molar, which was acting as an obstacle to the settling of the dentition, rather than actively applying pressure to anteriorly positioned teeth.

Lindqvist *et al*[55], in their study, examined a group of 52 patients with bilateral third molar impactions. It was a "split mouth" design study, with extraction of the impacted molars on one side and use of the contralateral quadrant as a control side. Their data indicated the existence of less crowding on the extraction side, in 70% of the patients. Forsberg[56] conducted a study with the objective to identify the relationship between the eruption status of third molars and the relative space in the dental arches. Two groups of 75, in total, adult, non-orthodontic patients were used; one group with patients that had all third molars erupted and another group with all third molars missing due to extraction. The degree of crowding was found to be higher in the first group, although only with a small difference.

Southard *et al*[57] attempted to detect the presence of a mesial force exerted by the unerupted third molars on the rest of the dentition, by measuring and comparing proximal contact tightness before and after bilateral third molar extractions in 20 patients. The authors concluded that the removal of third molars for the relief of "interdental pressure" and, therefore, for the prevention of mandibular incisor crowding could not be supported by the results of their study. Pirttiniemi *et al*[58] examined the effect of impacted third molar extraction on the dental arches in patients with a mean age of 23.2 years. As it is stated in their conclusions, the results of this investigation could not justify the prophylactic removal of third molars, due to the absence of relative evidence regarding their association with undesirable changes in the dental arches.

van der Schoot *et al*[59] conducted an investigation with the aim to determine the relationship between dental crowding and the presence of third molars. Their sample included 99 orthodontically treated patients. According to their results the presence of third molars did not have a clinically significant relationship with the development of post-treatment crowding. Basdra *et al*[60], in an evaluation of 19 patients, who had been recalled in a university dental clinic and had had orthodontic Class Ⅱ treatment with bilateral or unilateral upper second molar extractions, reported that all third molars had erupted in very good positions.

Sidlauskas *et al*[61] investigated in their study the effect of lower third molars in lower incisor crowding, by studying the records (study models and panoramic radiographs) of 91 patients, who had not received orthodontic treatment before the collection of the records. The study group included patients with present, removed or genetically missing third molars. They concluded that the third molars in their study group were not responsible for any considerable difference in the development of lower anterior dental arch crowding. Hasegawa *et al*[62] studied a group of Mongolian subjects, with a mean age of 21 years, in order to evaluate the influence of third molars on lower anterior crowding. The analysis of their data did not reveal any significant relationship between the presence and angulation of mandibular third molars and lower incisor crowding.

Karasawa *et al*[63], in a cross sectional-study, aimed to reveal a correlation between the presence of third molars and mandibular incisor crowding in a large group of 300 subjects, with a mean age of 20.4 years. Their final results revealed no correlation between maxillary or mandibular third molars and the incisor crowding. Nevertheless, in patients that had had orthodontic treatment there was a small correlation, although this result did not reach statistical significance.

Costa *et al*[64] recently conducted a systematic review in order to investigate whether the prophylactic removal of third molars is justified as a treatment option. After filtering of the initial studies with the use of specific eligibility criteria, only 4 papers of medium (3) and low (1) quality and inadequate sample sizes eventually contributed in the analysis. As stated by the reviewers, the currently available data is inadequate for the formation of safe conclusions, which could be used in clinical treatment decisions. However, their results point towards the opinion that prophylactic third molar extraction is unjustifiable.

DISCUSSION

With regards to the possibility of third molar eruption, it seems that most investigators agree on the fact that there is a correlation between third molar impaction and certain skeletal characteristics[7-9,10,12-16,18,20-24,26], although not everyone shares the same opinion[17,19,25]. The common associated factor is the shortage of the available eruption space, due to distally directed eruption of the dentition and/or lack of adequate resorption of the anterior border of the mandibular ramus or compensatory periosteal bone apposition at the posterior outline of the maxillary tuberosity. Another factor that is linked with third molar impaction is the existence of a vertical facial growth pattern, with a vertical direction of condylar growth. Finally, increased third molar angulation is also considered to be significantly linked to third molar impactions.

Concerning the impact of extraction treatment,

the majority of investigators have reported a positive influence of the removal of teeth for orthodontic reasons on third molar position, angulation and/or eruption[3,14,27,28,30,31,33,35-48,60]. The improvement of the position and reduction of the inclination of third molars, although not directly associated with their eruption, seems to be considered as a very positive effect. Many authors also believe that orthodontic borderline extraction cases with favorable initial third molar angulations could benefit from extraction therapy[41,44,47]. In addition, even in the event of a possible future extraction of impacted third molars, a more upright position could facilitate the surgical procedure and minimize possible complications and post-operative complications[3,8,41].

However, it is important to note that there is a variety of confounding factors that could have affected the results of the above studies and were not co-evaluated in most cases, including the age of the patients, their ethnical background, the developmental stage of third molars at the time of the extractions, the initial types of malocclusion and the type of mechanics that were used for the needs of the orthodontic treatment.

Further, concerning the role of third molars in mandibular incisor crowding, it is very interesting to note the differences between the authors' beliefs and results before the after the 1990's. In the chronologically older studies[50-56] third molars seem to be more significantly associated with the occurrence of crowding in the lower arch. In contrast, more recent studies[57-59,61-64] tend to exculpate third molars and characterize their prophylactic extraction as unjustifiable. Nonetheless, both recently conducted systematic reviews on this matter, although clearly not in favor of prophylactic extractions, reported the insufficiency of high quality studies, required for the formation of secure conclusions.

The fact still is that, currently, there is no sound research evidence supporting the prophylactic removal of non-pathological impacted third molars. However, in cases where extraction is indicated, it is preferable third molars to be removed before adulthood in order to decrease the risk of complications[65].

Finally, other important clinical issues, including the impact of orthodontic first molar distalization on third molar position, the effect of third molar eruption stage on the efficiency of first molar distalization, the orthodontic force application on autotransplanted third molars, the orthodontic extraction of third molars in unfavorable positions or in close proximity to the inferior alveolar nerve and the decision of the extraction of third molars before orthognathic surgery, are also still under investigation and are, hopefully, going to be included in other reviews.

CONCLUSION

Despite the fact that the role of third molars has been a subject of research, clinical interest, discussion and dispute for so many years, there is still a lack of scientific evidence from high quality clinical studies on that matter. Several weaknesses have been pointed out, including the heterogeneity of data and the small size of the examined samples. However, the information collected from the studies presented in this review contributes to our knowledge and allows us to create a fuller picture regarding the issues that have been examined.

Abstract

The gold standard of peripheral nerve repair is nerve autograft when tensionless repair is not possible. Use of nerve autograft has several shortcomings, however. These include limited availability of donor tissue, sacrifice of a functional nerve, and possible neuroma formation. In order to address these deficiencies, researchers have developed a variety of biomaterials available for repair of peripheral nerve gaps. We review the clinical studies published in the English literature detailing outcomes and reconstructive options. Regardless of the material used or the type of nerve repaired, outcomes are generally similar to nerve autograft in gaps less than 3 cm. New biomaterials currently under preclinical evaluation may provide improvements in outcomes.

Key words: Plastic surgery; Reconstructive surgical procedures; Nerve tissue; Conduit; Scaffold

Core tip: Nerve autograft is the gold standard for peripheral nerve reconstruction with gap. However, shortcomings of autograft have led researchers to investigate various biomaterials to improve outcomes. Clinical studies of peripheral nerve reconstruction with conduit other than autograft show similar outcomes in gaps less than 3 cm.

INTRODUCTION

The gold standard of peripheral nerve repair is primary end-to-end coaptation of nerves. Unfortunately, this treatment is not always feasible in clinical situations. Avoidance of tension during repair is the ultimate goal to enhance potential nerve regeneration[1,2]. Prior studies have shown that injury tends to occur when nerves are stretched to greater than 10% of their original length. It may even initiate the process with stretching as little as 4%-6%[3,4]. Negative outcomes have been reported with tension greater than 25 g[5].

Most surgeons do not attempt primary closure when encountering gaps greater than 4 mm[6]. Tensionless closure is paramount to satisfactory clinical outcomes in nerve repair.

Primary treatment for repair of a nerve gap is autologous nerve grafting[7,8]. However, limited availability of donor tissue, sacrifice of a functional nerve, and possible neuroma formation make this option less than ideal[9-11]. Gluck[12] first reported use of a nerve guide in 1880, bridging with a segment of decalcified bone. Other early attempts were equally unsuccessful. In order to overcome these shortcomings, researchers and surgeons continued to improve nerve repair methods. The ideal conduit must be readily available, biocompatible, size matched to the nerve stumps, prevent axonal escape, and prevents ingress of fibroblasts and inflammatory cells. Simultaneously it should allow growth and chemotactic factors to positively influence axonal growth. Also it should prevent compression and injury to the nerve once healed. The conduit should be flexible, yet resilient enough to resist collapse[13]. Currently, such a conduit remains unavailable. Ongoing studies continue to improve the qualities of available biomaterials. Our goal is to present a survey of clinical studies published in the English literature detailing outcomes and reconstructive options.

REGENERATION BY CONDUIT

Williams *et al*[14] demonstrated the basic steps of nerve regeneration with an inert silicone conduit. In the immediate postoperative period, a fluid containing proteins, clotting factors and growth factors fills within the conduit. By 1 wk, a longitudinally oriented fibrin matrix develops. In the second week, fibroblasts, Schwann cells, macrophages, and endothelial cells enter the matrix. At the same time, axons from the proximal nerve cone extend forward. By four weeks the nerve cone has extended about 10 mm.

MATERIALS

Silicone

Silicone is a non-resorbable, nonporous, biologically inert material. Silicone in medical devices and implants are clinically ubiquitous. Since silicone is non-resorbable, presence of conduit material can lead to compression and decreased axonal conduction[15-17]. For this reason, the tubing is frequently removed[18]. With the advent of resorbable synthetic grafts and processed allografts, clinical utilization of silicone conduits have declined.

Lundborg *et al*[19] first reported in a prospective randomized study the clinical use of silicone tubes in peripheral nerve reconstruction. He reconstructed median nerve gaps of 3 to 5 mm. He then compared silicone conduit to standard repair. He found no differences in motor function. Patients experienced improved sensory recovery within the silicone group. Braga-Silva[20] reported a case series of 26 patients with median, ulnar, or median and ulnar nerve injury. Patients presented with a nerve gap ranging from 2.5 to 5.5 cm. While motor scores for each patient were not published, size of the nerve gap negatively correlated with motor function outcomes.

Expanded polytetrafluoroethylene

Expanded polytetrafluoroethylene (ePTFE) is another nonresorbable, biologically inert material. It is commercially available as Gore-Tex (W.L. Gore and Assoc., Flagstaff, AZ). Like silicone, reports of ePTFE have declined over the years.

Stanec *et al*[21] first reported clinical use of ePTFE in 43 patients exhibiting median and ulnar nerve gaps ranging from 1.5 to 6 cm. Patients with smaller gaps (up to 4 cm) had significantly improved outcomes *vs* larger gaps (78.6% *vs* 13.3% functional recovery).

Pogrel *et al*[22] utilized ePTFE conduits for reconstruction of lingual and inferior alveolar nerve (IAN) injuries in 5 patients. Patients with negative outcomes had nerve gaps greater than 1.0 cm. Pogrel *et al*[22] reported their series of 6 patients with lingual or IAN continuity defects greater than 1 cm. Mixed results were reported.

VEIN

Vein grafts are among the first non-neural biological conduits used for peripheral nerve Usually they are harvested from the dorsum of the hand during digital, median, or ulnar nerve repair. During the regeneration period, they were found to be at risk for kinking or collapse[23-25].

Wrede[26] recorded the first successful use of a vein graft. He repaired a median nerve defect with a 45 mm graft. Platt[27] (1919) also described bridging nerve grafts with autogenous vein. It failed to produce functional return of the musculospiral nerve[27]. Gibb[28] reported a single case of functional restoration using a vein conduit to reconstruct a 1 cm facial nerve gap. It was not until several animal studies demonstrated efficacy that further clinical studies were explored[29,30]. Walton *et al*[25] reported return to normal two point discrimination (2PD; less than 4 mm) in 50% of patients undergoing repair of digital nerves. Nerve gaps ranged from 1 to 3 cm. Poor outcomes were associated with larger gaps. In 1990, Chiu *et al*[24] reported a series of 15 repairs on patients receiving vein grafts for "nonessential" peripheral nerve gaps up to 3 cm. After an average follow-up of 27 mo, the cohort receiving vein graft repair had similar outcomes to autologous nerve graft. However it was inferior to direct repair cohort. Tang *et al*[23] reported 61% good or excellent outcomes in 15 patients undergoing digital nerve repair, with

gaps ranging 0.5 to 5.8 cm[23]. Patients generally had favorable outcomes when gaps were less than 3 cm, thereby corroborating the results from Chiu *et al*[29]. Two years later, Tang published outcomes in median and radial nerve vein grafts. In this study, he inserted nerve fragments from the proximal nerve stump into the vein lumen. His data suggested positive outcomes could be achieved with this technique for gaps up to 4.5 cm[31].

Pogrel *et al*[32] reported a series of 16 patients treated for lingual or IAN nerve defects, ranging from 2 to 14 mm. Using saphenous vein or facial vein, he found that negative outcomes were associated with gaps greater than 5 mm. The author discussed that nerves of trigeminal origin have had poorer outcomes versus other peripheral nerves. It is likely the cause of difficulty in repair of such small gaps (see below).

COLLAGEN

Collagen is a naturally occurring, resorbable structural protein. Purified bovine collagen, the most common source for collagen conduits, has low immunogenicity. Resorption rate can be controlled by the degree of crosslinking induced during preparation. Depending on fabrication method, degradation occurs from 1 to 48 mo[33,34]. Furthermore, preclinical studies have demonstrated that collagen conduits enhance growth and differentiation of many cell types. It is flexible yet durable. This increases its facility as a conduit material[35]. Finally, its permeability allows for diffusion of chemotactic and neurotrophic agents in the extracellular fluid. This type of conduit is commercially available under the name NeuraGen® (Integra LifeSciences, Plainsboro, NJ). Conduit sizes range from 1.5 to 7 mm diameter and are 2 or 3 cm long. Neuromatrix® and Neuroflex® (Collagen Matrix, Inc) are also Type I collagen conduits. No published studies are currently available evaluating its clinical efficacy.

In 2005, Taras *et al*[36] reported the use of commercially available type I bovine collagen in the repair of a variety of peripheral nerves[36]. A prospective series of 22 digital nerve repairs using NuraGen® achieved excellent or good sensory outcomes in 15 of 22 digits. They excluded nerve gaps greater than 20 mm[37].

Ashley *et al*[38] reported treatment of brachial plexus birth injuries with nerve gaps less than 2 cm using collagen conduits. Four of the five patients had favorable outcomes at 2 years postoperative. Lohmeyer *et al*[39] reported a case series of 6 patients undergoing repair of nerve gaps in digital and palmar nerves up to 18 mm. Two-thirds of the patients had excellent 2PD at 12 mo postoperative. They extended follow-up with nine of twelve patients achieving excellent or good sensory scores at 12 mo follow up[40]. Bushnell *et al*[41] reported a series of 12 patients undergoing digital nerve repair for gaps ranging from 1 to 2 cm. Most (88%) had good or excellent 2PD after at least 1 year. In a larger study of 126 nerve injuries in 96 patients, Wangensteen *et al*[42] reported their experience using NeuraGen®. Mean nerve gap was 12.8 (range 2.5 to 20 mm). Overall, nerve function recovery was only 43%. A variety of nerves were repaired, and seven surgeons were involved in the study. Haug *et al*[43] added 45 digital nerve repairs with type Ⅰ collagen to the body of literature. Mean defect was 12 mm (range 5 to 26 mm). All sensory measures improved over 3-, 6-, and 12-mo follow-up interval.

Farole *et al*[44] reported their experience with the NeuraGen® conduit for challenging lingual and IAN repair. In their study, all patients underwent neurolysis with or without resection of neuroma (if present) and placement of the collagen conduit as a "cuff" over coapted nerve ends. They chose this technique to prevent axonal escape, minimize scar ingrowth and nerve entrapment, and to concentrate growth factors at the repair site. Eight of nine patients had improvement after at least one year.

Kuffler *et al*[45] reported a single case of ulnar nerve reconstruction after 3 years. Nerve gap was 12 cm. Using a sheet of collagen, they fashioned a custom-sized conduit. Then they filled it with autologous platelet-rich fibrin. By three months, the patient experienced improvement in neuropathic pain. By 2 years the patient no longer required analgesics. Within 1.5 years, the patient had 4 mm 2PD. Motor function had returned by 2 years. This study showed promising results in the reconstruction of large caliber, mixed function peripheral nerves using collagen conduits. Dienstknecht *et al*[46] recently published a series of 9 patients undergoing median nerve repair. All gaps were 1 to 2 cm long and repaired within 24 h of injury. Average return to work was 8 wk (range 1 to 17). Motor, sensory, pain, and disability scores were satisfactory in 8 of the 9 enrolled patients.

DECELLULARIZED NERVE ALLOGRAFT

Nerve allograft is an alternative to nerve autograft for repair of gaps, but requires the additional administration of immunosuppression for 18 mo. Using a decellularized nerve allograft preserves the three-dimensional collagen scaffolding of a nerve while avoiding immunosuppression[47]. This scaffolding promotes cell migration, nerve fiber elongation, and diffusion of growth factors[48,49]. Laminin, also present, facilitates axonal outgrowth[50]. Human decelullarized nerve is commercially available as Avance® (AxoGen, Inc, Alachua, FL). Available grafts encompass lengths ranging 15 to 70 mm and diameters between 1 and 5 mm.

Karabekmez *et al*[51] were the first to publish clinical data on Avance®. Ten digital nerve repairs were included in the study. Gap length ranged from 0.5 to 3 cm. After an average follow-up of

nearly 9 mo, static 2PD was 5.50 mm and moving 2PD was 4.4 mm. Brooks *et al*[52] then reported a multicenter prospective study with Avance®. These authors examined repair of sensory, motor, and mixed nerves. Of the patients that met follow-up requirements, acceptable outcomes were achieved in every group. Sensory, mixed, and motor nerves recovered at 88.6%, 77%, and 85.7%, respectively. With regards to nerve gap length, short (5 to 14 mm) recovered at 100%, medium (15 to 29 mm) recovered at 76.2%, and long (30 to 50 mm) recovered at 90.9% (mean follow up 265-279 d). Meaningful recovery was defined as S3-4 or M3-5 on the Medical Research Council Classification. Guo *et al*[53] supplemented previous digital nerve repair data with their own case series. Their five patients had a mean nerve gap of 22.8 mm and a mean follow up of 13.2 mo. At the time of final follow up, static 2PD averaged 6 mm and monofilament test ranged positive for monofilaments 4.31 to 4.56. Recently, Taras *et al*[54] reported 18 digital nerve gap repairs treated with processed allograft[54]. Average gap length was 11 mm (range 5 to 30 mm). Overall, 83% of patients had good or excellent results.

Shanti *et al*[55] reported a single case using Avance® for repair of an iatrogenic IAN injury. They did not record the length of the nerve gap. However, they did report improvements in sensory testing at 5 mo postoperative.

POLYGLYCOLIC ACID

Polyglycolic acid (PGA) is a bioabsorbable substance initially used for suture material or mesh[56,57]. Mean resorption time is 90 d[58]. Typically it appears as a tight-weave mesh rolled tube. Its pores are small enough to permit nutrients while impeding invasion by fibroblasts[59]. A tube of PGA is more expensive than suture material used in standard nerve repair[59]. Additionally, PGA is at risk for extrusion prior to complete resorption[59]. PGA is commercially available as Neurotube® (Synovis Life Technologies, Inc.), which has an internal diameter of 2.3, 4, or 8 mm and 2 or 4 cm length.

Initial clinical use of PGA was by Mackinnon *et al*[60] in 1990. Repairing nerve gaps ranging from 0.5 to 3.0 cm, they were able to achieve excellent or good 2PD in 86% of the 15 patients undergoing reconstruction. Weber *et al*[59] (2000) reported his randomized prospective study of 136 nerve injuries treated with either autologous graft or PGA conduit. Although the mean gap length was greater in the PGA conduit group, there was no difference in either moving or static 2PD between the two groups. For either small (less than 4 mm) or large (greater than 8 mm) gaps, the PGA conduit group had better sensory outcomes. Kim *et al*[61] reported successful treatment of a plantar neuroma in an 11-year-old male using a PGA conduit to span a 2.0 cm defect. Pain from the neuroma resolved. Normal sensation returned by 8 mo. In 2005, Navissano *et al*[62] reported their case series of seven patients treated with PGA conduits for traumatic facial nerve terminal branch injuries. Five of seven patients had good or excellent recovery of motor function compared to contralateral side. Nerve gap ranged from 1 to 3 cm.

Battiston *et al*[63] prospectively compared Neurotube® repair of digital nerves to patients treated with vein-muscle grafts. Even though nerve gaps were larger in the Neurotube® group, there were no significant differences in sensory outcomes between the two cohorts. Most (76.9%) of the muscle-vein group had very good results, as did 76.5% of the Neurotube group. Rinker *et al*[64] performed a similar study. They prospectively compared Neurotube repair ® to vein graft repair. PGA conduit group was similar to the vein conduit cohort, including length of nerve gap (9.1 mm mean *vs* 10.3 mm, respectively). There was no significant difference between the cohorts with regards to sensory outcomes. This was true for short (less than 10 mm) or long (greater than 10 mm) gaps.

Rosson *et al*[65] reported 6 cases of PGA used to repair motor nerves. One patient had accessory nerve injury. The remainder had median or ulnar nerve injuries. Nerve gaps ranged from 1.5 to 4 cm (mean 2.8). Follow up ranged from 4 mo to 5.5 years. All patients achieved significant improvement in motor function (rated M3 or greater).

PGA-COLLAGEN

PGA-collagen conduits are composed of a PGA tube coated with 1% amorphous collagen solution. It is then filled with collagen sponge[66]. Fibers usually undergo crosslinking to prevent rapid resorption. To date, this construct is not yet commercially available. Japan was the site of clinical studies of PGA-collagen[67]. Initially it was initially used for reconstruction of intrapelvic nerves damaged during rectal cancer extirpation. Clinical improvement in the patient prompted continued use of the conduit.

In 2004, Nakamura *et al*[67] reported 2 cases using PGA-collagen conduits. The first patient had a 20 mm digital nerve gap. Following treatment, function within normal range by 4 mo. The second patient had a 65 mm superficial peroneal nerve defect with normal sensation by 3 mo. The same group later reported their experience with treatment of Complex Regional Pain Syndrome type Ⅱ[68]. In the two case reports, they described successful resolution of an otherwise challenging clinical entity. It tends to follow a vicious cycle of relapsing pain due to nerve sprouting after injury or resection. The authors theorized that placing the cut ends into the conduit would prevent nerve sprouting and guide the nerve cone to the distal stump. In 2007, Inada *et al*[69] also reported their experience with repair of a frontal branch of the

facial nerve using the same type of conduit, bridging gaps measuring 11 to 30 mm[69]. In both patients, functional recovery was noted by 5 mo. Recently, they also reported chorda tympani nerve reconstruction using their PGA-collagen construct[70]. Average nerve gap was 7 mm among the three patients studied. Electrogustometry measurements returned to normal limits by two weeks postoperative. Dysgeusia resolved between 2 wk to 3 mo.

POLY (DL-LACTIDE-ε-CAPROLACTONE)

Poly (DL-Lactide-ε-Caprolactone) (PLC) is another synthetic bioabsorbable material. Degradation occurs at 1 year. Initial constructs had thicker walls that caused swelling. This negatively impacted nerve healing. Thinner-walled tubes tended to collapse[71]. Increasing the lactide content to 65% reduced the amount of swelling, but lost mechanical strength after 10 wk of implantation[72]. Clinically available PLC may be too rigid for small needles, requiring some softening in water before use[71]. PLC is also transparent, facilitating placement of nerve stumps. It is commercially available by the name of Neurolac® (Polyganics BV, Groningen, Netherlands). They offer 1.5 to 10 mm inner diameters and a length of 3 cm.

After publishing initial clinical studies in 2003, Bertleff *et al*[73] published their follow up findings from a blinded, randomized multicenter trial comparing standard treatment to PLC in repair of peripheral nerve defects of the hand in 54 patients. In treatment of nerve gaps less than 20 mm, they found no significant difference in sensory outcomes compared to controls. Follow up was 12 mo.

FUTURE DIRECTIONS

In addition to the above clinically-tested materials, there is a multitude of materials undergoing preclinical evaluation. These include non-mammalian biodegradable polymers, artificial biodegradable polymers manufactured with electrospinning, conducting polymers, and combinations of the above with Schwann-like neural stem cells and mesenchymal stem cells. Conduits seeded with stem cells, stem-like cells, or support cells theoretically improve nerve regeneration through delivery of growth factors and neurotropic factors into the conduit lumen. Several excellent reviews documenting these advances have been published. They are beyond the scope of the current discussion[74-80].

CONCLUSION

While preclinical studies are essential to bringing new technologies to reconstructive surgeons, further in depth clinical evaluation of materials is warranted. Almost all of the published studies consist of small case series. Outcomes measures are inconsistent from study to study. Furthermore, nerve type, cause of injury, and gap size are extremely variable, making comparison of repair materials and technique difficult. Nevertheless, the above studies suggest that small gaps up to 3 cm can be repaired with available conduits with outcomes similar to nerve autograft. Efficacy of bridging longer gaps with available conduits has yet to be demonstrated. Also, several roadblocks prevent developing technologies from becoming clinically available. Feasibility of stem cell harvest and cost of cutting-edge biomaterials are problematic. These will further delay human studies for these promising therapies.

Abstract

Coronary artery disease (CAD) remains the leading cause of death worldwide with approximately 1 in 30 patients with stable CAD experiencing death or acute myocardial infarction each year. The presence and extent of resultant myocardial ischaemia has been shown to confer an increased risk of adverse outcomes. Whilst, optimal medical therapy (OMT) forms the cornerstone of the management of patients with stable CAD, a significant number of patients present with ischaemia refractory to OMT. Historically coronary angiography alone has been used to determine coronary lesion severity in both stable and acute settings. It is increasingly clear that this approach fails to accurately identify the haemodynamic significance of lesions; especially those that are visually "intermediate" in severity. Revascularisation based upon angiographic appearances alone may not reduce coronary events above OMT. Technological advances have enabled the measurement of physiological indices including the fractional flow reserve, the index of microcirculatory resistance and the coronary flow reserve. The integration of these parameters into the routine management of patients presenting to the cardiac catheterization laboratory with CAD represents a critical adjunctive tool in the optimal management of these patients by identifying patients that would most benefit from revascularisation and importantly also highlighting patients that would not gain benefit and therefore reducing the likelihood of adverse outcomes associated with coronary revascularisation. Furthermore, these techniques are applicable to a broad range of patients including those with left main stem disease, proximal coronary disease, diabetes mellitus, previous percutaneous coronary intervention and with previous coronary artery bypass grafting. This review will discuss current concepts relevant to coronary physiology assessment, its role in the management of both stable and acute patients and future applications.

Key words: Ischaemia; Coronary physiology; Coronary flow reserve; Fractional flow reserve; Coronary artery disease

Core tip: Coronary artery disease remains the leading cause of death worldwide. There is increasing evidence to suggest that the use of invasive coronary angiography alone may not reliably identify all lesions associated with haemodynamic compromise. Technological advances have enabled the measurement of a number of coronary physiological indices which when incorporated into routine practice are associated with improved outcomes, reduced risks and greater economy. This review will

discuss current concepts relevant to coronary physiology assessment, its role in the management of both stable and acute patients and future applications.

INTRODUCTION

Coronary artery disease (CAD) is the leading cause of death worldwide[1] with approximately 1 in 30 patients with stable CAD experiencing acute myocardial infarction (AMI) or cardiovascular death each year[2]. The presence of resultant myocardial ischaemia and its extent has been shown to confer increased risk of adverse outcomes[3-6]. With an increasing burden of atherosclerotic coronary disease and the associated high event rate, there is a need to identify both patients at highest risk with most to benefit from revascularisation strategies and also those that would be best managed by a conservative approach to improve clinical outcomes and minimise exposure to procedural risks.

Prevention by risk factor control and optimal medical therapy (OMT) including aspirin[7], beta-blockers[8], statins[9] and angiotensin converting enzyme inhibitors forms the cornerstone of the management of patients with stable CAD[10,11]. However, a significant number of patients present with myocardial ischaemia refractory to OMT and subsequently undergo coronary revascularisation by percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) with the aim of reducing ischaemic burden and therefore risk[12].

Historically, visual assessment of coronary lesions by invasive coronary angiography in isolation has been used to determine the severity of coronary lesions in both stable and acute settings. It is increasingly clear that this approach fails to accurately and consistently identify the haemodynamic significance of lesions, especially those that are "intermediate" in severity[13] and that revascularisation based upon angiographic appearances may not reduce coronary events above OMT alone[14]. Recent advances in technology and understanding of coronary physiology have resulted in its central role in the assessment of patients in the catheterization laboratory and their optimal management[15,16]. This review will discuss current concepts relevant to coronary physiology assessment, its role in the management of patients and possible future applications.

CORONARY PHYSIOLOGY

Technological advances have enabled the measurement of a number of physiological indices including the fractional flow reserve (FFR), the index of microcirculatory resistance (IMR) and the coronary flow reserve (CFR). The advantages and disadvantages of each of the coronary physiology indices is summarised in Table 1.

FFR

FFR is the ratio of myocardial blood flow in a stenosed coronary artery at maximal hyperaemia in comparison to normal (proximal) myocardial flow. It quantifies the pressure drop measured across a coronary artery stenosis[17] and therefore the physiological significance of the lesion. The pressure drop is directly proportional to stenosis length, inversely proportional to lumen cross-sectional area and related to the square of the blood velocity. FFR is thus related to both lesion morphology and the volume of viable subtended myocardium and is independent of changes in haemodynamic conditions[18].

CFR

CFR is the ratio of hyperaemic to resting coronary flow and incorporates both the epicardial and microvascular circulations[19]. A value of < 2.0 is correlated with stenosis severity[20].

IMR

IMR is a measure of true microcirculatory resistance and is calculated by measuring the distal arterial pressure at hyperaemia divided by the inverse of the transit time. The IMR is not influenced by the presence or absence of epicardial artery stenosis[21]. There is no absolute validated "normal" value but a cut-off value of 32 units has been shown to be predictive of myocardial recovery following AMI[22].

Technique

To measure the FFR, a wire with a distal pressure sensor is advanced into a guiding coronary artery catheter, the pressure is equalised, and then passed distal to the coronary stenosis of interest (Figure 1A). The aortic pressure (Pa) is measured from the guide catheter and the distal pressure (Pd) from the pressure sensor distal to the stenosis (Figure 1B). To calculate the FFR, hyperaemia is achieved by the administration of intravenous (140 mcg/kg per minute) or intracoronary (20-50 mcg) adenosine and is the ratio of hyperaemia Pd/Pa (Figure 1C). Other hyperaemic stimuli can be used but adenosine is the most widely validated.

In the measurement of IMR and CFR, the shaft of the pressure wire is used to detect changed in the temperature-dependent electrical resistance and thus acts as a proximal thermistor. The sensor at the end of the wire is used to simultaneously measure pressure and temperature at the distal end of the artery. Therefore, the transit time of room-temperature saline injected through the guiding

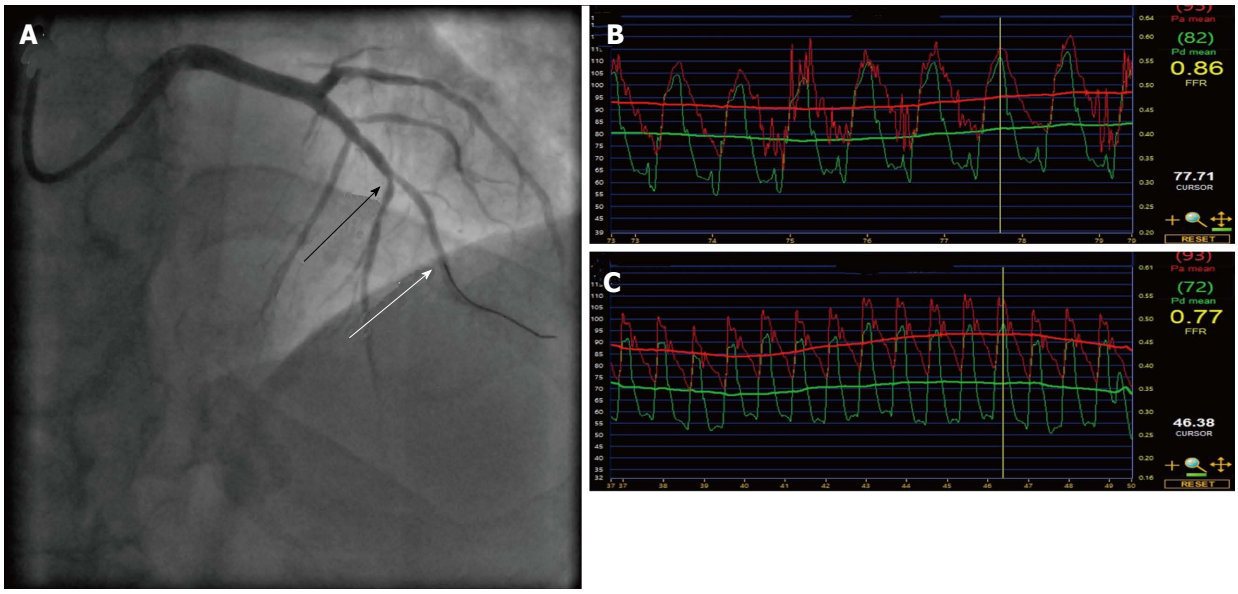

Figure 1 Fractional flow reserve of an "intermediate" lesion in the left anterior descending artery. A: Fluoroscopic image obtained in the right anterior oblique projection demonstrating an angiographically intermediate stenosis (black arrow) and a pressure wire in-situ (white arrow); B: Pressure trace demonstrating a fractional flow reserve (FFR) of 0.86; C: Pressure trace demonstrating a FFR of 0.77 at maximal hyperaemia that is positive. The patient then proceeded to successful percutaneous coronary intervention of the LAD.

coronary artery catheter can be calculated using a thermodilution technique[23]. The initial transit time is recorded (T_{mn}) following three injections of room-temperature saline. Following hyperaemia, three further injections of room-temperature saline are administered and hyperaemia T_{mn} is measured. The thermodilution CFR is calculated by dividing the resting T_{mn} by the hyperaemic T_{mn}. The IMR is calculated as the distal coronary pressure (Pd) at maximal hyperaemia divided by the inverse of the hyperaemic T_{mn}.

MYOCARDIAL ISCHAEMIA

Many studies have demonstrated that the presence and extent of myocardial ischaemia is closely related to adverse clinical events[5,6,24] with the annual rate of cardiac death and AMI positively correlated with the extent of myocardial ischaemia[24]. Coronary revascularisation has been demonstrated to be beneficial in individuals with moderate and severe ischaemia, with OMT being optimal in patients with mild or no ischaemia[25,26]. In patients with demonstrated extensive ischaemia (> 20% myocardium), an early revascularisation strategy (as opposed to OMT alone) is associated with a 30% reduction in risk of all-cause death[25].

The identification of the presence and extent of myocardial ischaemia in patients presenting with stable CAD is critical to their optimal management. Myocardial perfusion imaging is the most commonly used modality however stress echocardiography and magnetic resonance imaging are increasingly being employed.

There is some evidence that an ischaemia-guided revascularisation strategy is associated with improved prognosis and outcome[27,28]. In patients that underwent myocardial perfusion imaging prior to revascularisation (PCI or CABG) and then in the follow up period, the incidence of patients with worsening ischaemia (> 5% of total myocardium) was more common in patients treated medically in comparison to patients who underwent revascularisation (PCI or CABG) and was an independent predictor of adverse outcomes[29].

CORONARY PHYSIOLOGY AND STABLE CORONARY ARTERY DISEASE

PCI reduces mortality in patients with acute coronary syndromes[30], however, in patients presenting with stable CAD, PCI results in an improvement of angina symptoms alone without a mortality advantage in comparison to OMT alone[14]. These results may be a consequence of sub-optimal patient selection due to the sole reliance of visual assessment of coronary lesion by invasive coronary angiography to determine the severity of disease with no information as to the haemodynamic significance of these lesions[31,32]. This can result in inappropriate coronary revascularisation with little benefit and potential procedural risk.

The severity of a lesion (and resultant extent of myocardial ischaemia) is dependant on a number of factors including the severity of luminal narrowing, lesion length and extent of subtended myocardium. As discussed in the previous section, whilst non-invasive techniques can be employed to ascertain

Table 1 Advantages and disadvantages of the different coronary physiology indices

	Advantages	Disadvantages
FFR	Clear "cut-off" value	Requires administration of vasodilator
	Clinically validated	Risk of coronary artery injury
	Can be used in a wide range of patients	Relatively expensive
	Accounts for collateral circulation	
IMR	True measure of microcirculatory resistance independent of epicardial coronary disease	Requires administration of vasodilator
		The full extent of clinical utility is currently unknown
	A tool to potentially predict prognosis in acute patients	
CFR	A tool to potentially predict prognosis in acute patients	Value is affected by both epicardial disease and microvasculature
		The full extent of clinical utility is currently unknown
		Influenced by hemodynamics

FFR: Fractional flow reserve; IMR: Index of microcirculatory resistance; CFR: Coronary flow reserve.

the extent of myocardial ischaemia, many patients present to the cardiac catheterization laboratory without having undergone such assessment and indeed, in the setting of multi-vessel disease, non-invasive stress tests are often not able to definitively detect and localise ischaemia[33]. Furthermore, if a non-invasive image approach is taken, a positive test will result in repeat catheterization for PCI - thus further subjecting a patient to procedural complications, delaying revascularisation and being less economical. The use of coronary physiology provides the unique ability to gain immediate information with regards to the haemodynamic significance of specific coronary lesions in patients already in the cardiac catheterization laboratory attending for coronary angiography and identify those at highest risk who are most likely to benefit from PCI.

In stable CAD, CFR decreases as stenosis severity increases. When compared to non-invasive parameters a value of < 2.0 has been shown to correlate with significant ischaemia[20]. However, because CFR takes account of both epicardial and microvascular circulations, this measure can be influenced by exogenous factors[19] and therefore due to confounding factors is no longer used for stenosis assessment[34].

In the setting of stable CAD, the IMR has recently been shown to be independent of the severity of epicardial stenosis when collateral coronary flow is accounted for[35]. IMR may however, play a role in predicting outcome following elective PCI, with a high IMR pre-PCI predicting peri-procedural myocardial infarction following PCI[36].

FFR is a highly reproducible technique and is insensitive to external factors such as changes in haemodynamics[18]. The normal FFR is 1 with a value of $\leqslant$ 0.75 associated with ischaemia[37] and $\geqslant$ 0.8 not associated with significant ischaemia[38]. There is therefore a "grey zone" of between 0.75-0.8, however the majority of clinical studies to date have adopted a lower normal value of 0.8[12] to define significant ischaemia.

As opposed to relying solely on angiographic appearances, a FFR guided strategy has been shown to identify patients who would most benefit from coronary revascularisation. In the DEFER (deferral versus performance of PCI of non-ischaemia-producing stenoses) study[39], in patients with single-vessel coronary disease and a measured FFR $\geqslant$ 0.75, deferral of PCI was associated with similar event free survival in both OMT and PCI groups at five years[40].

In patients presenting with multi-vessel coronary disease, the clinical utility of myocardial perfusion imaging has been doubted. The technique measures relative differences (normal *vs* abnormal) in myocardial perfusion between coronary artery territories. Thus, in multi-territory ischaemia, the relative differences may be less pronounced resulting in "balanced ischaemia" even in the presence of significant ischaemia as determined by FFR. The FAME study[12] (FFR *vs* angiography for multi-vessel evaluation trial) which investigated patients with multi-vessel coronary disease, supported an FFR-guided strategy in comparison to angiography alone with an associated reduction in mortality or MI at 2 years[15]. This benefit was also found to be true when compared to contemporary OMT in the more recent FAME Ⅱ study[16] that indicated that an FFR-guided strategy resulted in a lower rate of urgent revascularisation.

FFR has been shown to be reproducible both in singe and multi-vessel coronary disease. However in certain instances, caution should be taken in interpreting coronary physiology parameters.

Left main stem disease

In patients presenting with left main stem disease, FFR has been shown to be useful in managing revascularisation strategies[41]. This is also true of left main stem disease and concomitant downstream stenosis if the pressure wire is placed in a non-stenosed downstream vessel and the other vessel does not have a critical proximal stenosis[42].

Post PCI

FFR following PCI has been shown to predict

outcome. Post PCI FFR was found to be the strongest predictor of major adverse cardiovascular events at 6 mo[43]. FFR has also been utilised following bifurcation stenting, illustrating that even in the presence of appearances in keeping with severe pinching of side branches, FFR was rarely $\leqslant$ 0.75 and therefore of no haemodynamic significance[44].

Myocardial scar

Following AMI, irreversibly injured myocardium is replaced by scar tissue that results in a reduction in the microcirculation to this territory. FFR in this context can therefore still be used to guide future management strategies, with the value representing viability of the subtended myocardium, but after an appropriate interval to allow for myocardial healing following AMI to ensure adequate hyperaemia[45].

Grafts

FFR can also safely be used in patients with previous CABG. In an observational study, patients with intermediate stenoses in both arterial and vein graft conduits that were managed by adopting a FFR-guided PCI strategy suffered significantly lower major adverse clinical endpoints as compared to an angiography guided group[46].

Diabetes mellitus

FFR depends upon the vasodilatative capacity of the coronary system and therefore achieving maximal hyperaemia. Patients with diabetes mellitus, suffer abnormalities in microvascular function with altered vasodilatative capacity and increased vascular resistance. Whilst caution should be taken in when using FFR in this patient group[47], a recent study comparing FFR in diabetic and non-diabetic patients has shown that FFR appears to be accurate and applicable in this patient group[48].

These studies highlight the critical role played by coronary physiology in identifying haemodynamically significant coronary stenoses that may benefit from revascularisation, and allow targeted vessel specific treatment beyond the angiographic appearances. The concept of the functional as opposed to the anatomical SYNTAX score appears to stratify patients appropriately to CABG or PCI or patients that would be best managed by OMT. FFR is broadly applicable to all patient groups and is associated with improved outcomes.

CORONARY PHYSIOLOGY AND ACUTE CORONARY SYNDROMES

In the setting of AMI, myocardial inflammation resulting in oedema can result in blunting of the hyperaemic response in the microcirculation resulting in falsely high FFR values, however coronary physiology parameters can potentially still be useful in guiding the management of this patient group.

The IMR when measured in the setting of primary PCI has been shown to correlate with the extent of microvascular obstruction and independently predicted left ventricular systolic function and infarct volume[22,49] and thus provides important prognostic information in this patient group. The clinical utility of this approach, however, is presently unknown.

The thermodilution CFR when measured in the first day after primary PCI also offers important prognostic information with a significant decrease in CFR in patients with impaired left ventricular systolic function. Conversely a greater increase in CFR by day 1 was associated with a higher salvage index[50].

A significant number of patients presenting with acute coronary syndromes also have visually severe "non-culprit" epicardial artery lesions. FFR of "non-culprit" lesions has been shown to be reliable[51] and has been used to guide revascularisation of these lesions. A large prospective multicentre randomised trial is currently underway to investigate the utility of this approach further[52].

LIMITATIONS

The adjunctive beneficial role that coronary physiology plays in the management of CAD has been discussed thus far. There are however, some limitations. The possibility of false negative or false positive results does exist, for example if maximal hyperaemia is not achieved or if instrumentation of the coronary artery induces coronary artery spasm. There is a risk of coronary artery injury (perforation or dissection) with instrumention of the artery to obtain measurements. Finally, there is an additional economic cost when adopting coronary physiology into routine clinical practice with the cost of pressure wires, cost of adenosine, and extra cardiac catheterization laboratory time required. These have all currently limited widespread uptake of these techniques.

FUTURE DIRECTIONS

A current limitation to invasive coronary physiology techniques is the need to induce maximal hyperaemia with agents such as adenosine. Patients may have contraindications to this agent, and additionally there is a time and cost implication. More recently an adenosine independent index of stenosis severity - the instantaneous wave-free ratio (iFR) has been developed[53]. The accuracy of this ratio in comparison to FFR has been shown to be approximately 80%[54] and outcome data from the on-going DEFINE-FLAIR (functional lesion assessment of intermediate stenosis to guide revascularisation) study[55] are awaited to ascertain if this index can be used routinely in clinical practice.

In the future, there may be non-invasive anatomical

and functional imaging surrogates for FFR. Current anatomical imaging modalities [*e.g.*, computed tomography (CT)] correlate poorly with lesion haemodynamic significance and do not capture information related to translesional energy/pressure losses[56]. Newer techniques including CT myocardial perfusion[57], the measurement of contrast gradients in conventional CT angiography[58] and the use of three-dimensional luminal anatomy are currently being evaluated to investigate if they correlate with FFR values for the evaluation of coronary stenoses[59]. Current technologies however have not been shown to equal the sensitivity and specificity of FFR[60].

DISCUSSION

The integration of invasive coronary physiology measurements into the routine management of patients presenting to the cardiac catheterization laboratory with CAD represents a critical adjunctive tool in the optimal management of these patients. The use of FFR can identify patients that would most benefit from revascularisation either by PCI or CABG and importantly also highlights patients that would not gain benefit and therefore reducing the likelihood of adverse outcomes associated with coronary revascularisation. In the setting of acute coronary syndromes, the use of IMR and CFR provides important information with regard to outcome and myocardial salvage, although the clinical value of these measures remains uncertain. The interpretation of the described coronary physiology indices is now essential in current interventional cardiology practice and is represented by current training medical curricula in this sub-specialty field.

The use of newer techniques to derive FFR– both invasively that do not depend on the administration of agents to induce hyperaemia and non-invasive functional imaging may result in coronary physiology parameters playing an even more central role in the future.

Abstract

The aim of the present systematic review is to summarize the existing knowledge about the human microbiota in the elderly and the effects of probiotics in elderly population. The elderly subjects, compared to adult population, show a reduction in the diversity of the microbiota, characterized by a large interindividual variability, with lower numbers of *Firmicutes*, *Bifidobacteria*, *Clostridium cluster* XIV, *Faecalibacterium Prausnitzii*, *Blautia coccoides-Eubacterium rectal* and higher presence of *Enterobacteriaceae* and *Bacteroidetes*. These differences of the intestinal microbiota of the elderly may not necessarily be caused by aging, but they could be associated with the decline of the general state of health with malnutrition and with increased need for medication, such as antibiotics and nonsteroidal anti-inflammatory drugs, situations that occur frequently in the elderly. Differences have been demonstrated in the composition of the microbiota between healthy elderly subjects and hospitalized or institutionalized elderly subjects. These findings which further indicates that the living conditions, health status, nutrition and drugs have a significant effect on the composition of the microbiota. According to the available knowledge, the use of probiotics is safe and could represent an useful intervention to prevent or treat antibiotic-associated diarrhea, in addition to reducing the severity of symptoms, other than to help the management of constipation.

Key words: Microbiota; Elderly; Probiotics; Antibiotic-associated diarrhea; Constipation

Core tip: The intestinal microbiota of elderly manifested a reduction in the diversity, characterized by a large interindividual variability, with lower numbers of *Firmicutes*, *Bifidobacteria*, *Clostridium cluster* XIV, *Faecalibacterium Prausnitzii*, *Blautia coccoides-Eubacterium rectal* and higher in *Enterobacteriaceae* and *Bacteroidetes*. These derangements may not necessarily

aging-correlated, but they can be consequent to the decline of general state of health, malnutrition and increased use of drugs. As regards probiotics, the main double-blind studies in the elderly have shown that use is safe and could represent an interesting support to reduced frequency and/or duration of antibiotic-associated diarrhea, other than to help for constipation.

INTRODUCTION

Differences in the composition of the microbiota have been shown in the literature, when healthy elderly and adult have been compared, but differences in the composition of the microbiota have been also shown when healthy elderly and hospitalized or institutionalized elderly patients have been compared. Then, the topic concerning the changes in the composition of the microbiota with age is much debated in the literature. Another issue of great interest is whether the use of probiotics may be effective in the elderly population.

Given this background, the aim of the present review is to summarize the state of the art according to the extant literature about two topics: the changes in the microbiota associated with aging and the activity of probiotics on the microbiota in this age group evaluated with two issues: (1) the effect on the composition of the microbiota after administration of probiotics; and (2) the efficacy of intake of probiotics on symptoms of major gastrointestinal diseases, including the iatrogenic ones, that frequently affect elderly subjects, including constipation, diarrhea secondary to the intake of antibiotics, particularly when linked to the presence of *Clostridium difficile*.

RESEARCH

The present systematic review was performed following the steps by Egger *et al*[1] as follows: configuration of a working group: three operators skilled in clinical nutrition in the geriatric age, of whom one acting as a methodological operator and two participating as clinical operators. Formulation of the revision question on the basis of considerations made in the abstract: "microbiota in elderly, use of probiotics during aging". Identification of relevant studies: a research strategy was planned, on PubMed [Public MedIine run by the National Center of Biotechnology Information (NCBI) of the National Library of Medicine of Bathesda (United States)], as follows: (1) definition of the key words (microbiota, elderly, probiotics), allowing the definition of the interest field of the documents to be searched, grouped in inverted commas ("…") and used separately or in combination; (2) use of: the Boolean AND Operator, that allows the establishments of logical relations among concepts; (3) research modalities: advanced search; (4) limits: time limits: papers published in the last 20 years; humans; languages: English; and (5) manual search performed by the senior researchers experienced in clinical nutrition through the revision of reviews and individual articles on microbiota in elderly published in journals qualified in the Index Medicus. Analysis and presentation of the outcomes: the data extrapolated from the revised studies were collocated in tables; in particular, for each study we specified: the author, the name of the journal where the study was published and year of publication, study characteristics. The analysis was carried out in the form of a narrative review of the reports.

MICROBIOTA IN ELDERLY POPULATION

This research has been carried out based on the following keywords: "microbiota" AND "elderly"; 1040 articles were found. Among them, 6 case control studies, 1 Randomized Controlled Trial (RCT), 6 cross sectional researches, 5 observational studies, 6 reviews, 1 prospective and 1 population based studies have been selected and discussed.

The changes in the microbiota associated with aging are still far from being clarified with certainty, but there are numerous studies that suggest that aging has a significant effect on the microbiota.

First of all, it has to be taken into account that changes in the intestinal microbiota of the elderly may not necessarily be caused by aging: they can be influenced by the decline of the general state of health, by malnutrition and increased need for medication, such as antibiotics and nonsteroidal anti-inflammatory drugs (NSAIDs)[2,3], that occur frequently in the elderly. Differences in the composition of the microbiota have been shown when healthy elderly and hospitalized or institutionalized elderly patients have been compared[4,5], thus proving that the living conditions, health status, nutrition and drugs have a significant effect on the composition of the microbiota.

Moreover, the colonic transit has a great influence on the function of the large bowel and increased transit time is related to a reduced fecal bacterial cell mass[6]. Due to a lack of exercise and long periods of bed rest[7,8], intestinal transit times are often significantly increased in hospitalized elderly patients[7], and this may be a factor influencing the changes in the intestinal microbiota in hospitalized or institutionalized elderly compared to healthy

subjects. Moreover, modified diets, parenteral and enteral artificial nutrition and different eating habits during hospitalization[9] may contribute to these variations.

The normal intestinal microbiota provides an important natural defence mechanism against invading pathogens and prevents the overgrowth of opportunistic microorganisms (colonization resistance). Therefore, alterations in the composition of the microbiota that occur in the elderly may lead to negative consequences, such as a decreased efficacy of in the immune system and a higher incidence of gastrointestinal infections, which is more frequent in the elderly than in the young[10]. The immunological changes associated with aging involve reductions of efficiency of the responses mediated by B and T cells[11]. In addition, the increase of circulating antibodies against commensal intestinal bacteria in the elderly has been associated with age-related changes, such as the reduction of gastric acid secretion and increased mucosal permeability[12].

The elderly subjects, compared to the young adult population, show a reduction in the diversity of the microbiota[13], characterized by a large interindividual variability, with a lower number of Bifidobacteria and a higher number of Enterobacteriaceae[14,15]. In addition, the *Bacteroidetes* are more numerous, while the *Firmicutes* appear to be fewer than in the elderly compared to younger adult controls[16]. The elderly population also shows decreased levels of *Clostridium cluster* XIV and *Faecalibacterium Prausnitzii*, which are known as major producers of butyrate[17,18]. Moreover, the levels of *Blautia coccoides - Eubacterium rectal* (formerly known as *Clostridium coccoides - E. Rectale*) are lower in the elderly than in adults[19]. Finally, aging has been associated with an increase in the diversity of species not yet identified[20]. In an interesting recent study[21], a cohort of 178 (non on antibiotic treatment) elderly subjects (mean age 78, range 64-102 years) were recruited by taking into account their place of residence (a group of healthy elderly were resident in a community and a group of frail elderly institutionalized in a long-term care center) and were compared with 13 young adults (mean age 36 years, range 28-46 years), who were used as a control group. The data were acquired through the reading of more than 5 million sequences generated from 16S rRNA amplicons of the gene. The results revealed that the composition of the intestinal microbiota of the elderly considered in the study was correlated with the place where they live. The elderly community residents had a greater number of *Firmicutes* and lower incidence of *Bacteroidetes* when compared the long-term care residents. Considering the division according to the enterotype, six co-abundance groups were detected. The dominant genera were *Bacteroides, Prevotella, Ruminococcus, Oscillibacter, Alistipes* and *CAG Odoribacter*. The transition from healthy elderly living in the community to elderly and frail institutionalized in a long-term care center is accompanied by the dominance of a CAG distinctive, with a significantly greater number of *Prevotella* and *Ruminococcus CAG* in the cohort residing in the community and *Alistipes* and *CAG Oscillibacter* in the cohort of elderly subjects institutionalized in a long-term care center. This study also demonstrated a correlation between alterations of the microbiota and the state of fragility of the elderly, confirming the results of previous study[22]. In addition, the study demonstrated a correlation with increased inflammation (as assessed by the determination of C-reactive protein and interleukin 6 and 8), thus confirming the hypothesis that there is a close association between the presence of the so-called "inflammaging" and alterations of the microbiota[23]. Finally, a clear association between diet and microbiota has been outlined in this study: thus confirms the results of many other studies[24-26].

A recent study by Biagi *et al*[15] evaluated, by means of "Human Intestinal Tract Chip" and quantitative PCR of the 16S rRNA genes of Bacteria and Archaea, the microbiota of centenarians and compared these data with the microbiota of young and not centenarians elderly subjects. The results show that *Firmicutes* and *Bacteroidetes* dominate the intestinal microbiota of centenarians (representing over 93% of total bacteria). Compared to adults and centenarians, in pre centenarian elderly subjects changes were observed in the relative proportion of specific subgroups of *Firmicutes*. A decrease in the contribution of *Clostridium cluster* XIV, an increase in Bacilli, and a rearrangement of *Clostridium cluster* IV, and of *Clostridium cluster* XIVa were found. *Clostridium cluster* XIVa is one of the main bacteria that produce methane, a short chain fatty acid, which is a source of energy for the enterocytes and has been implicated in the protection against intestinal inflammatory diseases. A lower number of several producers of butyrate was observed in centenarians when compared with other age groups, including *Ruminococcus obeum et rel*, *Roseburia intestinalis et rel*, *E. ventriosum et rel*., *E. rectale et rel*., *E. hallii et rel.* (all belonging to the *Clostridium cluster* XIV), and *Papillibacter cinnamovorans et rel*., and *F. Prausnitzii et rel*. (*Clostridium cluster* IV). Conversely, other butyrate producers, such as *Anaerotruncus colihominis et rel*. (*Clostridium cluster* IV), and *Eubacterium limosum et rel*. (*Clostridium cluster* XV) were increased in centenarians. The increase of *E. limosum* is high (about 15 times), and may indicate a group of bacteria characteristic of centenarians. Also the decrease of *F. prausnitzii* in centenarians is of interest, as this species is known to affect inflammation of the intestine. Finally, the intestinal microbiota of centenarians is more

rich in proteobacteria, a group containing many of those bacteria recently defined as "patobionti". These are considered minor and opportunistic components of human intestinal ecosystem that, in some circumstances (for example in the presence of inflammation) can get out of control and cause a disease.

Many therapeutic substances frequently taken by elderly subject[27], such as NSAIDs, are associated with alterations in the microbiota[3]. Mäkivuokko, thanks to the sequencing of the 16S rDNA, demonstrated in a group of 18 elderly people taking NSAIDs, that there are changes in all the major microbial phyla, such as a lower number of *Firmicutes* and an increase number of *Bacteroidetes*. In addition, it was reported a reduction in the number of the known butyrate producers belonging to *Clostridium cluster* XIV, as *Roseburia* and *Ruminococcus*, and, in the *Actinobacteria* cluster, a lower number of *Collinsella* spp. compared to both the young adults and the elderly subjects not taking NSAIDs.

EFFECTIVENESS OF THE USE OF PROBIOTICS IN THE ELDERLY POPULATION

The studies carried out in the elderly population to test the activity of probiotics on the microbiota in this age group, has been evaluated with two topics: the effect on the composition of the microbiota after administration of probiotics; the efficacy of intake of probiotics on symptoms of major gastrointestinal diseases, including the iatrogenic ones, that frequently affect elderly subjects, including constipation, diarrhea secondary to the intake of antibiotics, particularly when linked to the presence of *Clostridium difficile*.

This research has been carried out based on the keywords: "probiotics" AND "elderly" AND "aging"; 56 articles were sourced. Among them, as far as variations in the composition of the microbiota in the elderly after use of probiotics are concerned, 3 randomized double blind clinical trials and 1 observational research have been selected and discussed. Concerning the efficacy of use of probiotics on symptoms of major diseases that affect the elderly, 2 RCT, 7 double blind studies, 3 reviews and 1 cross sectional research have been selected and discussed.

Variations in the composition of the microbiota in elderly after use of probiotics

Regarding changes in the composition of the microbiota following the intake of probiotics, in the elderly population, three double-blind studies versus placebo were selected: (1) the study of Lahtinen *et al*[28] that considered the effect of a fermented oat beverage containing 10^9 cfu/mL *Bifidobacterium longum* 46 (DSM 14583) and *B. longum* 2C (DSM 14579) given daily for 6 mo; (2) the study by Ahmed *et al*[29] that considered the effect of a drink made of reconstituted skim milk containing 3 different doses (5 x 10^9 CFU/die, 1.0 x 10^9 CFU/die and 6.5 x 10^7 CFU/die) of *Bifidobacterium lactis* HN019 (DR10TM) administered daily for 4 wk; and (3) the study of Bartosch *et al*[4] that considered the effect of *Bifidobacterium bifidum* and *B. lactis* in combination with inulin.

Table 1 shows the changes in the composition of the microbiota of the treated group when compared to the placebo group.

Efficacy of use of probiotics on symptoms of major diseases, including iatrogenic, that affect the elderly

In a large controlled study conducted in 360 subjects older than 60 years, the effect of a 3-wk intervention of a fermented milk containing cultures of yogurt and the probiotic casei DN-114001 showed that the incidence of winter infections was not different than in the placebo group, but the duration of all pathologies was significantly lower in the intervention group (7.0-3.2 d) when compared to the control group (8.7-3.7 d)[30].

One double-blind study, which involved 24 elderly patients who had undergone artificial enteral nutrition, evaluated the effects of a 12-wk administration of fermented milk containing *Lactobacillus johnsonii* LA1. The group who took the probiotic had significantly fewer days with infections at the end of the intervention: a decrease from 15.4% of days with infection to 5.7% was observed, and this reduction was significantly greater than that recorded for the control group[31].

Numerous studies conducted in the elderly population have shown that the intake of probiotics determines a reduced frequency and/or duration of episodes of antibiotic-associated diarrhea (AAD), in addition to reducing the severity of symptoms. Probiotics have been used in combination with antibiotics as therapy for *Clostridium difficile*, which represents 20% to 25% of cases of AAD, causing more than 95% of cases of pseudomembranous colitis[32]. A study of Hickson *et al*[33] evaluated 135 hospitalized patients, with an average age of 74 years, before and after 1 wk of consumption of 100 g (97 mL) of a drink containing *Lactobacillus casei*, *L bulgaricus* and *Streptococcus thermophilus* taken twice per day during a course of antibiotics. The placebo group received a sterile milkshake. As a primary outcome the appearance of antibiotic-associated diarrhea was considered, while a secondary outcome, the presence of *Clostridium difficile* toxin and diarrhea were identified. The results showed that 7/57 (12%) of those taking the probiotic drink developed diarrhea associated with

Table 1 Changes in the composition of the microbiota of the treated group when compared to the placebo group

Design of the study	Subjects	Age	Probiotics	Results in intervention *vs* placebo	Ref.
Double blinded controlled trial	*n* = 33 placebo group;	83 ± 7 yr	Oat drink fermented with Bifidobacter um longum and *B. longum*	↑*B.catenulatum* ↑*B. bifidum* ↑*B. breve*	Lahtinen *et al*[28]
	n = 33 control group	84 ± 8 yr			
Double blinded controlled trial	*n* = 20 placebo; *n* = 20 low dose of probiotics; *n* = 20 medium dose of probiotics; *n* = 20 high dose of probiotics	> 60 yr	Reconstituted skim milk containing *Bifidobacterium lactis*	↑*Bifidobatteri* ↑*Lactobacilli* ↑*Enterococci* ↓*Enterobatteri*	Ahmed *et al*[29]
Double blinded controlled trial	*n* = 9 placebo	Mean 71 yr	*Bifidobacterium bifidum* and *B. lactis*	↑*Bifidobacteria*	Bartosch *et al*[4]
	n = 9 symbionts (mixture of probiotics and prebiotics)	Mean 73 yr	together with inulin	↑*Lactobacilli* ↓*B. bifidum*	

antibiotic use, compared with 19/56 (34%) of the placebo group (P = 0.007). Logistic regression for control of other factors gave an odds ratio of 0.25 (95%CI: 0.07-0.85) for the use of probiotics. The absolute risk reduction was 21.6% (6.6%-36.6%). No one in the group that received the probiotic and 9/53 (17%) in the placebo group had diarrhea due to *Clostridium difficile* (P = 0.001). The absolute risk reduction was 17% (7%-27%).

A further study on the use of probiotics as adjuvants to antibiotic therapy for the preventing of gastrointestinal disorders was conducted by Beausoleil in 89 elderly men with a mean age of 72 years[34]. The preparation employed was a fermented milk containing at least 50 × 10^9 colony-forming units of *L acidophilus* CL1285 and *L casei*. The scheme of administration was 49 g once a day for two days, followed by 98 g once a day to cover the entire duration of antibiotic treatment. The antibiotic-associated diarrhea occurred in 7 out of 44 patients (15.9%) in the group that received *lactobacilli* and in 16 out of 45 patients (35.6%) in the placebo group (OR = 0.34, 95%CI: 0.125-0.944, P = 0.05). The median length of hospital stay was eight days in the group that received the probiotics, compared to 10 d in the placebo group (P = 0.09). The prevention of CDAD is an important result to be considered in the elderly population, because this condition has been associated with increased mortality and morbidity[35].

In the elderly, constipation is a common condition characterized by a constellation of symptoms defined by the criteria "Rome Ⅲ criteria"[36]. A review published in 2010[37], included 3 double-blind, placebo-controlled studies conducted by Koebnick *et al*[38], Möllenbrink *et al*[39], and by Yang *et al*[40]: as a whole 266 patients were evaluated and the most of them were elderly patients. This review confirmed the efficacy of treatment with *Bifidobacterium lactis* DN-173010, *Lactobacillus casei Shirota*, and *E. coli Nissle* 1917 on the frequency of defecation and stool consistency. This improvement is secondary to the decrease of the colonic pH value that follows the probiotics intake, thanks to the production of short chain fatty acids (butyric acid, propionic acid and lactic acid). A lower pH enhances peristalsis in the colon, and thereafter, it may decrease the intestinal transit time[37].

A double blind *vs* placebo study conducted by Ouwehand *et al*[41] studied the effects of a symbiotic combination of lactitol and *Lactobacillus acidophilus* NCFM (total daily dose of 10 g lactitol and 2 × 10^{10} cells probiotic bacteria) taken twice a day for 2 wk, in a group of elderly subjects. The results of the study showed a higher frequency of evacuation in the group that received the probiotic, as well as significantly higher levels of PGE2, as well as a changes of IgA level and spermidine, thus demonstrating positive effects on the function of the intestinal mucosa.

The same working group[42] recently assessed by means of a double- blind, placebo-controlled trial, the efficacy of the same combination of *Lactobacillus acidophilus* NCFM and lactitol in 51 elderly people who followed NSAIDs treatment. Before, during and after the intervention period, the amount of six stool bacterial phylogenetic groups was determined using quantitative PCR, and variations in the composition of total microbiota were assessed by percent profiling guanine-plus-cytosine. The results of the study showed an increase of lactobacilli and bifidobacteria and also a possible stabilizing effect on the levels of *B. coccoides-E.* XIVab and *Clostridium cluster*.

CONCLUSION

The changes in the microbiota associated with aging are still far from being clarified with certainty, but there are numerous studies that suggest that aging has a significant effect on the microbiota.

Alterations in the intestinal microbiota of the elderly may not necessarily be caused by aging, but they can be consequent to conditions that occur frequently in the elderly, such as the decline of the general state of health or malnutrition or increased need for medication (*i.e.*, antibiotics and nonsteroidal anti-inflammatory drugs). Differences in the composition of the microbiota have been

found when healthy elderly and hospitalized or institutionalized elderly subjects were compared. This further indicates that the living conditions, health status, nutrition and drugs have a significant effect on the composition of the microbiota.

When compared to young adult populations, elderly subjects show a reduction in the diversity of the microbiota, which is usually characterized by a large interindividual variability, with a lower number of *Firmicutes*, *Bifidobacteria*, *Clostridium cluster* XIV, *Faecalibacterium Prausnitzii*, *Blautia coccoides-Eubacterium rectal* and a higher number of *Enterobacteriaceae* and *Bacteroidetes.* In the elderly, the intake of and NSAIDs is followed by a significant change on the composition of the microbiota. A reduction in the proportion of the known butyrate producers belonging to *Clostridium cluster* XIV, as *Roseburia* and *Ruminococcus*, and, in the *Actinobacteria* group, a lower number of *Collinsella* spp. has been reported in elderly subjects taking NSAIDs when compared to both young adults and elderly subjects who are not taking NSAIDs.

The use of probiotics in elderly population is safe and could represent an interesting support to prevent or treat AAD, in addition to reducing the severity of symptoms, other than to help the management of constipation.

Abstract

Patients with coronary artery disease vary widely in terms of prognosis, which is mainly dependent on ventricular function. In relation to the major outcomes of death and myocardial infarction, it is not clear in the literature if an invasive strategy of myocardial revascularization is superior to a conservative strategy of optimized medical therapy. Moreover, with the exception of patients with left main coronary disease, this similarity in prognosis also occurs in different subgroups of patients.

Key words: Coronary artery disease; Angina pectoris; Myocardial revascularization; Coronary angioplasty; Myocardial infarction; Prognosis; Disease-free survival

Core tip: Despite the evolution of myocardial revascularization techniques, the mainstay of treatment of stable coronary artery disease is optimal medical therapy. With the better understanding of the mechanisms underlying atherosclerosis, medical therapy develops and shows similar results in terms of survival and freedom from myocardial infarction compared to coronary interventions. Moreover, clinical trials have also demonstrated similar results between conservative and invasive strategies in various subgroups of patients, previously found to benefit from coronary interventions. In this review article, the authors discuss the results from main trials on specific groups of coronary artery disease patients which compared conservative and invasive strategies.

INTRODUCTION

The first studies on the evolution of patients with stable coronary artery disease (CAD) and preserved left systolic ventricular function demonstrated a low incidence of major cardiac events, death or myocardial infarction, in non-revascularized patients, despite their anatomical complexity. Moreover, retrospective studies that compared optimized medical therapy (OMT) alone with coronary artery

bypass surgery (CABG) demonstrated similar rates of death or myocardial infarction in patients both with single-vessel or multivessel disease, in the presence of preserved systolic ventricular function.

In clinical conditions like diabetes mellitus or in elderly patients, the literature demonstrates that the conservative strategy of OMT is as safe as invasive strategies are, for the majority of CAD patients.

Although sub analyses from important studies have suggested surgery would be a safer strategy in patients with CAD and impaired ventricular function, this information has been questioned by a recent important prospective randomized clinical trial, which demonstrated similar results of medical therapy compared to bypass surgery.

Despite the evolution of CABG and percutaneous coronary intervention (PCI) in the last 20 years, with the widespread use of arterial grafts and surgery without the use of extra-corporeal circulation, and the emergence of pharmacological stents, the improvement in medical therapy also occurred substantially with the use of antiplatelets, beta-blockers, angiotensin-converting enzyme inhibitors and statins. Currently, these are the basis of pharmacological CAD treatment, but other options with specific mechanisms of action as ranolazine and ivabradine have also emerged as potential adjunct therapy. In addition, technical problems of invasive strategies, such as graft failure and restenosis of stents, deserve attention in this matter. Moreover, clinical complications of interventions also carry risks, especially related to cerebrovascular accidents after surgery and the possible need for future interventions with PCI. On the other hand, some specific subgroups of CAD patients do benefit by invasive strategies.

Thus, a conservative OMT strategy with multi-factorial control is a safe option for the treatment of the majority of CAD patients, especially those with well-preserved ventricular function. Invasive strategies are important tools for the management of CAD patients, and should be reserved particularly for patients with refractory symptoms, for those who develop acute coronary syndromes, and possibly for select patients with ischemic heart failure.

In this review article, the authors discuss the major findings of studies, especially clinical trials, comparing medical therapy with invasive coronary interventions, in terms of major outcomes, death and MI, in different clinical settings.

EVOLUTION OF CORONARY ARTERY DISEASE PATIENTS

The natural history of patients with CAD is impossible to observe in epidemiological studies for ethical reasons. Even if patients refuse coronary interventions, they still receive medical therapy and instruction on lifestyle modifications, which result in changes in their clinical evolution. Consequently, the evolution of CAD patients may be observed in prospective studies, and especially in randomized groups that include patients receiving medical therapy alone.

The evolution of patients with chronic, stable CAD was demonstrated in an important study published in 1989[1]. In this study, from 1977 to 1983, 150 stable CAD patients, including 92% with multivessel disease and also patients with left main coronary disease or equivalent (39.3%) with a formal indication for coronary surgical revascularization refused the procedure. They were followed for two to eight years until 1985, and medically treated with beta-blockers, nitrates, calcium-channel blockers, aspirin, and dipyridamole. Differently from modern treatment, at that time, they were not treated with angiotensin-converting enzyme inhibitors or with statins, important medications of current therapy. Despite anatomic complexity, the estimated overall survival in eight years was 89%, which represents an average annual mortality rate of 1.37%. Of note, only 10% of patients had myocardial infarction and 4% requested surgical revascularization during follow-up.

One of the first randomized studies that compared medical therapy alone with coronary bypass surgery in stable CAD patients was the Coronary Artery Surgery Study (CASS) trial[2], published in 1983. In this study, 780 CAD patients were randomized to one of the two strategies and followed for 5 years. Interestingly, in this study, the average annual mortality rate for patients assigned to medical therapy was 1.6% and to surgery 1.1% (P = 0.34). Analyzing only the patients with an ejection fraction ≥ 0.50 (75% of the entire population of the trial), those assigned to medical therapy had annual mortality rates of 1.1%, 0.6%, and 1.2%, respectively, for single-, double-, and triple-vessel disease. Patients with an ejection fraction $\geqslant$ 0.50 assigned to surgery had similar mortality rates 0.8%, 0.8%, and 1.2%, respectively, for single-, double-, and triple-vessel disease. There were no statistical differences between the two treatment strategies.

Analysis of ten-year follow-up of patients from the CASS trial[3] demonstrated an overall survival of 79% and 82% in medical and surgery groups, respectively, or an average annual mortality rate of 2.1% and 1.8% (P = 0.25).

The results of these studies demonstrate that annual mortality rates for stable CAD patients with normal ejection fraction is low and range from 0.8% to 2.1%, even in those with multivessel disease. In addition, these studies were performed during a time when patients did not receive statins or angiotensin-converting enzyme inhibitors, which are medications with the potential to lower this risk. Although great numbers of patients in these studies had a low-risk profile (preserved systolic ventricular function, stable non-limiting symptoms, and young patients), their

prognostic information is essential for understanding the results of studies on invasive strategies.

SINGLE-VESSEL CAD PATIENTS

As mentioned previously, the CASS trial as well as other trials have demonstrated that single-vessel CAD patients have low annual mortality rates, especially in the presence of preserved ventricular function (1.1% and 0.8%, respectively, for medical therapy and bypass surgery). Moreover, this good prognosis is similar among different treatment strategies.

One of the studies that addressed the comparative results of different strategies in this scenario of single-vessel CAD patients was the Medical, Angioplasty or Surgery Study Ⅰ trial[4]. This study evaluated 214 CAD patients with an isolated severe lesion > 80% at the proximal portion of the left anterior descending coronary artery. Patients with stable symptoms and well-preserved ventricular function were selected and randomized to medical therapy alone (n = 72), balloon angioplasty (n = 72), or CABG (n = 70) with an internal thoracic artery. After an average of 3-year follow-up, the primary end-point of cardiac death, myocardial infarction, or refractory angina requiring revascularization was 12%, 17%, and 3%, for medical therapy, angioplasty, and CABG. This difference was mainly dependent on new revascularizations, because mortality and myocardial infarction were similar in the 3 treatment strategies.

Another important study on single-vessel CAD patients was published in 1992[5] and compared medical therapy alone with angioplasty with the use of stents. Patients with severe stenosis in one coronary artery were randomized and followed for 6 mo. In that period, myocardial infarction occurred in 5 patients who underwent angioplasty and in 3 patients in the medical therapy group. However at the end of the follow-up, a higher number of patients assigned to angioplasty were free of angina (64% × 46% in angioplasty and medical therapy, respectively, P < 0.01), and performed better on exercise treadmill tests, despite higher costs and complications in the angioplasty group.

Thus, in the subset of single-vessel CAD patients, unless limited by refractory symptoms, the strategy of optimal medical therapy poses a similar prognosis in terms of survival and myocardial infarction compared to invasive strategies. However, patients with severe symptoms, especially if refractory to medical interventions may benefit in terms of alleviation of symptoms with angioplasty.

MULTIVESSEL CAD PATIENTS

The three most important studies conducted in the 1970's and 1980's that compared the strategy of medical therapy alone with bypass surgery were the Veterans Affairs (VA) Cooperative Study[6], the European Coronary Surgery Study (ECSS)[7], and CASS[2].

Most of the patients enrolled in these trials had multivessel CAD, and the European Study only enrolled such patients.

The VA Cooperative Study included 686 CAD patients with stable angina, electrocardiographic signs of previous infarction or ischemic changes in exercise, and at least one major coronary artery with ⩾ 50% stenosis. Patients were randomized to medical therapy alone or bypass surgery and were followed for 18 years. This study demonstrated similar rates of overall survival (33% and 30% for MT and CABG, respectively, P = 0.60), and similar rates of myocardial infarction (41% and 49% for MT and CABG, respectively). Importantly, in patients with preserved ventricular function, irrespective of the number of diseased coronary arteries, patients assigned to medical therapy had similar rates of death and myocardial infarction as those assigned to bypass surgery. On the other hand, the group with left main disease or with a high angiographic risk, characterized as triple-vessel disease associated with impaired left ventricular function, had better survival associated with bypass surgery. Of note, 41% of medical therapy patients underwent surgery during the entire 18-year follow-up.

Consistent with the findings of the VA Study, the CASS trial also showed that patients with single-, double-, or triple-vessel coronary disease had similar rates of overall survival and myocardial infarction in medical therapy and bypass surgery, if they had preserved systolic ventricular function (defined as an ejection fraction ⩾ 0.50). CASS also showed that in patients with impaired ventricular function and triple-vessel disease, surgery was a better survival option. Of note, these 5-year results were confirmed by a 10-year follow-up study[8].

Another important study, the ECSS demonstrated some differences compared to the two previous studies. This trial included 767 men with normal left ventricular function and multivessel disease and randomized them to bypass surgery or medical therapy. Differently from VA and CASS, ECSS showed higher survival rates after 5- and 12-year follow-up for surgically treated patients, but the difference between treatments in the 5-year follow-up decreased in the 12-year results (70.6% ± 5.8% *vs* 66.7% ± 5.3%, P = 0.04). However, this better survival with bypass surgery only occurred in triple-vessel disease patients. Survival of double-vessel disease patients was similar in the two strategies.

After these 3 studies, the only study that compared an invasive with a conservative strategy of OMT and included three groups of treatments was the Medical, Angioplasty or Surgery Study (MASS-Ⅱ)[8]. In this study, 611 patients with multivessel proximal CAD, preserved systolic ventricular function and stable

symptoms were randomized to receive OMT alone (n = 203), CABG surgery (n = 203), or PCI (n = 205) with the use of conventional stents. After 5-year follow-up[8], the combined primary end-points of death, myocardial infarction, and additional revascularization favored the patients assigned to bypass surgery (21.2%, 32,7% and 36.0%, respectively, for CABG, PCI and MT, P = 0.0026), especially due to a significant reduction in the rates of new revascularizations (3.9%, 11.2%, and 9.4%, respectively for CABG, PCI, and MT). However, mortality and myocardial infarction rates were statistically similar between the 3 groups. After 10-year follow-up[9], overall survival was similar between the 3 treatment groups (74.9%, 75.1%, and 69%, respectively, for CABG, PCI, and MT, P = 0.089). However, the incidences of myocardial infarction and cardiac deaths favored the surgical group. Importantly, after 10 years about 40% of MASS Ⅱ trial patients assigned to medical therapy did not develop any complications. In addition, combined and isolated end-points were similar between medical therapy and angioplasty groups.

Compared to the first studies (VA, ECSS, and CASS), the MASS trial was a more contemporary study, in which medical therapy included the use of statins, angiotensin-converting enzyme inhibitors, and dual antiplatelet therapy after PCI. However, the higher annual mortality in this trial compared to the previous ones may be due to a higher-risk profile, as patients were older at study entry, had a higher proportion of diabetics, and more complex and diseased coronary arteries (higher frequency of triple-vessel disease and lesions at the proximal portion of the left anterior descending artery). Thus, this higher-risk profile of patients from the MASS trial seemed to benefit from surgery, information similar to that of the VA and ECSS trials. The high-risk profile patients from the CASS trial also demonstrated the benefits of bypass surgery, but in this study this profile included patients with impaired ventricular function.

The MASS trial showed that medical therapy had similar outcomes when medical therapy was compared to angioplasty. However, this was not the primary objective of this study.

However, this was the major finding of another important study published in 2007, the COURAGE trial[10]. This study aimed at evaluating the clinical significance of PCI in stable CAD patients. With this purpose, 2287 patients with objective evidence of myocardial ischemia and significant CAD were randomized between 1999 and 2004 to OMT alone (n = 1138) or PCI with OMT (n = 1149). After a median 4.6-year follow-up, the primary end-point of overall death and myocardial infarction occurred in 19.0% in the PCI group and 18.5% in the medical therapy group (P = 0.62). Other isolated end-points such as myocardial infarction or hospitalization for acute coronary syndromes had similar rates in both groups. On the other hand, symptoms were better controlled by PCI, but still with a modest reduction in these rates compared to OMT.

Some meta-analysis of studies comparing PCI with medical therapy alone[11,12] demonstrated similar results, even when only patients with objective myocardial ischemia were included in the analysis[13].

Thus, the information from these trials shows that even for multivessel patients, with preserved ejection fraction, stable non-limiting symptoms, medical therapy is a safe alternative. The groups of patients who benefit from bypass surgery are those with a higher anatomical or clinical risk profile, such as patients with left main disease or limiting symptoms. The option for bypass surgery should also consider peri-procedural risks and the possibility of recent graft failure, which is mainly dependent on the surgeon's technical ability but also by anatomic characteristics, especially the coronary bench that will receive the graft. The option for PCI in stable CAD patients should also be carefully evaluated because it does not protect patients from myocardial infarction, hospitalizations, and or from the risk of death. PCI could be indicated for those patients with limiting symptoms despite optimized medical therapy and with an anatomy favorable to the procedure.

IMPAIRED VENTRICULAR FUNCTION AND CAD

As already mentioned, the CASS trial[2] was one of the first randomized trials to demonstrate that bypass surgery is superior in terms of overall survival compared to medical therapy alone in patients with triple-vessel CAD and impaired ventricular function. Interestingly, in this context, only patients with a great percentage of jeopardized ischemic myocardium had the benefits of revascularization, because single- and double-vessel disease patients with impaired ventricular function had similar survival rates with bypass surgery compared to medical therapy. However, one should consider that the CASS trial enrolled only 160 patients with left ventricular dysfunction, so that it could not have power enough to demonstrate potential differences between treatment groups. On the other hand, medical therapy at that time was quite different from current medical therapy for heart failure. For the entire population of the CASS trial, 64% of the medical group received beta-blockers at 60 mo after randomization, while only 34% of the surgical group received beta-blockers at the same follow-up period. Besides, angiotensin-converting enzyme inhibitors were not disposable at that time, nor were aldosterone blockers, which are also current essential medications for the treatment of heart

failure patients. Similarly, anesthesia, cardioplegia methods, and surgical technique have also improved since CASS trial.

Interestingly, an analysis from the CASS registry[14] with patients with severe left ventricular dysfunction, manifested by an ejection fraction below 0.36, demonstrated that the group of patients assigned to surgery had an improvement in survival compared to medical therapy patients, despite a high operative mortality of 6.9%. Moreover, a higher benefit of surgery over medical therapy was observed in patients with ejection fraction below 0.26 (5-year survival of 63% *vs* 43%, respectively, for surgery and medical therapy, $P = 0.005$) and in patients with predominantly anginal symptoms. The patients in whom heart failure symptoms predominated did not receive benefits from surgery over medical therapy. Thus, surgery probably benefited heart failure patients who had some extent of viable and ischemic myocardium, and probably did not benefit those with non-viable, fibrotic myocardium.

The findings from the CASS trial and registry were the basis for cardiology guidelines recommendations and cardiology practice supporting CABG in this scenario in the following decades.

Recently, the STICH (Surgical Treatment for Ischemic Heart Failure) trial[15], published in 2011, questioned the superiority of CABG for CAD patients with impaired ventricular function. This was a multicenter, randomized, clinical trial, in which CAD patients amenable to surgery who had an ejection fraction of 0.35 or less were randomized to OMT or CABG plus OMT. During the 56-mo follow-up, the primary end-point of overall death occurred in 41% of the medical therapy group and in 36% of the CABG group ($P = 0.12$). Of note, 17% of medical therapy group patients underwent CABG during follow-up.

In this contemporary trial, the hypothesis tested in previous studies, including CASS, that bypass surgery would be superior to medical therapy in terms of survival was contradicted by the results of such a well-designed study. Some reasons might be pointed out for this interesting finding. First, medical therapy for heart failure has improved continuously during the last 20 years. The better knowledge of the physiopathology of heart failure lead to the development and use of classes of medications directed to neurohormonal cascades[16,17] related to the progression of ventricular dysfunction. In many clinical trials[18-20], these medications were proven to positively influence survival, and currently beta-blockers, angiotensin-converting enzyme inhibitors, and aldosterone blockers are the main stain of modern treatment. On the other hand, despite its higher initial risk of complications, bypass surgical treatment of ischemic heart failure may benefit patients with jeopardized ischemic myocardium, amenable to revascularization. Of note, 52% of the population of the STICH trial had Canadian Cardiac Society (CCS) angina class 0 or 1, and 37% had dyspnea New York Heart Association (NYH) class Ⅲ or Ⅳ. However, subgroup analysis did not show differences when angina or dyspnea groups were compared. Thus, a great percentage of patients might have fibrotic ischemic scars not amenable to improving its function by bypass surgery. Thus, on the one hand, medical therapy improved substantially over time and changed the outcomes of heart failure patients. On the other hand, surgery was performed in patients with a great variability of ischemic heart disease. The patients with the highest likelihood of benefitting from CABG would be those with a higher percentage of hibernating myocardium (potential to improve function with revascularization), and especially if suitable to be revascularized (good distal benches to receive an arterial or venous grafts).

DIABETES AND CAD

In stable CAD patients, diabetes mellitus confers higher rates of complications and a worse prognosis[21]. Considering that some previous trials have demonstrated that CABG was superior to medical therapy alone in high-risk groups of patients, the BARI 2D trial[22] proposed studying the comparative results of a strategy of OMT *vs* a strategy of coronary revascularization (PCI or CABG) for type-2 diabetic CAD patients. After 5 years, the primary end-point of overall survival was similar between the 2 groups (survival rates of 88.3% and 87.9%, respectively, for revascularization and medical therapy alone, $P = 0.97$). Moreover, the rates of freedom from cardiovascular events (death, myocardial infarction, or stroke) were also similar between groups (77.2% and 75.9%, respectively, for revascularization and medical therapy groups, $P = 0.70$). When patients were stratified by the choice of PCI or CABG as the appropriate intervention, in the PCI stratum, survival and composite end-points were similar between medical therapy and PCI. In CABG stratum, survival was similar between medical therapy and CABG, although the rates of cardiovascular events were higher in medical therapy than in CABG.

Contrary to results of the BARI 2D trial, a substudy of 10-year results of the MASS Ⅱ trial[23] analyzed diabetic CAD patients in terms of comparative outcomes among medical therapy, PCI, and CABG in a long-term follow-up. Among diabetic patients ($n = 232$), mortality rates were 37.5%, 31.3%, and 27.5%, respectively, for medical therapy, PCI, and CABG ($P = 0.015$ for CABG *vs* medical therapy). Cardiac mortality also favored CABG-assigned patients, as the rates were 26.1%, 18.8%, and 12.5%, respectively ($P = 0.005$ for CABG *vs* medical therapy).

The strong evidence from BARI 2D is not con-

Table 1 Main randomized clinical trials comparing medical therapy alone with coronary interventions in stable coronary artery disease patients

Clinical scenario	Clinical trial	Randomization period	*n*	Study groups	Annual mortality	Main findings
Single-vessel CAD	MASS I (3.5 yr)	1988-1991	214	MT 72 PCI 72 CABG 70	MT 0 PCI 0.4% CABG 0.4%	Similar mortality and MI among the 3 groups
Multivessel CAD (majority of trials' patients)	VA (18 yr)	1972-1974	686	MT 354 CABG 332	MT 3.7% CABG 3.9%	Similar mortality and MI rates in the 2 groups
	ECSS (12 yr)	1973-1976	767	MT 373 CABG 394	MT 2.7% CABG 2.4%	Mortality higher in MT group in 3-vessel disease patients
	CASS (10 yr)	1975-1979	780	MT 390 CABG 390	MT 2.1% CABG 1.9%	Similar mortality in 1, 2 or 3-vessel with EF ⩾ 0.50. CABG was superior in 3-vessel with EF < 0.50
	MASS II (5 yr)	1995-2000	611	MT 203 PCI 205 CABG 203	MT 2.4% PCI 2.3% CABG 1.6%	Similar mortality in the 3 groups. Similar events in MT and PCI. CABG superior in terms of reinterventions
	COURAGE (4.6 yr)	1999-2004	2287	MT 1138 PCI 1149	MT 1.8% PCI 1.65%	Similar mortality and events in the 2 groups
Impaired ventricular function	STICH (4.6 yr)	2002-2007	1212	MT 602 CABG 610	MT 8.8% CABG 7.7%	Similar mortality rates. CABG superior in terms of hospitalization for cardiac causes
Diabetes mellitus	BARI 2D (5.3 yr)	2001-2005	2368	MT 1192 CABG/ PCI 1176	MT 2.3% CABG/PCI 2.2%	Similar mortality and MI rates in the 2 strategies
Elderly	TIME (3.1 yr)	1996-2000	282	MT 142 CABG/PCI 140	MT 7.2% CABG/PCI 6.8%	Similar mortality and MI rates between the 2 strategies

CAD: Coronary artery disease; MASS: Medical, Angioplasty or Surgery Study; VA: Veterans Affairs; ECSS: European Coronary Surgery Study; STICH: Surgical Treatment for Ischemic Heart Failure; TIME: Medical Therapy in Elderly patients; MT: Medical therapy; PCI: Percutaneous coronary intervention; CABG: Coronary artery bypass surgery.

firmed by other substudies like the MASS trial. A higher risk profile in the MASS trial, as well as the intensity of treatment in BARI 2D may explain in part such differences.

ELDERLY PATIENTS AND CAD

With the aging of the world population in recent decades, CAD has become more frequent. In addition, in the elderly, the likelihood of severe and diffuse CAD is higher than in younger populations[24]. Moreover, due to higher rates of procedure-related complications[25,26] and a lack of clinical trials comparing treatments in patients older than 65 years, the treatment of this specific population becomes even more challenging.

A sub analysis from the CASS registry[27] showed that in 1985 older CAD patients surgically treated had better survival rates compared to medically treated patients, during a 6-year follow-up (adjusted 6-year survival 79% and 64%, respectively, for surgical and medical therapy groups, $P < 0.0001$). However, this study should be carefully analyzed as this was a non-randomized study, and there were important baseline differences between the two treatment groups.

Another prospective, observational study published in 2002 analyzed clinical data and outcomes of all patients who underwent catheterization and revascularization in the province of Alberta, Canada[28]. This study showed that in 3 age cohorts (< 70 years, 70-79 years, and ⩾ 80 years), CABG was superior to PCI and medical therapy alone in terms of overall survival during 4-year follow-up. However, this study has also to be analyzed carefully because its design was observational, non-randomized, and included a great range of risk profiles, such as acute coronary syndrome patients as well as patients with impaired ventricular function, which may have favored surgical results.

One of the few studies designed to compare a conservative *vs* an invasive strategy for the treatment of elderly CAD patients was the Trial of Invasive *vs* Medical therapy in Elderly patients (TIME), published in 2004[29]. In this study, patients age 75 years or older, with Canadian Cardiac Society (CCS) class Ⅱ or greater angina, despite taking at least 2 classes of anti-anginal drugs, were randomized to medical therapy alone or to angiography and appropriate coronary revascularization (PCI or CABG). Despite their high-risk profile (mean age at entry 80-year-old, 82% with CCS class Ⅲ or Ⅳ angina), survival was similar between patients in the two strategies (91.5% *vs* 95.9% after 6 mo, 89.5% *vs* 93.9% after 1 year, and 70.6% *vs* 73.0% after 4.1 years, respectively, for medical therapy and revascularization strategies, P = NS). However, late revascularizations were more frequent in the medical therapy than in the revascularization group (45% *vs* 12%, $P < 0.0001$).

Post-hoc analysis of elderly CAD patients from the COURAGE trial[30] also demonstrated similar survival rates between conservative and invasive

strategies.

A recent post-hoc analysis of patients 65 years or older from the 10-year follow-up of the MASS Ⅱ trial[31] also showed similar overall survival rates comparing the three treatment strategies, medical therapy, PCI with conventional stents or CABG (63%, 69% and 66%, P = 0.93). The rates of myocardial infarction were also similar among the three groups. However, as demonstrated in the TIME trial, the rates of additional revascularizations were lower in the CABG group (Table 1).

EXTENSION OF MYOCARDIAL ISCHEMIA

Although ESC guidelines[32] and some retrospective studies[33,34] have suggested that patients with myocardial ischemia extension greater than 10% benefit from myocardial revascularization, no prospective study have confirmed this finding. Currently, the on-going International Study of Comparative Health Effectiveness with Medical and Invasive Approaches (ISCHEMIA) trial, which aims at randomizing 8000 coronary artery disease patients with moderate or severe ischemia to an invasive or a conservative strategy, should help to bring some reliable information in this matter.

CLINICAL IMPLICATIONS AND CONCLUSION

Despite the strength of several study findings, significant developments in aggressive MT and lifestyle prescriptions with comprehensive risk factor modification have continued to occur since trials were conducted, and this may impact the outcomes of an MT-based strategy, even in the long-term follow-up. Further evidence in this long-running debate will be provided by the results of current trials of the initial MT strategy in patients with stable multivessel disease and preserved ventricular function. Moreover, results of studies on drug-eluting stents demonstrating the superiority of CABG over PCI have been questionable, and some might argue that this procedural refinement makes the present results obsolete. However, data from randomized and nonrandomized trials show that this new type of stent has no advantageous effect on death and nonfatal MI relative to bare-metal stents despite yielding striking reductions in rates of restenosis and repeat revascularization procedures. Thus, we believe that the observations reported herein with respect to death and MI remain applicable to contemporary practice.

In summary, several trials strongly show the benefits of PCI and CABG over MT in regard to some end points at long-term follow-up, although with similar rates of overall mortality. Additionally, CABG surgery is associated with higher rates of event-free survival.

Abstract

AIM: To assess the correlation between blood pressure levels and fasting plasma glucose levels among young adults attending Chatrapati Shahuji Maharaj University, Kanpur, India.

METHODS: The present study was cross-sectional in nature, conducted among students in the Institute of Paramedical Sciences, Chatrapati Shahuji Maharaj University, Kanpur. Study subjects included 185 young adults. Among them, 94 were males and 91 were females, in the age group 17 to 19 years.

RESULTS: Mean age among males was 18.5 ± 1.5 years and among females was 17.9 ± 1.8 years. Of the total 185 study subjects, 61 (32.9%) were classified as pre-diabetic and 20 (10.8%) as pre-hypertensive. Mean waist circumference, systolic blood pressure and serum high density lipoprotein did not vary significantly between normoglycemic and pre-diabetic subjects. However, the mean diastolic blood pressure of pre-diabetics (82 ± 5 mmHg) was significantly higher than normoglycemics (79 ± 6 mmHg). Mean

serum cholesterol, serum triglycerides, serum low density lipoprotein (LDL) and serum very low density lipoprotein was also higher among pre-diabetic subjects in comparison to normoglycemic subjects and the difference was statistically significant. Upon multiple linear regression analysis, it was observed that body mass index (BMI) (β = 0.149), diastolic blood pressure (β = 0.375) and serum LDL (β = 0.483) were significantly associated with fasting plasma glucose. Multiple linear regression with diastolic blood pressure as the outcome variable showed that BMI (β = 0.219), fasting blood glucose (β = 0.247) and systolic blood pressure (β = 0.510) were significantly associated.

CONCLUSION: A significant prevalence of pre-diabetes and pre-hypertension in young adults is a matter of concern therefore all young adults need to be targeted for screening of diabetes and hypertension and lifestyle modification.

Key words: Adolescent; Hypertension; Diabetes; Co-prevalence; India

Core tip: In the present study, 32.9% young adults were pre-diabetic whereas 10.8% were pre-hypertensive. Around 2.7% young adults had both pre-diabetes and pre-hypertension. Among the pre-hypertensives, 25% also had pre-diabetes. However among the pre-diabetics, 8.2% had pre-hypertension. The correlation between systolic blood pressure and fasting plasma glucose was not statistically significant. However, the correlation between diastolic blood pressure and fasting plasma glucose was significant. The mean diastolic blood pressure of pre-diabetics (82 ± 5 mmHg) was significantly higher than normoglycemics (79 ± 6 mmHg). Upon multiple linear regression analysis, it was observed that body mass index (β = 0.149), diastolic blood pressure (β = 0.375) and serum LDL (β = 0.483) were significantly associated with fasting plasma glucose.

Midha T, Krishna V, Shukla R, Katiyar P, Kaur S, Martolia DS, Pandey U, Rao YK. Correlation between hypertension and hyperglycemia among young adults in India. *World J Clin Cases* 2015; 3(2): 171-179 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i2/171.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i2.171

INTRODUCTION

Diabetes and hypertension is the twin epidemic, rapidly on the rise in the developing countries[1]. Diabetes mellitus or chronic hyperglycemia is a metabolic disorder which results from defects in carbohydrate, fat and protein metabolism that occur as a consequence of deranged insulin secretion or action. Long term hyperglycemia is associated with the development of cardiovascular disease, renal disease, neuropathy, retinopathy, peripheral vasculopathy, and stroke[2]. World Health Organization (WHO) has estimated that globally the number of adults with diabetes will increase from 171 million in 2000 to 366 million in the year 2030[3]. In 2004, worldwide, around 3.4 million people died as a result of hyperglycemia[4]. Of the total deaths among diabetics, around 80% occur in developing countries[5]. According to WHO, diabetes will be the 7th leading cause of global mortality in 2030[6]. India has been declared as the capital of diabetes because approximately 41 million Indians have diabetes to date and every fifth diabetic in the world is an Indian[7].

Worldwide, hypertension or high blood pressure has caused around 7.5 million deaths, which accounts for 12.8% of the global mortality. Around 57 million disability adjusted life years (DALYS) or 3.7% of total DALYS have been attributed to hypertension[8]. The global prevalence of hypertension in adults more than 25 years of age, averaged around 40% in 2008[8]. The WHO has estimated that hypertension is directly responsible for about 62% of stroke and 49% of coronary artery disease, worldwide[9]. In a meta-analysis of prevalence studies on hypertension in India, from January 2000 to June 2012, it was observed that the prevalence of hypertension in the urban population was 40.8% whereas that in the rural population was 17.9%[10]. Hypertension leads to cardiovascular disease, peripheral vasculopathy, cerebrovascular disease, and nephropathy[11].

It has been observed that diabetes and hypertension often exist together in the population. The risk of developing hypertension is 1.5-2.0 times higher in diabetics as compared to non-diabetics, whereas around one-third of the hypertensives develop diabetes[12]. These co-morbidities hasten the progress of vascular complications[13-15].

Diabetes and hypertension both can be prevented and managed by lifestyle modification and medical intervention. Moreover, screening and early management of diabetes and hypertension, through periodic surveillance, will slow down the progress of the disease and prevent complications[16]. American Diabetic Association has described a new entity of impaired glucose metabolism as prediabetes in which two categories are included-Impaired Fasting Glucose, when fasting plasma glucose is between 100 and 125 mg/dL and Impaired Glucose Tolerance, when 2-h result following oral glucose tolerance test is between 140 and 199 mg/dL[17]. Persons with prediabetes, are at greater risk for the future development of diabetes as well as cardiovascular disease[18]. According to JNC-7,

systolic blood pressure 120-139 mmHg and/or diastolic blood pressure 80-89 mmHg was classified as pre-hypertension[19]. Similarly, individuals with pre-hypertension are pre-disposed to developing hypertension in the later years of life.

Though the manifestation of cardiovascular disease occurs in middle age and later, it has now been proved that the initiation of cardiovascular disease occurs in childhood and adolescence[20]. The known risk factors of cardiovascular disease such as hypertension, raised blood glucose, raised serum cholesterol, tobacco consumption, high fat diet and obesity start early in childhood and adolescence and then continue into adulthood[20]. Screening and early identification of these risk factors and their progenitors like pre-diabetes and pre-hypertension may go a long way to prevent cardiovascular morbidity and mortality in adults.

The overall prevalence of glucose intolerance among adolescents in South India was reported to be 3.7%[21]. Prevalence of hypertension among children and adolescents in north India was observed to be 9.4%[22].

The rising prevalence of diabetes and hypertension in India, their beginning in the adolescent age group, and the co-occurrence of the two disease entities, is a cause of concern, therefore this study was planned to study the association between hypertension and hyperglycemia in Indian young adults.

MATERIALS AND METHODS

Study design and sample size

It was a cross-sectional study. The minimum sample size required (n = 89) was calculated taking a prevalence of glucose intolerance of 3.7%, as reported in the ORANGE-2 study, with a precision of 4% and a confidence level of 95%[21]. The formula used was, $n = Z_{(1-\alpha/2)}{}^2 pq/d^2$ (where $Z_{(1-\alpha/2)}$ was taken at 95%CI; P = prevalence of obesity, q = 100-p; d = absolute precision). For this study, P = 3.7%; q = 96.3%; d = 4%. Adding a 10% for incomplete answers, the total number came out to be 98. A design effect of 2 was included to minimize any error due to inherent variation in the population. The calculated sample size was multiplied by 2 to obtain the sample size of 196.

Sampling

The study was conducted among students in the Institute of Paramedical Sciences, affiliated to Chatrapati Shahuji Maharaj University, Kanpur. The Institute of Paramedical Sciences provides a course of 4 years in Paramedical Sciences and enrols around 100 students annually. A list of all the students enrolled in the Institute in the first, second and third year was obtained. Systematic random sampling technique was applied to identify the required number of study subjects. Written informed consent was taken from the students and their parents/guardians. In case a student refused to participate in the study, the next consecutive student was included. The data was analyzed for 185 subjects only whose laboratory test results were available. Among the study subjects thus selected, 94 were males and 91 were females, in the age group 17 to 19 years.

Methodology

A standard mercury sphygmomanometer, Diamond Co., Industrial electronics and Allied Products, Pune, Maharashtra, India, was used for recording blood pressure. Blood pressure (BP) was measured on the left arm, in the sitting position, using appropriate size cuffs. Before the measurement was taken, the subject was seated for at least 5 min. Care was taken that the arm muscles were relaxed and the arm was placed at heart level. The cuff was applied to the left upper arm and was inflated until the manometer reading was 30 mmHg above the level at which the radial pulse disappeared, and thereafter the cuff was slowly deflated. The Korotkoff sounds were monitored using a stethoscope applied over the brachial artery. The first (appearance) and the fifth (disappearance) Korotkoff sounds were noted as the systolic and diastolic blood pressure, respectively. Blood pressures were measured twice and their mean was recorded. Subjects were categorized into normotensive, pre-hypertensive and Stage I and Stage II hypertensive based on the blood pressure classification for adolescents for subjects of age 17 years and according to JNC-7 for subjects $\geqslant$ 18 years[19,23]. JNC-7 has classified systolic blood pressure (SBP) < 120 mmHg and a diastolic blood pressure (DBP) < 80 mmHg as normal blood pressure; SBP 120-139 mmHg and/or DBP 80-89 mmHg as pre-hypertension; SBP 140-159 mmHg and/or DBP 90-99 mmHg as Stage I hypertension and SBP $\geqslant$ 160 mmHg and/or DBP $\geqslant$ 100 mmHg as stage II hypertension[19]. For adolescents upto 17 years of age, normal BP was defined as systolic and diastolic blood pressure < 90th percentile, Prehypertension as systolic or diastolic blood pressure 90th percentile to < 95th percentile or blood pressure > 120/80 mmHg to < 95th percentile, Stage 1 Hypertension (HTN) as systolic and/or diastolic blood pressure 95th percentile to 99th percentile plus 5 mmHg and Stage 2 HTN as systolic and/or diastolic blood pressure > 99th percentile plus 5 mmHg[23].

According to American Diabetic Association, subjects were classified as normoglycemic when fasting plasma glucose was less than 100 mg/dL after 8 h fasting, prediabetic when fasting plasma glucose was between 100 and 125 mg/dL and diabetic when fasting plasma glucose was more than

126 mg/dL[17].

Body weight was estimated, using Krup's weighing machine, with a least count of 0.5 kg. The subject was made to stand on the weighing scale, feet around 15 cm apart, and weight distributed on both the legs. Zero setting was done before each measurement. Height was estimated, with the subject standing upright against the wall such that the roof of the external auditory meatus was in line with the lower margin of the orbit. A hard board was placed on the wall, just over the head and height was marked on the wall and measured with a measuring tape with a least count of 0.5 cm. Waist circumference was measured, at the level of the umbilicus, with the subject in the erect position, breathing silently.

Fasting blood samples were drawn on the day subsequent to the interview. A total of 10 mL blood was collected from each subject: 4 mL in EDTA tube and 6 mL in plain tube. The samples were immediately sent to the laboratory in the Department of Biochemistry, Chatrapati Shahuji Maharaj University, Kanpur. The samples were centrifuged without any delay. The samples were analyzed for glucose on the same day. Remaining plasma and serum was aliquoted and stored at -70 deg C. Lipid

Normotension	56	33.9	109	66.1	165

estimations were done in batches in serum samples. Standard internal quality control procedures for laboratory were followed. Fasting plasma glucose was estimated using the Enzymatic colorimetric GOD-PAP method, Serum Cholesterol using Enzymatic Colorimetric High Performance CHOD-PAP method, Serum HDL using Enzymatic Colorimetric High Performance CHOD-PAP method, and Serum triglycerides using colorimetric method[24].

Data was compiled using Microsoft Excel and analysed using SPSS 17.0. Pearson's Chi square test was applied to study the difference between categorical variables. Student's t-test was used to analyse the difference between continuous variables. Two-tailed P-value less than 0.05 was considered significant. Pearson's correlation coefficient was applied to determine the association between fasting plasma glucose and systolic and diastolic blood pressure. Multiple linear regression analysis was done to analyse the association of various determinants with fasting plasma glucose.

Statistical analysis

The statistical methods are adequately and appropriately applied to the best of the authors' knowledge.

RESULTS

Data was analyzed for 185 subjects, 94 males and 91 females. Mean age among males was 18.5 ± 1.5 years and among females was 17.9 ± 1.8 years. Among the subjects living in urban area, 47.1% were males whereas among those living in rural areas 57.6% were males (Table 1). Subjects predominantly belonged to Hindu religion. Among those who were sedentary, 40.6% were males, whereas among heavy workers, 66.7% were males. However, there was no statistically significant association between physical activity and gender. Of all the study subjects, 12 (6.4%) were smokers and all were male (100%). The association between smoking and gender was statistically significant.

Among the total study subjects, 61 (32.9%) were pre-diabetic whereas 20 (10.8%) were pre-hypertensive. Five (2.7%) subjects had both pre-diabetes and pre-hypertension. Among the pre-hypertensives, 25% also had pre-diabetes (Table 2). However among the pre-diabetics, 8.2% had pre-hypertension.

The correlation of systolic blood pressure with fasting plasma glucose was not found to be stati-

Table 3 Correlation between fasting plasma glucose and systolic and diastolic blood pressure among study subjects

Fasting plasma glucose	Pearson's correlation coefficient	*P* value[1]
Systolic blood pressure	0.045	0.546
Diastolic blood pressure	0.301	< 0.001[2]

[1]Pearson's Correlation coefficient; [2]*P* value < 0.05 is significant.

stically significant. However, the correlation of diastolic blood pressure with fasting plasma glucose was significant ($P < 0.001$) (Table 3).

Among the normoglycemic subjects, mean BMI was 20.6 ± 42.0 kg/m^2 whereas among the pre-diabetic subjects the BMI was 21.8 ± 3.0 kg/m^2 and the association was found to be significant (Table 4). There was no significant association between the waist circumference, systolic blood pressure and serum HDL of normoglycemic and pre-diabetic subjects. However, the mean diastolic blood pressure of pre-diabetics (82 ± 5 mmHg) was significantly higher than normoglycemics (79 ± 6 mmHg). Mean serum cholesterol, serum triglycerides, and serum VLDL was also higher among pre-diabetic subjects as compared to normoglycemic subjects and the association was found to be significant. Mean serum LDL was also significantly higher in prediabetics (104.1 ± 22.7 mg/dL) than in normoglycemics (92.7 ± 23.6 mg/dL).

Multiple linear regression analysis for the determinants of fasting plasma glucose was done and the adjusted R^2 was 23.5% (Table 5). Waist circumference, systolic blood pressure, serum cholesterol, serum triglycerides, serum HDL, serum VLDL were not significantly associated with fasting plasma glucose. For every 1 mmHg increase in diastolic blood pressure, the fasting plasma glucose was expected to rise by 0.375 mg/dL ($\beta = 0.375$) and this association was found to be significant ($P < 0.05$). Similarly, BMI ($\beta = 0.149$), and serum LDL ($\beta = 0.483$) were also significantly associated with fasting plasma glucose.

Multiple linear regression analysis was done for systolic blood pressure as the outcome variable and the adjusted R^2 was 43.7% (Table 6). Diastolic blood pressure and serum LDL were observed to be significantly associated. Multiple linear regression analysis for diastolic blood pressure as the outcome variable showed an adjusted R^2 of 49.6% (Table 7). BMI ($\beta = 0.219$), fasting plasma glucose ($\beta = 0.247$) and systolic blood pressure ($\beta = 0.510$) were found to be significantly associated.

DISCUSSION

In this study, the overall prevalence of pre-diabetes was 32.9%. In another study from Dhaka, Bangladesh, around 20% subjects aged 11-18 years, with BMI $\geqslant$ 95th percentile for age and sex using CDC growth chart, were reported to have impaired glucose tolerance as detected after two hours oral glucose tolerance test[25]. A study from United States revealed that 21 percent of obese adolescents between 11 and 18 years had impaired glucose tolerance following two hours oral glucose tolerance test[26]. The difference from our study may be due to the criteria used for impaired glucose tolerance as we have considered fasting plasma glucose, whereas the other studies have considered the plasma glucose after a two hours oral glucose tolerance test which may have greater specificity in labelling impaired glucose tolerance. In a study from South India, the prevalence of impaired glucose tolerance was 3.7% in children and adolescents 6-19 years following oral glucose tolerance test[21]. The low prevalence as compared to our study may be due to the large age range of study subjects and the criteria used for impaired glucose tolerance.

In our study, the prevalence of pre-hypertension was 10.8%. The prevalence of pre-hypertension among adolescents from Wardha, in central India, was reported as 10.6%, which was very similar to our results[27]. This was also in concordance with the results of another study from Shimla, in north India wherein the prevalence of prehypertension was found to be 12.3%[28].

The present study revealed that 5 (2.7%) subjects had both pre-diabetes and pre-hypertension. However, the multi-center Screening India's Twin Epidemic (SITE) survey revealed that 20.6% of the study subjects had co-existent diabetes and hypertension[16]. In our study, among the pre-hypertensives, 25% also had pre-diabetes whereas in the SITE study, among 7212 hypertensives, 3227 (44.7%) had diabetes. The present study showed that among the pre-diabetics, 8.2% had pre-hypertension whereas in the SITE study, among 5427 diabetics, 59.5% were hypertensive.These differences may be because only adult subjects more than 18 years were studied in the SITE survey whereas our study included subjects in the 17 to 19 years age group.

Hypertension is responsible for acceleration of the vascular complications of diabetes, including coronary artery disease, renal disease, and retinopathy[29]. The pathophysiology of hypertension occurs at the cellular level in the intima of the arteries, which involves the function of the endothelial cells. Hypertension and diabetes both alter the endothelial cell structure and function. In large and medium size vessels and in the kidney, endothelial dysfunction causes proliferation of vascular smooth muscle cells and vasoconstriction of mesangial cells[29]. These alterations in the smooth muscle cells lead to atherosclerosis and glomerulosclerosis. Similarly, proliferation of retinal capillary endothelial cells causes retinopathy. Therefore, endothelial

cell damage is responsible for the complications of diabetes and this damage is accelerated by co-existing hypertension[29].

Co-occurrence of hypertension in diabetics increases the risk of development of macrovascular and microvascular complications[30,31]. Diabetic

individuals with coexisting hypertension have a much higher occurrence of cerebrovascular accidents as compared to diabetics with normal blood pressure[30,32,33]. The risk of peripheral vasculopathy also increases in case of co-existence of hypertension in diabetics[33]. Both hypertension and diabetes lead to coronary artery disease[34]. It has been observed that in hypertensive diabetics, the risk of death due to cardiovascular disease is almost doubled[34]. Hypertension accelerates the progress of diabetic retinopathy and nephropathy[35,36]. Hypertension in diabetics hastens the occurrence of microalbuminuria and the progress of nephropathy after the development of proteinuria[36].

In our study, mean waist circumference, systolic blood pressure and serum HDL did not vary significantly between normoglycemic and pre-diabetic subjects. However, the mean diastolic blood pressure of pre-diabetics (82 ± 5 mmHg) was significantly higher than normoglycemics (79 ± 6 mmHg). Correlation between systolic blood pressure and fasting plasma glucose was not statistically significant. However, the correlation of diastolic blood pressure with fasting plasma glucose was significant ($P < 0.001$).

In the present study, upon multiple linear regression analysis for fasting plasma glucose, BMI (β = 0.149) diastolic blood pressure (β = 0.375) and serum LDL (β = 0.483) were found to be significantly associated. However, in the study from South India, on multiple regression analysis, only family history of diabetes (OR 4.11) and HOMA-IR (insulin resistance assessed by homeostasis model assessment) (OR 11.22) were found to be significant in girls and only HOMA-IR (OR 5.19) was associated with glucose intolerance in boys[21]. Due to financial constraints, HOMA-IR assessment was not included in our study. Upon multiple linear regression for diastolic blood pressure, it was observed that BMI (β = 0.219), fasting plasma glucose (β = 0.247) and systolic blood pressure (β = 0.510) were significantly associated.

The present study reveals that prediabetes and pre-hypertension begin to occur in young adults. It is well known that the prevalence of cardiovascular disease is increasing among Indians, occurring especially at a younger age[12]. Therefore it is imperative that policies and programs be developed for identifying and successfully managing hypertension and diabetes at an early age.

Given the risk associated with co-prevalence of diabetes and hypertension, it is important to identify young adults with pre-diabetes and pre-hypertension who are prone to develop full blown disease as adults, and it is the need of the hour that guidelines be formulated under the National Program for Prevention and Control of Cancer, Diabetes, CVD and Stroke (NPCDCS) for primordial and primary prevention efforts through evidence-based screening and health education initiatives. Health education programs among young adults regarding lifestyle modification to curb diabetes and hypertension in their incipient stage may be considered as a cost-effective public health approach in dealing with the morbidity attributed to consequent cardiovascular diseases.

COMMENTS

Background

As per World Health Organization estimates, globally the number of adults with diabetes will rise from 171 million in 2000 to 366 million in the year 2030. India has been declared as the capital of diabetes because approximately 41 million Indians have diabetes till date and every fifth diabetic in world is an Indian.The global prevalence of raised blood pressure or hypertension in adults aged 25 and over was around 40% in 2008. A meta-analysis of prevalence studies on hypertension in India, from January 2000 to June 2012, revealed a high prevalence of hypertension in the urban (40.8%) as well as rural population (17.9%). The co-prevalence of diabetes and hypertension is strongly associated with cardiovascular disease. Prevalence of cardiovascular disease

is on the rise among Indians, especially at a younger age, therefore early detection and management of hypertension and diabetes may hold the key to reducing cardiovascular mortality in India. Prevalence of glucose intolerance among adolescents in South India was reported to be 3.7%. Prevalence of hypertension among children and adolescents in north India was observed to be 9.4%. The high prevalence of diabetes and hypertension in India with their beginning in the adolescent age group, and the co-occurrence of the two disease entities leading to cardiovascular diseases, is an area of concern. Screening and health education programs regarding lifestyle modification may be considered as a cost-effective public health approach in dealing with the morbidity attributed to cardiovascular diseases. Therefore, a precise estimate of the prevalence of diabetes and hypertension among Indian young adults is required to assess the magnitude of the problem that has to be addressed and to design programs and policies for prevention and control.

Research frontiers

Pre-diabetes and pre-hypertension have a high degree of co-prevalence among Indian young adults and this knowledge will help in shaping primordial and primary level preventive programs for our country.

Innovations and breakthroughs

In India, very few studies are available on the prevalence of diabetes and hypertension among young adults and none have analysed the association between the two co-morbidities. Given the risk associated with co-prevalence of diabetes and hypertension, it is important to estimate their prevalence among Indian young adults to provide evidence-based guidelines for preventive efforts through screening and health education initiatives.

Applications

Very few studies on the prevalence of diabetes and hypertension among young adults are available in India; and this study reveals their co-prevalence in the indigenous population and emphasizes the need to develop a strategy for prevention of these co-morbidities to bring down the consequent cardiovascular morbidity and mortality in India.

Terminology

Regression analysis is a statistical process for estimating the relationships among variables. It includes many techniques for modeling and analyzing several variables, when the focus is on the relationship between a dependent variable and one or more independent variables. More specifically, regression analysis helps one understand how the typical value of the dependent variable changes when any one of the independent variables is varied, while the other independent variables are held fixed. In statistics, linear regression is an approach for modeling the relationship between a scalar dependent variable y and one or more explanatory or independent variables denoted X. The case of one explanatory variable is called simple linear regression. For more than one explanatory variable, the process is called multiple linear regression. The beta (β) regression coefficient is computed to assess the strength of the relationship between each predictor variable and the dependent variable.

Abstract

AIM: To systematically review the literature to assess the efficacy of corticosteroids in treating post-parotidectomy facial nerve palsy (FNP).

METHODS: We searched the Cochrane library, EMBASE and MEDLINE (from inception to 2014) for studies assessing the use of corticosteroids in post-parotidectomy FNP. Studies were assessed for inclusion and quality. Data was extracted from included studies.

RESULTS: Two randomised controlled trials met the inclusion criteria. One study assessed the use of dexamethasone and the other prednisolone. None of the studies demonstrated a significant difference in the outcome of FNP post-parotidectomy with the use of corticosteroids *vs* no therapy. The majority of FNP post-parotidectomy is transient. Preoperative factors (size of tumour and malignancy), intraoperative factors (extent of parotidectomy and integrity of facial nerve at the end of the operation) are important in determining prognosis of FNP if it does occur.

CONCLUSION: Corticosteroids do not appear to improve FNP prognosis post-parotidectomy. Further studies assessing patients by cohort and with long term follow-up are required to increase scientific evidence.

Key words: Adrenal cortex hormones; Facial paralysis; Parotid diseases; Steroids

Core tip: Parotidectomy is a common operation performed to treat benign and malignant parotid lesions. Facial nerve palsy (FNP) is a well documented complication of parotidectomy that can significantly impair quality of life. Steroids have been proposed as a treatment option for post-parotidectomy FNP. In this systematic review of randomised controlled trials, we found minimal evidence to suggest steroids improve the prognosis of FNP after parotidectomy. However, more trials are required to assess the effectiveness of steroids in specific cohorts of patients.

INTRODUCTION

Parotid surgery remains a key surgical intervention for the treatment of both benign and malignant parotid tumours. Facial nerve palsy (FNP) is a potential complication that can occur as a consequence of a parotidectomy.

When post-parotidectomy FNP occurs it is usually transient. The incidence of temporary FNP post-parotidectomy has a reported range of 12% to just over 40%[1-6]. Permanent FNP is less common with a reported incidence of 0%-6%[1-5]. Key factors linked to increased risk of postoperative FNP include: the extent of the parotidectomy[1,3,6,7], revision surgery[3,7], proximity of the tumour to the facial nerve[5,7], malignancy[6] and inflammatory conditions (*e.g.*, sialadenitis)[4,5,7].

FNP can significantly affect quality of life[8], leading to distress for the patient[9] in addition to the potential for ocular complications[10]. Reducing the risk of FNP is therefore paramount. Intraoperatively this includes the use of key anatomical landmarks[11] and a facial nerve monitor as an adjunct[12].

As most cases of post-parotidectomy FNP are temporary there is a paucity of evidence assessing interventions to improve recovery of FNP. The use of corticosteroids significantly improves chance of complete recovery of FNP in Bell's palsy, with a reduction in neural oedema of the FN as a postulated mechanism[13]. Although Bell's palsy is a distinct entity to post-parotidectomy FNP, it is thought that corticosteroids could improve FNP prognosis through a similar mechanism[14].

To date there has been no systematic review assessing the efficacy of corticosteroids in ameliorating post-parotidectomy facial nerve paralysis. We sought to assess the effectiveness of corticosteroids versus no treatment in patients with post-parotidectomy FNP.

MATERIALS AND METHODS

Inclusion Criteria for considering studies

Types of studies: Well-designed randomised control trials that compared the use of steroids with no steroids for post-parotidectomy facial nerve paralysis were included.

Types of participants: Patients undergoing parotidectomy (superficial and deep) for benign parotid lesions and malignant parotid lesions.

Types of interventions: We included trials that utilised corticosteroids of any type for post-parotidectomy facial nerve paralysis.

Outcome measures: The primary outcome measure was facial nerve function monitored at increments after parotidectomy. Objective assessment of the facial nerve function is undertaken utilising the House Brackmann scale, and further classified based upon the location of the facial muscle.

Search strategy

We developed a search strategy to identify randomised controlled trials in the following databases: MEDLINE, EMBASE, Cochrane Library and NHS Evidence (from inception until August 2014). Search terms were as follows: "steroids" AND "parotidectomy", "dexamethasone" AND parotidectomy and "prednisolone" AND "parotidectomy". Relevant articles were then selected and their references screened to identify further articles.

Data collection and analysis

Study selection: Two review authors (KV and IB) assessed abstracts for relevant articles and the full text of these was obtained. The review authors (KV and IB) independently assessed these full-text articles, and any disagreements on inclusion were resolved by discussion with a third author (ND).

Data extraction: Two review authors (KV and IB) extracted data from included studies with standardised forms. Data extracted included: authors, year of publication, participants (sample size, demographics, type and extent of parotid lesion, type of parotid surgery performed, *etc.*), intervention (type of steroid used and duration) and results (primary and secondary outcome measures, effect size, statistical significance, adverse effects).

Quality assessment: To assess the risk of bias in included studies we utilised the Cochrane risk of bias tool[15].

Statistical analysis

Due to a variation in the type of corticosteroids utilised in included studies (with regards to potency and duration of action) and variations in the protocol of administration, a meta-analysis was not appropriate and thus not carried out.

RESULTS

Description of studies

The original search produced 46 abstracts, from which 11 duplicate studies were excluded. The remaining 35 articles were screened for relevance. 33 articles were rejected as they did not meet the inclusion criteria. A total of two papers met the

eligibility criteria[14,16].

Reasons for exclusion included the study having no relevance to the research question (n = 32) and not being a randomised controlled trial (n = 1). Table 1 summarises included studies.

Interventions

Of the two included studies the interventions used to assess corticosteroid efficacy in post-parotidectomy FNP were dexamethasone[14] and prednisolone[16].

Dexamethasone was administered in two doses intravenously (stratified based on extent of parotid surgery with superficial receiving 0.51 mg/kg and deep receiving 1.41 mg/kg) administered at 8 and 16 h postoperatively[14].

Prednisolone was administered orally as a 10-d reducing course (50 mg/d for 5 d, 30 mg/d for 3 d and 10 mg/d for 2 d)[16].

The control groups received intravenous saline[14] and oral lactose[16] administered with the same protocol as their respective interventions.

Participants

The participant cohort varied slightly between both trials. One included all patients undergoing parotid surgery[14], whilst the other only included those who developed a postoperative FNP[15]. Parotid operations ranged from superficial to total (or deep) parotidectomy in both trials and both studies included only adult patients[14,16].

Outcomes and follow-up

Both trials assessed facial nerve function through clinical assessment. One assessed four facial nerve muscle groups and graded percentage function[14]. The other utilised the House Brackmann scale[17] [grading facial from 1 (normal function) to 6 (total paralysis)][16]. Duration of postoperative follow-up ranged from 6 mo[16] to 12 mo[14].

Risk of bias in included studies

Both included studies were assessed for quality focusing particularly on: randomisation methods, concealment of allocation, effectiveness of blinding, follow up and attrition rates, comparability of groups at baseline and adherence to treatment.

Neither trial described the methods of randomisation, but both had adequate allocation concealment and effective blinding from both the patients and clinicians[14,16].

Both trials had some limitations with regards to comparability of control and intervention groups at baseline. Neither trial made reference to comparability with regards to tumour factors [type of tumour (malignant or benign) or size of the tumour][14,16]. With regards to use of a single surgeon allowing prevention of technique confounding the results, one trial utilised more than one surgeon (including surgeons in training)[14], whilst the other did not specify if a single surgeon undertook the operations[16].

One trial made no reference to extent of compliance and adherence to treatment[15], whilst the other administered treatment intravenously in the immediate postoperative period allowing total compliance[14].

Effects of interventions

Dexamethasone: A variety of analyses were undertaken due to the varying doses within the treatment protocol. Overall, no therapeutic advantage was found with the use of dexamethasone[14]. A higher dose of dexamethasone conferred no functional advantage[14]. Interestingly, early postoperative facial nerve function was better in the placebo group (overall and in superficial and deep parotidectomy cohorts) although not statistically significant; median time to complete recovery of facial nerve function was shorter in the placebo group (150 d in the dexamethasone group *vs* 60 d in the control group)[14].

Prednisolone: There was minimal difference in extent of recovery from FNP in prednisolone *vs* placebo treated patients at 1, 3 and 6 mo ($P > 0.10$)[16]. Eighty-four percent of patients with FNP had full recovery at 3 mo, increasing to 98% by 6 mo[16]. One patient that had a total parotidectomy had a permanent FNP that persisted at 18 mo[16].

Adverse effects: No adverse effects from short term dexamethasone therapy were noted[14]. One patient was found to have "minor symptoms" from the use of prednisolone (although the precise symptoms were not stated)[16].

DISCUSSION

Overall, there appears to be no benefit conferred by corticosteroids for FNP recovery post-parotidectomy. However, this systematic review demonstrates that there is a paucity of evidence assessing the use of corticosteroids in treatment of FNP post-parotidectomy.

Two corticosteroid preparations have been assessed in RCTs with slightly varying mechanisms and durations of actions[14,16]. Prednisolone has mixed glucocorticoid and mineralocorticoid properties, whilst dexamethasone only has glucocorticoid properties (albeit much more potent than prednisolone) and a longer duration of action[18]. This variation in the mechanisms of action allowed different dosing regimens in the two included trials. Despite the variation in types of steroids and dosing regimens, there was no evidence to demonstrate an improved chance of full recovery nor improve recovery

Table 1 Characteristics of included studies

Roh and Park[16]	
Methods	Randomised controlled trial
Participants	Patients undergoing parotidectomy (superficial, partial, total) ± neck dissection 44 patients Exclusion: 1 Direct FN invasion of FN requiring FN sacrifice and reconstruction 2 Incidental cutting of the facial nerve
Interventions	Started day 1 or day 2 postoperatively Reducing dose of oral prednisolone (50 mg/d for 5 d, 30 mg/d for 3 d and 10 mg/d for 2 d) Placebo group received lactose with similarly formulated doses
Outcomes	House Brackmann grading of FN by two blinded experts Assessed postoperatively: immediately, 1 wk, 1 mo, 3 mo and 6 mo
Results	Overall recovery times from FNP: At 3 mo: 84% had fully recovery At 6 mo: 98% had full recovery Prednisolone *vs* placebo recovery at 1, 3 and 6 mo (minimal difference) ($P > 0.10$)
Notes	One patient was lost to follow-up and excluded from the analysis (prednisolone group)
Risk of Bias	
Method of randomisation	Not specified
Allocation concealment	Adequate
Other confounding factors	Groups comparable demographically and extent of postoperatively FNP, however tumour size, type or type of parotid surgery not compared in between intervention and placebo groups
Lee *et al*[14]	
Methods	Randomised controlled trial
Participants	Patients undergoing superficial or total parotidectomy 49 patients Exclusion criteria: Diabetes, age < 18, peptic ulcer disease, previous adverse reaction to steroids and any other contraindication to steroids Prior parotid surgery, anticipated section of FN and pre-existing FNP
Interventions	Two doses of dexamethasone (0.51 or 1.41 mg/kg) depending on type of surgery (superficial or total parotidectomy respectively) at 8 and 16 h postoperatively Placebo group received saline at the same intervals
Outcomes	Facial nerve function in the four major regions was assessed (frontal, orbital, midface, upper lip and lower lip) at a percentage 0-100 depending on extent of function Assessed postoperatively: immediately and every month for 12 mo (or until facial nerve function returned to normal)
Results	Average early postoperative facial nerve function: All patients ($n = 49$): 75.4% Overall: Dexamethasone (69.5%) *vs* placebo (81.3%) ($P = 0.239$) Dose of dexamethasone: High (63.9%) *vs* low (74.7%) ($P = 0.118$) Type of surgery: Superficial ($P = 0.637$) and deep ($P = 0.465$) Time to full recovery of facial nerve (median): Placebo (60 d) *vs* Dexamethasone (150 d) (no *P* value stated)
Notes	As intervention administered intravenously, total compliance can be ensured
Risk of Bias	
Method of randomisation	Not specified
Allocation concealment	Adequate
Other confounding factors	Initial power calculation required 120 patients, however a nationwide shortage of the intervention drug (dexamethasone) allowed only 52 patients to be enrolled in the trial No comparison of the type of parotid lesion excised within the trial groups (*i.e.*, malignant or benign and tumour size) Operations were conducted by more than one surgeon (including junior residents)

times[14,16].

The use of corticosteroids is thought to reduce neural oedema, a proposed mechanism for their excellent efficacy in treating Bell's Palsy[13]. One postulated mechanism of FNP in parotidectomy is stretch of the FN[4,19] leading to neural degeneration[20]. This may explain the lack of efficacy of corticosteroids in treating FNP post-parotidectomy.

There is compelling evidence to suggest that most cases of FNP post-parotidectomy are transient. Moreover, the risk of FNP is associated with a plethora of tumour and intraoperative factors (deeper parotidectomy[1,3,6,7] revision surgery[3,7], the facial nerve being near the tumour[5,7], malignancy[6] and inflammatory conditions[4,5,7]).

Prevention of FNP in parotidectomy is therefore largely linked to operative techniques, including the use of key anatomical landmarks to identify the FN[11]. The use of a facial nerve monitor has been suggested as an adjunct to help prevent postoperative FNP, with reasonable efficacy demonstrated[12,21]. Unfortunately, if FNP does occur its extent may dictate likelihood of full recovery, with a FNP preventing closure of the eyes being a predictor of permanent dysfunction[22].

Nonetheless, when FNP does occur it can significantly reduce quality of life[8]. It is therefore

key to ascertain interventions that can improve time to recovery. Unfortunately, both RCTs included in this trial did not account for the variety of tumour factors that can increase of postoperative FNP. The need for a high quality RCT assessing the use of corticosteroids in specific cohorts of patients is highlighted (particularly low risk patients, *e.g.*, patients with benign parotid tumours undergoing superficial parotidectomy, in whom the perceived risk of FNP should be lower).

Few adverse effects were reported by both randomised controlled trials, highlighting the relative safety of their use.

Limitations

The randomised trials included in this study had some limitations. Most importantly, statistical assessment of confounding factors in control and treatment groups did not specifically assess tumour factors[14,16]. Moreover, one trial did not achieve the power calculation sample size[14], limiting interpretation of its statistical analysis. The methods of randomisation were also unclear in both trials[14,16].

Implications for practice

Based upon current best evidence the use of corticosteroids to ameliorate postoperative FNP cannot be recommended. It is likely that preoperative and intraoperative factors play a more important role in the risk of permanent FNP. Moreover, the majority of cases of FNP are likely to recover, an important factor to consider in preoperative counselling of patients.

Implications for research

Given the extensive effect of FNP on quality of life, it is in the interest of patients to ascertain methods of improving recovery times. Future research should focus on assessing the cohort of patients in whom permanent FNP is more likely, allowing better preoperative counselling. Moreover, well-designed randomised controlled trials that assess the use of corticosteroids in more statistically comparable groups (*i.e.*, with regards to the type of parotid operation and tumour factors), that will allow assessment of specific cohorts of patients in whom corticosteroids may provide benefit.

COMMENTS

Background

Facial nerve palsy (FNP) is a potential complication that can occur after parotidectomy. FNP can be temporary or permanent, and can significantly affect quality of life. Corticosteroids have been proposed as a treatment for post-parotidectomy FNP. A systematic review of clinical trials is needed to provide scientific evidence for the efficacy of the use of corticosteroids for post-parotidectomy FNP.

Research frontiers

Parotidectomy, facial nerve palsy.

Innovations and breakthroughs

Both studies in this systematic review demonstrated no evidence that corticosteroids improve the prognosis of FNP after parotidectomy. Preoperative factors including the size of tumour and presence of malignancy, as well as intraoperative factors including the extent of parotidectomy (superficial or deep) and facial nerve integrity at the end of the operation are key in determining prognosis of FNP when it occurs.

Applications

There is no convincing evidence to propose the routine use of corticosteroids for post-parotidectomy FNP. Further clinical trials are needed to assess the efficacy of corticosteroids in ameliorating FNP in specific cohorts of patients.

Terminology

Parotidectomy is a commonly performed operation for the treatment of both benign and malignant parotid gland pathology. The facial nerve is at risk during parotidectomy.

Peer review

This study is well conducted and written.

Abstract

Diffuse large B cell primary hepatic lymphoma is a rare disease with limited available information regarding treatment strategy. Although the liver contains lymphoid tissue and is an important site for lymphocytes activation, primary hepatic lymphoma is rare. Host factors make the liver a poor environment for malignant lymphoma development. Its coexistence with human immunodeficiency virus (HIV) infection increases morbidity and mortality risks. Additionally, jaundice increases chances of developing adverse effects from chemotherapy. Here, we report a case of diffuse large B cell primary hepatic lymphoma in a 32-year-old HIV positive man. Due to elevated liver enzyme levels and jaundice, the patient was initially treated with an R-DHAP regimen, which was replaced with an R-CHOP regimen. Restaging images with a positron emission tomography scan after the latest chemotherapy cycle confirmed remission. This is the first report of complete remission of primary hepatic diffuse large B cell lymphoma in an HIV positive patient in the English literature.

Key words: Primary hepatic lymphoma; Diffuse B cell lymphoma; Human immunodeficiency virus; R-DHAP; R-CHOP

Core tip: There are limited reports related to successful management of primary hepatic lymphoma in human immunodeficiency virus (HIV) patients. This case report is not only considered as the first report of complete remission of primary hepatic diffuse large B cell lymphoma in an HIV positive patient in the English literature, but also describes the use of R-DHAP as an induction regimen in the setting of significant impaired liver function and severe immunocompromised status. The use of R-DHAP as an induction regimen in management of primary hepatic lymphoma in HIV patients was never reported.

Complete remission of primary hepatic lymphoma in a patient with human immunodeficiency virus. *World J Clin Cases* 2015; 3(2): 186-190 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i2/186.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i2.186

INTRODUCTION

Primary hepatic lymphoma (PHL) is a rare disease associated with immunodeficiency diseases and chronic viral hepatitis. From 1981 to 2003, only 358 cases of primary hepatic lymphoma were reported[1]. Data surrounding disease managements in patients with human immunodeficiency virus (HIV) infection is lacking. Here, we present a case of an HIV positive man whose PHL subsided into complete remission after chemotherapy.

CASE REPORT

A 32-year-old man with no known significant chronic medical problems was admitted to the hospital due to severe right upper quadrant abdominal pain, fever, night sweats, and unintentional weight loss. There was no history of recent heavy alcohol consumption. The patient appeared jaundiced and had a tender and firm hepatomegaly with a liver span of 19 cm. The lymph node was not enlarged. An abdominal ultrasound revealed multiple small hypoechoic lesions throughout the liver, common bile duct of 3.2 mm and normal gallbladder without gallstones. A computed tomography (CT) scan of the abdomen and pelvis with intravenous contrast revealed hepatomegaly with multiple small low attenuation nodules throughout the liver parenchyma, normal common bile duct and small ascites in the pelvis (Figure 1). Magnetic resonance imaging of the abdomen with intravenous contrast confirmed CT scan findings. All imaging studies showed no extrahepatic lymphadenopathies. A liver biopsy of lesions revealed diffuse large B cell lymphoma with non-specific lobular hepatitis (Figure 2). Immunohistochemical stains of the liver specimen revealed $CD20^+$, $CD79^+$, $CD79a^+$, $CD4^-$, and $CD3^-$ cells (Figure 3). The patient also tested positive for HIV infection. Tests for hepatitis B and C were negative. Additional tests results are shown in Table 1.

The patient was diagnosed with Stage 1BE primary liver large B cell lymphoma, and started on anti retroviral therapy along with chemotherapy during in-patient care. The initial anti retroviral medications were efavirenz, emtricitabine, and tenofovir. On the 7th day of the treatment, efavirenz was changed to raltegravir due to the presence of G190A mutation on HIV genotyping testing which confers resistance to non-nucleoside reverse transcriptase inhibitor mutation. Eight cycles of chemotherapy were administered together with anti retroviral therapy. In view of elevated liver enzymes and jaundice, chemotherapy with a platinum based regimen (R-DHAP) was initiated. The regimen of this first cycle consisted of 1.5 mg/kg of oral prednisone, 375 mg/m^2 of rituximab, 100 mg/m^2 of cisplatin, and 2000 mg/m^2 of cytarabine. As the co-administration of cisplatin and tenofovir might have increased his risk of toxicity to the kidney proximal tubule, serum creatinine was monitored closely. His serum creatinine levels were always less than 1 mg/dL and the calculated creatinine clearance was maintained at the level of 77 mL/min per 1.73 m^2. Nine days after starting the first chemotherapy cycle, he developed significant thrombocytopenia (nadir of 10000 cells/uL) and neutropenia (nadir of 300/uL). When platelet count was 10000/uL, the patient had an episode of epistaxis which was controlled after platelets transfusion. He did not develop fever during the episode of neutropenia. Filgrastim was given for 3 d when neutropenia was 300/uL. Upon the completion of first cycle of chemotherapy, the patient remained afebrile and became less jaundiced. Chemotherapy normalized liver enzymes and bilirubin (Table 1). Next, a CHOP regimen containing cyclophosphamide (600 mg/m^2), adriamycin (50 mg/m^2), vincristine (1.1 mg/m^2), and prednisone was administered. Rituximab (375 mg/m^2) was added to the CHOP regimen to start a third cycle of chemotherapy administered every 3 wk. As there was no known significant drug-drug interaction between the R-CHOP regimen and the anti retroviral regimen (tenofovir, emtricitabine and raltegravir), all medications were given according to the standard doses. After the second cycle, the patient remained anicteric with a body weight improvement of 5 kg from baseline. A CT with positron emission tomography (PET) scan performed after the 4th cycle of chemotherapy showed that the liver had reduced in size from 19.5 cm (prior to treatment) to 16.5 cm without evidence of hypermetabolic foci in the neck, chest, abdomen, or pelvis. Re-staging images with CT-PET after the 6th cycle revealed normal uptake within liver, spleen, adrenal glands, renal cortices, and the collecting system. A CT-PET scan at 5 and 11 mo after the last cycle confirmed remission (Figure 4). He is still in remission 19 mo after the treatment. During the chemotherapy, the CD4 count had improved and HIV viral loads were always undetectable (Table 1).

DISCUSSION

Fifty thousand incident cases of lymphoid neoplasms and 19000 related deaths occurred in the United States in 2005[2]. Diffuse large B-cell lymphoma is the most common non-Hodgkin lymphoma subtype and accounts for approximately 23% of all cases[3]. Chronic hepatitis C and hepatitis B and autoimmune diseases increase the risk of PHL[4,5]. Although the liver contains lymphoid tissue and is an important site for lymphocytes activation[6], PHL is rare. Host factors make the liver a poor environment for malignant lymphoma development[4,7].

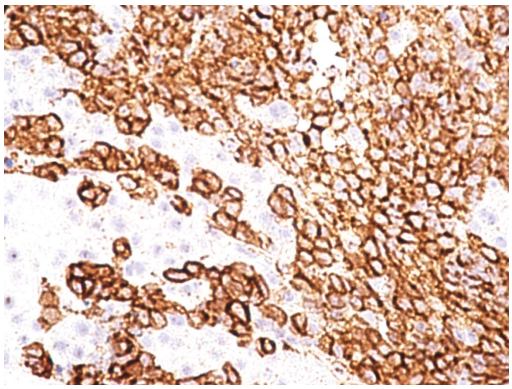

Figure 3 Immunohistochemical stain of liver specimen showing the lymphoma cells are strongly immunoreactive to CD 20.

Figure 4 Maximum intensity projection of positron emission tomography/computed tomography scan at 11 mo after the last cycle of chemotherapy showing no hypermetabolic lesions in the liver.

Criteria for establishing the diagnosis of PHL include clinical, histopathological, and radiological findings. Lei *et al*[8] listed the following criteria to establish diagnosis: (1) signs and symptoms related to liver involvement at presentation including laboratory abnormalities and right upper quadrant mass or pain; (2) absence of both palpable adenopathy at presentation and radiologically evident distant lymphadenopathy; and (3) absence of leukemia on a peripheral smear.

A report from Lei[9] showed that among 90 patients with PHL, the most frequent presenting symptoms were upper abdominal pain or discomfort (56%), weight loss (40%), and fever (22%), which

occasionally mimic pyogenic liver abscess. Other symptoms included fatigue (13%), nausea and vomiting (12%), anorexia (8%), night sweats (8%), hemorrhagic diathesis (2%), dysphagia (2%), and rarely, immune thrombocytopenic purpura (1%) and hepatic encephalopathy (1%). In this particular report, 10% of patients were diagnosed incidentally without preceding symptoms. Physical examinations frequently revealed a modest hepatomegaly (82%), but jaundice infrequently presented only as a late manifestation of disease progression or related to underlying cirrhosis (13%)[9]. Lactate dehydrogenase and alkaline phosphatase are sometimes elevated[10]. Alpha-fetoprotein and carcinoembryonic antigen are often normal[4,10]. Radiologically, the presentation of multiple well-defined liver masses is more common than single lesions or diffuse hepatic involvement[11]. On ultrasound imaging, PHL is usually hypoechoic relative to a normal liver. CT scans of PHL usually show hypoattenuating lesions[4,11]. FDG-PET studies are extremely useful in evaluating treatment responses in PHL[12]. Histologically, primary diffuse large B cell lymphoma shows demarcated tumors with no intrasinusoidal invasion, atrophic reactive lymph follicles, and tests positive for the following antigens: CD10, Bcl2, Bcl6, MUM1, and CD25[5].

The United States National Comprehensive Cancer Network recommends managing diffuse large B cell lymphoma with rituximab, cyclophosphamide, adriamycin, vincristine, and prednisone (R-CHOP protocol)[13]. Other regimens include CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, high dose methotrexate alternating with ifosfamide, etoposide, high dose cytarabine with or without rituximab), dose adjusted EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin), dose adjusted EPOCH with rituximab, CDE (cyclophosphosphamide, doxorubicin and etoposide), CDE with rituximab, and hyperCVAD (cyclophosphamide, vincristine, doxorubicin and dexamethasone alternating with high-dose methotrexate, and cytarabine with or without rituximab)[13]. Serrano-Navarro *et al*[1] highlighted a patient with PHL who developed complete response to R-CHOP treatment regimen, remaining symptom free for more than two years. Others also reported complete response to R-CHOP in non-HIV infected patients with diffuse large B cell type primary hepatic lymphoma[14-17]. Besides the R-CHOP regimen, a regimen contains rituximab, dexamethasone, high dose cytarabine, and cisplatin (R-DHAP) has been used as a salvage therapy in patients with CD20+ diffuse large B cell lymphoma who develop first time relapse or failure with first line therapy[18]. In addition, R-DHAP, given as remission induction chemotherapy, improved progression free survival and failure free survival in patients with aggressive CD20+ non-Hodgkin lymphomas[19].

In an article in French literature, Walter *et al*[17] reported the only favorable response to an R-CHOP treatment regimen for diffuse large B cell type PHL in an HIV infected patient. The case report described a 34-year-old man whose abdomen CT scan showed multiple liver masses, the largest of which was 14 cm. After four cycles of R-CHOP treatment, the masses markedly regressed with only a residual 5 cm hypodense lesion. Our patient developed complete remission without residual hepatic lesions. To our knowledge, this is the first report of PHL treatment in an AIDS patient that resulted in a complete response. After initial treatment with an R-DHAP regimen, serum levels of liver enzymes and bilirubin, very important in preventing the prolonged half-life of cyclophosphamide and neurotoxicity of vincristine[20], decreased. This may have facilitated further remission from the R-CHOP regimen. Further studies in HIV positive patients may confirm these findings.

COMMENTS

Case characteristics

A 32-year-old man with recent history of unintentional weight loss presented with right upper quadrant pain.

Clinical diagnosis

Patient appeared jaundiced and had a tender and firm hepatomegaly with a liver span of 19 cm.

Differential diagnosis

Acute ascending cholangitis, alcoholic hepatitis and infiltrative liver disease.

Laboratory diagnosis

WBC 5.9 K/μL; ALT 270 unit/L; AST 529 unit/L; serum alkaline phosphatase 1686 unit/L; serum GGT 872 unit/L; serum total bilirubin 9.7 mg/dL; human immunodeficiency virus (HIV) viral load 485 K copies/mL.

Imaging diagnosis

Computed tomography (CT) scan of the abdomen and pelvis with intravenous contrast revealed hepatomegaly with multiple small low attenuation nodules throughout the liver parenchyma, normal common bile duct and small ascites in the pelvis. Magnetic resonance imaging confirmed CT scan findings.

Pathological diagnosis

A liver biopsy of lesions revealed diffuse large B cell lymphoma with non-specific lobular hepatitis. Immunohistochemical stains of the liver specimen revealed $CD20^+$, $CD79^+$, $CD79a^+$, $CD4^-$, and $CD3^-$ cells.

Treatment

Eight cycles of chemotherapy were administered. R-DHAP regimen was given in the first cycle. CHOP regimen was started in the second cycle. R-CHOP regimen was started in the third cycle.

Related reports

In view of elevated liver enzymes and jaundice, chemotherapy with a platinum based regimen (R-DHAP) was given in the first cycle of chemotherapy. Upon completion of the first cycle, the patient became less jaundiced.

Term explanation

Cluster of differentiation (CD) of immunohistochemical stain is referred to a group of antibodies recognizing an antigen. For example, the T-helper cell antigen is called CD4 antigen and the various antibodies reacting with this antigen are called CD4 antibodies.

Experiences and lessons

This case report is not only considered as the first report of complete remission of primary hepatic diffuse large B cell lymphoma in an HIV positive patient in the English literature, but also describes the use of R-DHAP as an induction regimen in the setting of significant impaired liver function and severe

immunocompromised status. The use of R-DHAP as an induction regimen in management of primary hepatic lymphoma in HIV patients was never been reported.

Peer review

This case report well written overall.

Abstract

We report the successful use of RADPLAT to treat a patient with an unresectable T4N0 sinonasal undifferentiated carcinoma. This patient received 4 cycles of weekly intra-arterial cisplatin together with thiosulfate infusion with concurrent radiation therapy. Radiation therapy was given in 28 daily fractions to 54 Gy using intensity-modulated radiation therapy followed by a hypofractionated stereotactic boost of 3 fractions to 13 Gy to a total dose of 67 Gy in 31 fractions to the nasal sinus and bilateral neck. Intra-arterial cisplatin was administered using a bilateral approach due to the midline site of this tumor. Within days of the first intra-arterial cisplatin, there was an obvious decrease in tumor size. She has been followed with magnetic resonance imaging and positron emission tomography, and remains disease-free 47 mo post-treatment. Centers with expertise in intra-arterial chemotherapy could consider the RADPLAT approach for patients with unresectable sinonasal undifferentiated carcinoma.

Key words: Sinonasal undifferentiated carcinoma; Radiation; Intra-arterial cisplatin; Survival; RADPLAT

Core tip: Our patient with unresectable sinonasal undifferentiated carcinoma has enjoyed nearly 4 years disease-free survival after concurrent intra-arterial cisplatin and radiation.

INTRODUCTION

Sinonasal undifferentiated carcinoma (SNUC) is a

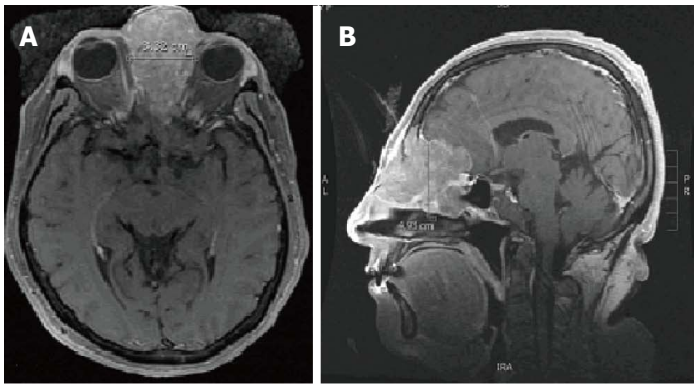

Figure 1 T1 magnetic resonance imaging of sinonasal undifferentiated carcinoma neoplasm prior to treatment. A: Axial T1 magnetic resonance imaging (MRI) and B: Sagittal T1 MRI show an avidly enhancing mass centered in the left ethmoid air cells with extension into the left frontal sinus with adjacent retained fluid and maxillary sinus with erosion of the medial orbital walls bilaterally, left greater than right. The majority of the ethmoid air cells are replaced by the neoplasm. Extension through the cribriform plate is noted with involvement of the left olfactory lobe, predominantly along the gyrus rectus. There is extensive surrounding edema in the left frontal lobe, extending back to the frontal horn of the left lateral ventricle.

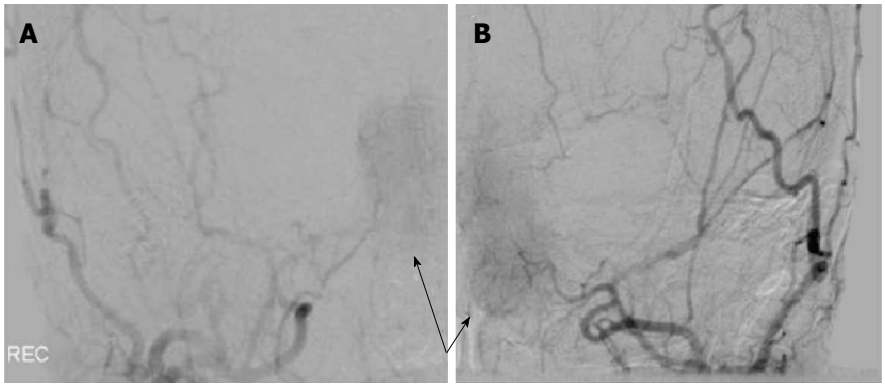

Figure 2 Right and left external carotid artery angiography injections. A: Right and B: Left external carotid angiographic injections demonstrate the tumor blush (arrows) at the first chemo treatment.

rare and highly aggressive neoplasm of the nasal cavity and paranasal sinuses[1]. Thus far, there have been less than 200 reported cases of SNUC[2]. SNUC has a poor prognosis and high mortality with one meta-analysis of 167 cases finding that the disease-free survival was only 26.3%[2]. Currently, there is not a standard treatment of care for SNUC. Treatment for SNUC typically involves a multimodal approach involving surgery (if feasible) and radiation therapy (RT) with concurrent chemotherapy[2-4]. A phase Ⅱ clinical trial in inoperable stage Ⅳ head and neck cancer previously found that the RADPLAT protocol (radiation and intra-arterial cisplatin) achieved an initial tumor response in 91% of patients with 1 and 2 years locoregional control of 82% and 69%, respectively[5]. Here, we describe the successful use of RADPLAT to treat a patient with an unresectable T4N0 SNUC.

CASE REPORT

A 60-year-old woman presented with nasal congestion and a prominence on the left side of her nose. Computed tomography (CT) revealed a tumor arising from the ethmoid sinus extending through the cribriform plate and into the anterior cranial fossa without metastasis to the chest and neck. Magnetic resonance imaging (MRI) of the face showed edema in the left frontal lobe, interpreted as suspicious for brain invasion (Figure 1). Biopsy revealed large pleomorphic tumor cells with a high nuclear to cytoplasm ratio, prominent nucleoli and focal areas of necrosis. Immunohistochemistry was positive for pancytokeratin and CD56 and weakly positive for chromogranin. She was diagnosed with a T4N0 SNUC. Since the tumor was deemed unresectable due to brain involvement, the RADPLAT protocol was chosen in hopes of maximizing her chance for local control. She received concurrent 4 cycles of weekly intra-arterial (IA) cisplatin at 150 mg/m^2, administered as a divided dose through left and right-sided feeding arteries for this midline tumor (Figure 2). With the IA cisplatin, she received intravenous (IV) thiosulfate bolus followed by thiosulfate infusion. Radiation therapy was given in 28 daily fractions to 54 Gy using intensity-modulated radiation therapy (IMRT) followed by a hypofractionated stereotactic boost of 3 fractions to 13 Gy to a total dose of 67 Gy in 31 fractions to the nasal sinus and bilateral neck. The biologically effective dose for the radiation treatment is equivalent to 82 Gy_{10} and 117 Gy_3.

Response to RADPLAT

After the first administration of intra-arterial cisplatin, there was an obvious and rapid decrease in tumor size, suggesting response to the chemotherapy. There was marked tumor size reduction after the final cycle of chemotherapy (Figure 3). She tolerated treatment well, with no toxicity from chemotherapy and expected acute sequelae including grade 2 mucositis, grade 2 dermatitis, and grade 1 conjunctivitis. Collagenase and polysporin powder with Xeroform

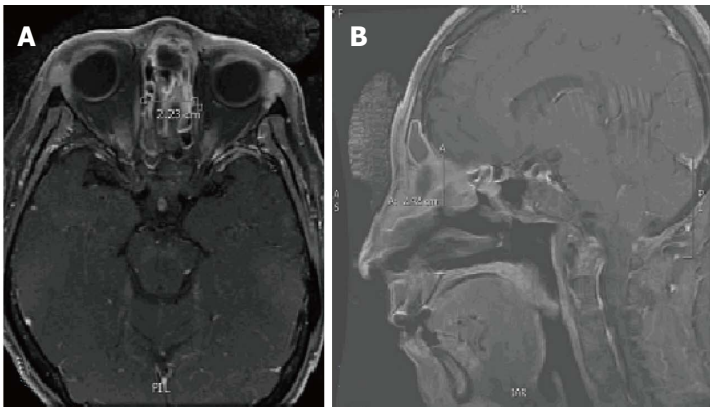

Figure 3 T1 Magnetic resonance imaging after completing fourth dose of chemotherapy. A: Axial T1 magnetic resonance imaging (MRI) and B: Sagittal T1 MRI show the mass had decreased in size as compared to the prior to treatment MRI. The mediolateral dimension is 2.23 cm which is decreased in size from the prior examination at which time it measured 3.32 cm. The AP appears to have decreased in size to 2.42 cm as compared to 4.93 cm on the prior MRI. There appears to be residual enhancing tissue in the right posterior ethmoid. The intracranial enhancement and edema within the inferior left frontal lobe is significantly decreased.

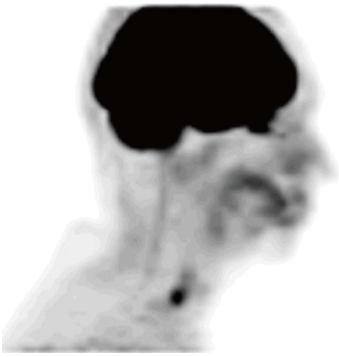

Figure 4 Positron emission tomography performed at four months post-treatment. The Positron emission tomography shows no definite or abnormal fluorodeoxyglucose (FDG) activity to suggest the presence of metabolically active tumor with special attention to the ethmoidal region adjacent to the cribriform plate. Linear FDG activity in the distal esophagus likely represents esophagitis.

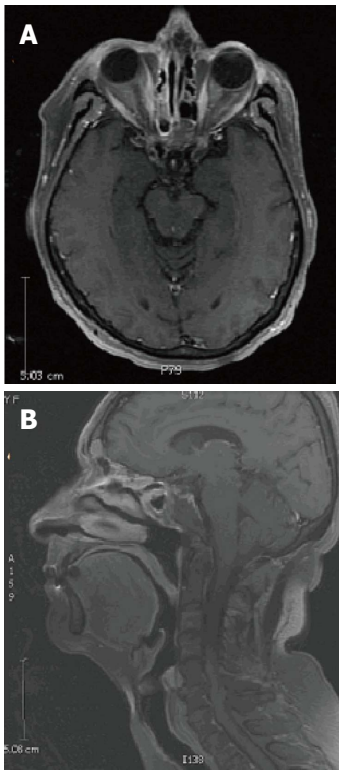

Figure 5 T1 magnetic resonance imaging 30 mo post-treatment. A: Axial T1 magnetic resonance imaging (MRI) and B: Sagittal T1 MRI show no evidence of recurrent disease. There is a decrease of the previously noted inflammatory changes in the sinuses. There is retained fluid in the bilateral frontal and left sphenoid sinuses, without bony destruction or expansion.

was used to treat radiation conjunctivitis. Positron emission tomography (PET)/CT four months post-treatment showed persistent soft tissue density in the anterior ethmoid sinuses, without fluorodeoxyglucose (FDG) uptake (Figure 4). Thirty months post treatment, MRI revealed no evidence of recurrent disease and a decrease in the previously noted inflammatory changes in the sinuses (Figure 5). The patient continues to be disease-free 47 mo post-treatment.

DISCUSSION

This case report presents long survival in a patient with an inoperable SNUC treated with concurrent intra-arterial cisplatin and radiation therapy.

Similar to our case, 84% to 92% of patients with SNUC present with T4 disease[4,6-9]. In many cases, the cancer can extend beyond the nasal and paranasal sinuses to involve the orbit and/or brain[5].

Currently there is no standard of care available for SNUC. Unresectable SNUC is generally treated with radiation or concurrent chemoradiation. Because the interventional radiologists and treating oncologists were familiar with RADPLAT, we opted to utilize this protocol in hopes of maximizing local control. In 213 patients with stage Ⅲ-Ⅳ head and neck squamous cell cancer (SCC) treated with RADPLAT, Robbins *et al*[10] reported a 5 year overall survival of 38.8% and locoregional control of 74.3%[10]. Similarly, Rabbani *et al*[11] reported locoregional control in 78% and four year overall survival in 57% in a study of 35 patients with stage Ⅲ head and neck cancer. Homma *et al*[12] evaluated the efficacy of RADPLAT for untreated advanced cancers (T3, T4a, and T4b) of the nasal and paranasal sinuses in 47 patients. During the median follow-up period of 4.6 years, the 5-year local progression-free survival rate was 78.4% for all patients[12]. Furthermore, the 5-year overall survival rate was 69.3% for all patients[12].

This study indicates that the RADPLAT protocol can not only effectively treat SCC of the head and neck, but also provide locoregional control and long-term survival in cancers specific to the paranasal and nasal sinuses.

The RADPLAT protocol involves intra-arterial infusion of cisplatin with intra-venous systemic neutralization using thiosulfate. The rapid infusion of cisplatin enables high doses of the drug to directly reach the tumor bed while the thiosulfate infusion prevents the systemic toxicity of large doses of cisplatin[10,11]. The cytotoxic effects of cisplatin are potentiated by radiation[13]. This effect was first demonstrated in murine models of tumors[14]. Studies have found that tumor resistance to cisplatin can occur within 2-4 cycles[15,16]. However, resistance can be overcome by increasing doses of cisplatin as demonstrated by *in vitro* and *in vivo* studies[17,18]. Elevated doses are not well-tolerated in patients because they can lead to undesirable side-effects such as neurotoxicity, nephrotoxicity, mucositis, and other systemic effects[19]. To circumvent the high-dose toxicity of the cisplatin, the intra-arterial infusion of cisplatin with concomitant thiosulfate enables high doses of cisplatin to reach the tumor bed without systemic toxicity. With the RADPLAT protocol, it is possible to deliver doses 10 times higher than can be delivered intravenously[17,18].

Many studies highlight the importance of surgery in improving survival in patients with SNUC[2,6,20,21]. In our case, brain involvement of the patient's SNUC made her a poor candidate for surgery, so she was treated with radical chemoradiotherapy to the primary site and bilateral neck. Elective neck irradiation for node negative SNUC is important for regional control[3,20]. Chemoradiation has previously been shown to be a viable treatment option for advanced SNUC. In one study, the 2-year progression-free survival and overall survival were 43% and 64%, respectively, with three cycles of platinum and 5-fluorouracil followed by radiation with two cycles of concurrent platinum, suggesting that induction chemotherapy followed by concurrent chemoradiation is effective[22]. This study found that among patients with SNUC treated to 50-60 Gy, all 4 patients treated with at least 60 Gy were alive without local progression at last follow-up[22]. Another study found that all patients that achieved cause-specific survival when treated with doses greater than 62.5 Gy[3]. Thus, doses of at least 60-70 Gy_2 to the primary site are recommended, if feasible.

In conclusion, our patient was effectively treated with RADPLAT with minimal toxicity and lasting disease control for nearly 4 years. Centers with expertise in intra-arterial chemotherapy could consider this modality for patients with unresectable SNUC.

COMMENTS

Case characteristics

A 60-year-old woman presented with nasal congestion and a prominence on the left side of her nose is diagnosed with unresectable T4N0 sinonasal undifferentiated carcinoma (SNUC).

Clinical diagnosis

Dullness to percussion and decrease breath sounds over the upper lobe of the right lung.

Differential diagnosis

Esthesioneuroblastoma, rhabdomyosarcoma, squamous cell carcinoma, adenocarcinoma, adenoid cystic carcinoma, lymphoma, melanoma, other soft tissue sarcoma.

Laboratory diagnosis

Labs were drawn but were found to be unremarkable.

Imaging diagnosis

Computed tomography revealed a tumor arising from the ethmoid sinus extending through the cribriform plate and into the anterior cranial fossa without metastasis to the chest and neck. Magnetic resonance imaging of the face showed edema in the left frontal lobe, extending back to the left lateral ventricle.

Pathological diagnosis

Biopsy of the mass revealed large pleomorphic tumor cells with a high nuclear to cytoplasm ratio and prominent nucleoli and focal areas of necrosis. Immunohistochemistry was positive for pancytokeratin and CD56 and weakly positive for chromogranin.

Treatment

The patient was treated with RADPLAT (concurrent intra-arterial cisplatin with simultaneous thiosulfate and radiation therapy).

Related reports

Sinonansal undifferentiated carcinoma is difficult to treat and there is currently no standard treatment protocol.

Term explanation

The RADPLAT protocol involves intra-arterial infusion of cisplatin with intra-venous systemic neutralization using thiosulfate and concurrent radiation therapy. The rapid infusion of the cisplatin enables high doses of the drug to directly reach the tumor bed while the thiosulfate infusion prevents the systemic toxicity of large doses of cisplatin.

Experiences and lessons

This case report represents long survival in a patient with an unresectable T4N0 SNUC using RADPLAT. Centers with expertise in intra-arterial chemotherapy could consider this modality for patients with unresectable SNUC.

Peer Review

These data are thorough and convincing.

Abstract

The differentiation syndrome is an inflammatory reaction with increased capillary permeability that occurs in up to 25% of patients with acute promyelocytic leukemia treated with all-trans retinoic acid. A 50-year-old man with acute promyelocytic leukemia underwent chemotherapy with idarubicin and all-trans retinoic acid. On day +21 the patient developed pruritic prepatelar papules as well as several 10 mm subcutaneous nodules in both thighs accompanied by persistent fever. On the day +25 the patient presented with bilateral pulmonary crackles, infiltrates in the right lower lobe and severe hypotension which required dopamine infusion. Biopsy of one of the thighs nodules was performed. A Sweet syndrome associated to a differentiation syndrome was suspected. All-trans retinoic acid therapy was discontinued and dexamethasone was administered. In 48 h the patient showed remission of the fever and the infiltrates and the skin lesions acquired a residual aspect. It is debatable whether these two syndromes are distinct entities with common mechanisms or whether they are poles of the same spectrum. Dermatologists and hematologists must be aware of these two syndromes and its pathophysiologic association.

Key words: Differentiation syndrome; Sweet syndrome; Acute promyelocytic leukemia; All-trans retinoic acid

Core tip: It is debatable whether the differentiation syndrome and the sweet syndrome are distinct syndromes with common mechanisms or whether they are poles of the same spectrum. We believe that there may be more cases of differentiation presenting with skin sweet syndrome lesions, which are underdiagnosed, overshadowed by the critical state of these patients. Dermatologists and hematologists must be aware of these two syndromes and its pathophysiologic association. It is very likely that these two specialties are staring the same phenomenon from two different points of view.

INTRODUCTION

All-trans retinoic acid (ATRA) therapy induces the differentiation of the myelogenous leukemic cells in acute promyelocytic leukemia (APL). The differentiation syndrome (DS) is an inflammatory reaction with increased capillary permeability that occurs in up to 25% of patients with APL treated with ATRA. It is characterized by respiratory distress, fever, pulmonary infiltrates, pleuropericardic effusions, renal failure and hypotension, with a mortality of up to 30% without treatment[1]. The association of sweet syndrome (SS) and DS has been exceptionally described in the literature.

CASE REPORT

A 50-year-old man presented with pancytopenia on a routinal analysis. A bone marrow (BM) aspirate showed 73% of blasts; homogeneous medium to large cells with visible nucleoli in most cases and clasmatosis. Auer rods were also seen. The red series was decreased without megakaryocytes. The BM biopsy showed that the hematopoietic parenchyma was replaced by a proliferation of myeloid cells showing a monomorphic appearance. The neoplastic cells were positive for myeloperoxidase and CD117 and negative for CD34, TdT and Glycophorin. Thirty percent of BM cells were positive for PML-RARa by fluorescence *in situ* hybridization (FISH). Diagnosed of APL the patient underwent chemotherapy with idarubicin 12 mg/m^2 and ATRA 45 mg/m^2. On day +21 of ATRA therapy, the patient developed pruritic erythematous 3-5 mm prepatelar papules as well as several 10 mm subcutaneous nodules in both thighs along with persistent fever (Figure 1). On day +25, the patient presented with bilateral pulmonary crackles, infiltrates in the right lower lobe and severe hypotension which required dopamine infusion. No features of disseminated vascular coagulation were present. The patient did not gain or lose weight and no renal or hepatic dysfunction was observed. Empirical antibiotic and antifungical treatment was started. A cutaneous biopsy of one papule showed moderate edema in the papillary dermis with perivascular infiltrates consisting predominantly of confluent neutrophils, without vasculitis or involvement of the adipose tissue (Figure 2). Blood, urine and biopsy cultures were negative. Skin lesions occurred along with the neutrophil count recovery and the disappearance of the promyelocytes in the BM smears. Based on the data, a diagnosis of SS associated with DS was made. ATRA therapy was discontinued and dexamethasone 10 mg every 12 h was administered. In 48 h the patient showed remission of the fever and the pulmonary infiltrates and skin lesions cleared. On day +29, a new BM aspiration FISH study did not show the PML-RARa translocation.

Haematologists reintroduced ATRA as maintenance therapy for the APL along with corticosteroids without new recurrences.

DISCUSSION

Cases of drug-induced SS associated with ATRA has been exceptionally described in the literature. Although systemic manifestations in SS are uncommon, there are cases of biopsy proven pulmonary involvement[2-4].

As far as we are concerned, there are only 2 cases of SS associated with DS in patients with APL (Table 1)[2,5].

It is debatable whether the DS and the SS are distinct syndromes with common mechanisms or whether they are poles of the same spectrum. They share common features such as fever, infiltration of neutrophils and improvement with steroid therapy. One of the differences between these two syndromes is that in most cases of SS, the involvement is limited to the skin while the main difference is the capillary leakage in the DS which is produced by the cytokine storm released by the promyelocytes as they mature. ATRA induces the differentiation of myelogenous leukemic cells into mature myeloid cells conferring them functional properties with modification of their migratory capability.

We know that these two syndromes are caused by ATRA therapy but we cannot rule out the possibility that they can be the sides of the same phenomenon with common mechanisms. For some authors, the SS and the DS are different inflammatory reactions with common mechanisms induced by ATRA therapy[6] while Ueno *et al*[7] thought that the SS due to ATRA therapy could represent a partial form of the DS.

We believe that there may be more cases of DS presenting with skin SS lesions which are underdiagnosed, overshadowed by the critical state of these patients. Dermatologists and hematologists must be aware of these two syndromes and its pathophysiologic association. It is very likely that these two specialties are staring the same phenomenon from two different points of view.

COMMENTS

Case characteristics

A 50-year-old man with acute promyelocytic leukemia presented with erythematous prepatelar papules as well as several subcutaneous nodules in both thighs along with persistent fever, pulmonary crackles and hypotension.

Clinical diagnosis

Sweet syndrome lesions and systemic symptoms in a patient who underwent chemotherapy with idarubicin and all-trans retinoic acid (ATRA).

Differential diagnosis

Sepsis, drug reaction.

Table 1 Cases of sweet syndrome associated with differentiation syndrome in patients with acute promyelocytic leukemia treated with all-trans retinoic acid

Ref.	Age(yr)/sex	Cutaneous location	Biopsy	Onset of skin lesions after ATRA induction therapy (d)	Onset of the DS after ATRA induction therapy (d)	DS signs and symptoms	Steroid response	Time until improvement
Takada *et al*[5]	49/F	Arms	Yes	18	28	Respiratory distress	Yes	24 h
Astudillo *et al*[2]	46/M	Trunk, arms, lower extremities	Yes	6	uk	Weight gain	Yes	Unknown
This case	50/M	Trunk lower extremities	Yes	21	25	Respiratory distress Hypotension	Yes	48 h

DS: Differentiation syndrome; ATRA: All-trans retinoic acid; M: Male; F: Female.

Figure 1 Papules and nodules appeared on day +21 of all-trans retinoic acid therapy.

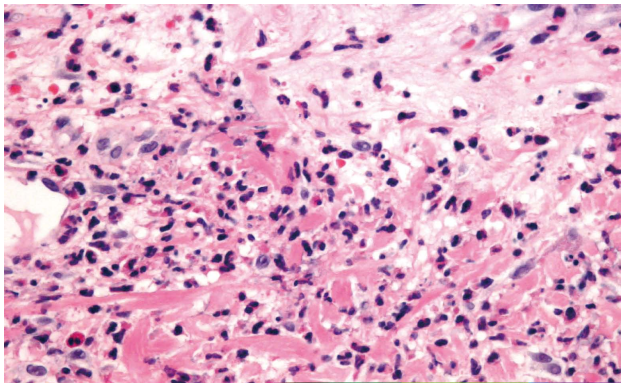

Figure 2 Infiltrates consisting predominantly of neutrophils, without vasculitis (HE, × 20).

Laboratory diagnosis

Blood, urine and biopsy cultures were negative.

Imaging diagnosis

Pulmonary infiltrates in the right lower lobe on a chest radiography.

Pathological diagnosis

A biopsy of a papule showed moderate edema in the dermis with perivascular infiltrates consisting predominantly of confluent neutrophils, without vasculitis or involvement of the adipose tissue.

Treatment

Dopamine infusión, empirical antibiotics, ATRA therapy discontinued and dexamethasone 10 mg every 12 h.

Related reports

As far as the author are concerned, there are only 2 cases of Sweet syndrome associated with differentiation syndrome in patients with acute promyelocytic leukemia.

Term explanation

Sweet syndrome is an inflammatory neutrophilic skin condition characterized by a sterile infiltrate of normal polymorphonuclear leukocytes.

Experiences and lessons

The authors believe that there may be more cases of differentiation syndrome presenting with skin sweet syndrome lesions which are underdiagnosed, overshadowed by the critical state of these patients.

Peer review

In the submitted manuscript the authors described a rare disorder–a drug-induced sweet syndrome associated with ATRA therapy for a patient with acute promyelocytic leukemia (APL). The association of sweet syndrome and ATRA-induced differentiation syndrome is rarely observed in APL. The case in this report is well-described, along with relevant lab results.

Abstract

The most significant factor for the success in soft tissue grafts is the synergistic relation between vascular configuration and involved tissues. In the soft tissue graft procedures, site specific donor tissue is assumed to have improved potential for function and aesthetic survive at recipient sites. On a clinical level, using site specific gingival unit graft that placed on traditionally prepared recipient site, results in predictable root coverage. In this case report the clinical effectiveness of gingival unit transfer (GUT) technique performed on Miller Ⅲ recession was presented and a similar recession case treated with free gingival graft (FGG) technique for comparison. Probing depth, recession depth, keratinized tissue width and clinical attachment level clinical parameters were measured at baseline and postoperative 8 mo. Percentage of defect coverage was evaluated at postoperative 8 mo. Creeping attachment was assessed at postoperative 1, 3, 6 and 8 mo. The GUT revealed better defect coverage and creeping attachment results than the FGG in the treatment of Miller Ⅲ defects.

Key words: Autografting; Gingiva; Gingival recession; Tooth root; Transplants

Core tip: On a clinical level, using site specific vascular configuration gingival unit graft for donor tissue that placed on traditionally prepared recipient site, results in predictable defect coverage. This report was to evaluate effectiveness of gingival unit transfer technique in comparison with free gingival graft technique on clinical parameters in the Miller Ⅲ recessions treatment.

INTRODUCTION

Gingival recession is the denudation of root surfaces as a result of the relocation of the gingival margin apical to the cement-enamel junction (CEJ)[1] that causes root hypersensitivity and aesthetic problems[2].

Recession defects can be treated with numerous surgical procedures such as free gingival grafts[3], connective tissue grafts[4], acellular dermal matrix grafts[5], various pedicle flaps[6,7], combinations of

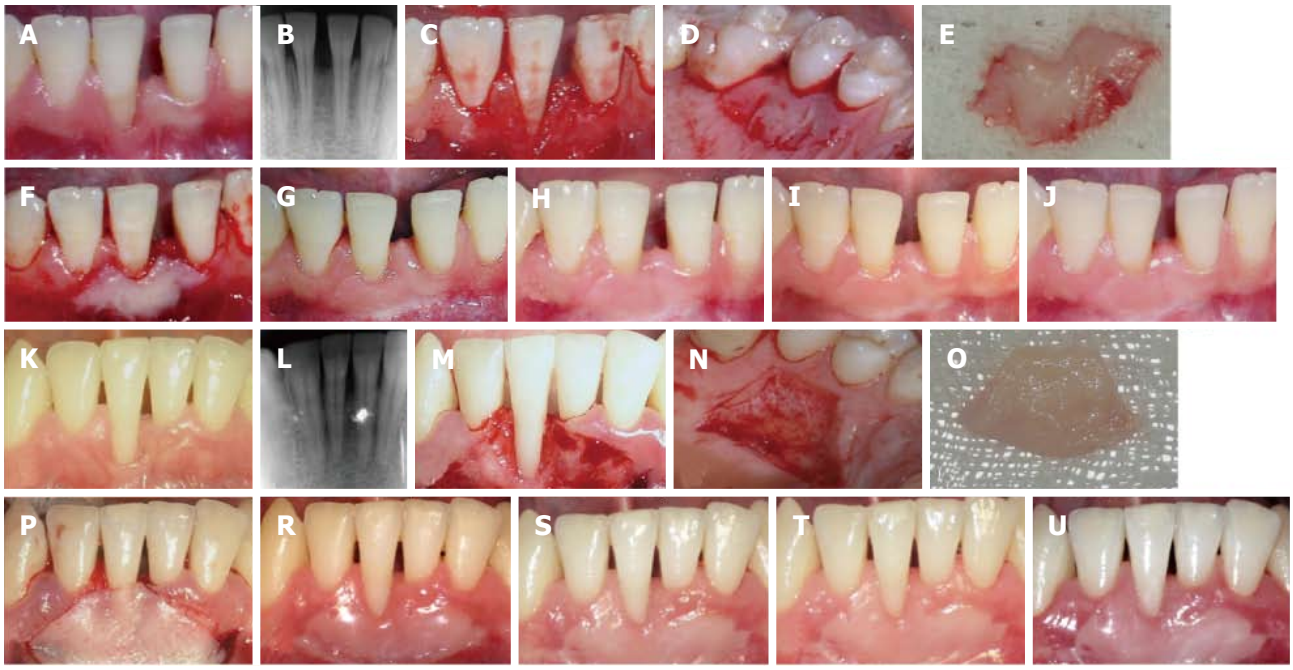

Figure 1 Surgical procedures and follow-ups in treatment with gingival unit transfer and free gingival graft. Surgical procedures and follow-ups in treatment with gingival unit transfer: (A: Initial clinical appearance; B: Radiographic appearance; C: Recipient site; D: Donor site; E: Gingival unit graft; F: Gingival unit graft in place; G: 1 mo after surgery; H: 3 mo after surgery; I: 6 mo after surgery; J: 8 mo after surgery); surgical procedures and follow-ups in treatment with free gingival graft: (K: Initial clinical appearance; L: Radiographic appearance; M: Recipient site; N: Donor site; O: Free gingival graft; P: Free gingival graft in place; R: 1 mo after surgery; S: 3 mo after surgery; T: 6 mo after surgery; U: 8 mo after surgery).

these pedicle flaps and graft techniques[8,9] and guided tissue regeneration[10]. The literature review presents different rates of success and predictability with these surgical procedures[11-13]. Nevertheless, additional clinical studies are needed to define the issues that are in a relation with the predictable and successful results[12].

The synergistic relation between vascular configuration and related tissues is one of the major factors for the success in soft tissue grafts[14,15]. Gingival tissue has complex and unique vascularity[16]. Supracrestal part of gingiva, as well as the donor tissue, is naturally created and specifically designed to function and survive above avascular denude root surfaces[14] in the soft tissue grafts procedures[17]. Gingival unit (GU) graft with site specific vascular supply placed on traditionally prepared recipient area may have capacity for survival on root surfaces and results in predictable root coverage[18].

Most clinical studies about root surface coverage have focalized on Miller Ⅰ-Ⅱ recession treatment[19]. Defect coverage by using gingival unit transfer (GUT) on Miller Ⅰ-Ⅱ recession defects revealed successful results in a previous clinical study[18]. However, there is a lack of success and ability to provide root coverage in Miller Ⅲ recession defects, because of interproximal bone and soft tissue loss[20]. There are different anatomical characteristics when compared with Miller Ⅰ-Ⅱ recession defects, as if prominent and avascular root surfaces, decreased periosteal bed and occasionally deep periodontal pocket depths[21].

The purpose of this case report is to present the clinical results of two cases of Miller Ⅲ localized recessions treated by using GUT and free gingival graft (FGG).

CASE REPORT

In April 2009, a 25-year-old woman (case Ⅰ) and 21-year-old man (case Ⅱ) with single Miller Ⅲ recession defects on mandibular right central incisor were applied to the Periodontology Department of Marmara University (Figure 1A, B, K and L). Case Ⅰ had complaints about aesthetics and tooth loss whereas case Ⅱ about hypersensitivity. Patients were non-smokers, did not have any medical problems and there were no contraindications for periodontal surgery. After clinical examination, oral hygiene motivation and mechanical periodontal treatment were performed.

Recession depth (RD) was recorded from CEJ to margin of the gingiva, probing depth (PD) was recorded from margin of the gingiva to the bottom of the pocket, clinical attachment level (CAL) was recorded from CEJ to bottom of the pocket, keratinized tissue width (KTW) was recorded from the margin of the gingiva to mucogingival junction, at baseline and postoperative 8 mo with a manual probe (PCP UNC-15, Hu-Friedy, Chicago, IL.). Only RD parameter was measured at 1, 3 and 6 mo for the evaluation of soft tissue creeping coronally.

One clinician (BK) performed surgical procedures

Table 1 Clinical parameters at baseline (0 d) and 8 mo

Parameters	Case Ⅰ gingival unit graft technique			Case Ⅱ free gingival graft technique		
	0 d	8 mo	Gain	0 d	8 mo	Gain
Recession depth (mm)	3	0.5	2.5	4	2	2
Probing depth (midbuccal) (mm)	1	1	0	2	1.5	0.5
Clinical attachment level (mm)	4	1.5	2.5	6	3.5	2.5
Keratinized tissue width (mm)	2	7	5	1.5	6	4.5
Defect closure (%)		83			50	

and another clinician (SY) evaluated clinical measurements. Local anesthesia was made and then in both cases, the recipient site was prepared by two vertical beveled incisions that extending apically to adjacent teeth, 3 to 4 mm across to the mucogingival line, and the surfaces of interdental papillae was removed (Figure 1A, C, K and M)[14]. The incisions were divergent therefore the recipient site was trapezoidal. At the mucogingival line, vertical incisions were connected by a horizontal incision. A partial thickness dissection was made apical to the alveolar mucosa. The epithelial surfaces within these incisions were deepithelized. The base of the recipient site was ⩾ 5 mm apical to the apical part of the exposed portion of the root surface. The root planning was made in the exposed portion of the root surface with hand instruments. Then irrigated with saline[18].

In case Ⅰ, the GU graft was harvested from the palatal part of the premolar area (Figure 1D) including the marginal gingival tissue and the papillae. In case Ⅱ, the donor FGG was conventionally dissected from the palate aspect of the premolar area, but ⩾ 2 mm apical from the margin of the gingiva (Figure 1N)[18]. In both cases, thickness of grafts were about 1 mm[22]. Then the grafts were sutured at the level to the CEJ (Figure 1E, F, O and P), and compressed for 2 min[18]. The periodontal dressing was applied to the donor sites for closing the wound. After 1 wk, the dressing and sutures were removed.

At the postsurgical care for infection control, the patients were advised rinse twice daily with 0.2% chlorhexidine solution for 3 wk, avoid brushing and hard chewing. After that, a gentle coronally directed brushing in the surgical area was recommended. During the first 2 mo recall appointments were scheduled every second week, and then patients were called once a month for the postoperative following period[18].

At postoperative period in both patients clinical healing in both the recipient and donor sites was complete and no complications were observed. Pre (0 d) and postsurgical (8 mo) clinical parameters are shown in Table 1. At 8 mo, 2.5 mm defect coverage with a PD of 1 mm, CAL gain of 2.5 mm and KTW gain of 5 mm was observed in case Ⅰ grafted with a GUT. Two millimetre defect coverage with a PD of 1.5 mm, CAL gain of 2.5 mm and KTW gain of 4.5 mm was observed in case Ⅱ grafted with FGG (Table 1). Percentage of defect closure were 83% and 50% in cases Ⅰ and Ⅱ, respectively. The creeping attachment level in case Ⅰ was 1.5 mm between 1 and 8 mo period (Table 2). The margin of the GU graft was moved coronally, and an acceptable colour and configuration harmony with adjacent gingival tissues was seen (Figure 1G, H, I and J). In case Ⅱ, there was no color harmony with the adjacent tissue and 1 mm of creeping was detected at the same follow-up period (Figure 1R, S, T and U) (Table 2).

DISCUSSION

GUT technique, using GU graft as a donor tissue with site specific vascular supply, was evaluated in treatment of a single Miller Ⅲ gingival recession case. GUT is a modification of FGG with the difference of including marginal gingiva and papillae in the conventional palatal tissue graft that vascular supply matches intimately with the recipient site[14,18]. After 8 mo in this case, RD reduction and defect coverage were found in favor of GU graft compared to FGG.

This is the first case reporting the use of GUT technique in the Miller Ⅲ localized gingival recession treatment. There are no clinical studies or case reports with which to compare our clinical outcomes. There is one case report in which gingival unit was used as a FGG[14] and a randomized clinical trial evaluating GUT in comparison with FGG in the Miller Ⅰ-Ⅱ recession defects treatment[18]. In this case report, the GU graft performed in the Miller Ⅲ recession defect treatment, 2.5 mm of RD reduction; 83% defect coverage together with gains in CAL and keratinized tissue (KT) were reported. The reduction in recession was in accordance with the attachment gain. The mean defect coverage was 50% in the FGG case, presenting an obvious difference from the GUT case.

According to our clinical outcomes, GUT resulted in almost indistinguishable texture and colour with neighbouring soft tissues. Creeping defines the postoperative movement of marginal gingiva coronally[23]. Allen[14] presented equivalent results in his case report that the marginal position of the

Table 2 Recession reduction in 1-3, 3-6, 6-8, and 1-8 mo periods

Recession reduction (mm)	Case I	Case II
1-3 mo	0	0.5
3-6 mo	0.5	0
6-8 mo	1	0.5
1-8 mo	1.5	1

GU graft is more coronal than the neighbouring gingival tissue at 3 mo. Creeping has been detected in several clinical studies[24-27]. With an average of 1 mm, creeping can be seen within 1-12 mo after FGG in narrow recessions[25,26]. However, after 8 mo, the coronal ascent of gingival margins in case Ⅰ, treated with a GUT (1.5 mm) was higher than in case Ⅱ (1 mm). The unique vascular supply of GU graft is believed to be of importance for this difference[18]. The present outcomes support the usefulness of GUT for suitable root coverage in aesthetic areas. Although FGG has lost its popularity for aesthetic area[28,29], it may be still the gold standard surgical technique to increased KT[30] especially when it is modified with the inclusion of marginal and papillary gingival tissue.

The GU donor site healed uneventfully. No unacceptable attachment loss or recession were detected at the premolar site where the GU graft was harvested from in case Ⅰ after postoperative 8 mo. Inevitable recession at donor site were reported in laterally positioned flap procedure[6]. This does not possible for GUT procedure. Harvesting donor graft with marginal gingiva is easy, less invasive. Any harmful results can be prevented with cautious manipulation. Before harvesting the GU graft, the depth of gingival sulcus at palatal donor premolar area was measured. Donor tissue was harvested carefully not to cause any attachment loss. If some injury had happened at the attachment, new attachment apparatus would have been developed quickly[31].

In conclusion, the GUT technique performed on case Ⅰ can be successfully used for the Miller Ⅲ recession defect treatment.

COMMENTS

Case characteristics

Twenty-five (female) and 20-year-old (male) patients with Miller Class Ⅲ localized gingival recession defects on mandibular anterior teeth.

Clinical diagnosis

Miller Class Ⅲ recession defect on mandibular anterior teeth.

Treatment

One patient was treated with gingival unit transfer whereas the other with free gingival graft technique.

Term explanation

Gingival unit graft is masticatory palatal tissue involving marginal gingival and papillary tissue.

Experiences and lessons

Surgical treatment of Miller Ⅲ gingival recessions are more challenging, due to loss of interproximal bone and soft tissues. This case report represents the effectiveness of gingival unit transfer technique in comparison with free gingival graft technique on clinical parameters in the treatment of Miller Ⅲ gingival recession.

Peer review

This is an interesting case report.

Abstract

In commenting on a case report of a 55-year-old man who suffered Takotsubo syndrome (TTS), in the setting of receiving chemotherapy with cytarabine and daunorubicin for acute myeloid leukemia, the author expresses his views that TTS in the setting of chemotherapy for malignancies may not be chemotherapeutic drug-specific (like in the chemotherapeutic drug induced-cardiomyopathy), but may be due to the emotional and physical stresses resulting from the realization of having diagnosed with a malignancy, and the diagnostic testing, and therapeutic management which follows.

Key words: Daunorubicin; Radiotherapy; Cardiotoxicity; Takotsubo syndrome; Malignancies; Chemotherapy; Cytarabine; Anthracyclines; Cardiomyopathy; Autonomic sympathetic Nervous system.

Core tip: Is Takotsubo syndrome, in time proximity to chemotherapy, due to the specific chemotherapeutic agent?

Madias JE. Is Takotsubo syndrome in patients receiving chemotherapy drug-specific? *World J Clin Cases* 2015; 3(2): 204-205 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i2/204.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i2.204

TO THE EDITOR

The interesting report by Goel *et al*[1], published in the October, 2014 issue of the Journal, about the 55-year-old man who suffered Takotsubo syndrome (TTS), in the setting of receiving chemotherapy with cytarabine and daunorubicin for acute myeloid leukemia, is well documented and discussed; however it makes one wonder whether we are on the right track in terms of attributing causation of TTS to specific chemotherapeutic agents. A number of cases of patients receiving a variety of chemotherapeutic drugs[2], and radiotherapy[3], have been reported, and their authors, like in the present paper, delved in the issue of cardiotoxicity of the particular drug administered, akin with what is done for cases of drug-specific (*e.g.*, anthracyclines) chemotherapy-induced cardiomyopathy, which certainly should be

differentiated from TTS. The intimate association of TTS with malignancies is intriguing[4-7], and has made some to recommend that patients with TTS should undergo evaluation for an underlying malignancy[4,5]. In terms of mechanisms many have attributed TTS, in the setting of malignancies, to paraneoplastic manifestations[4-6], a heightened autonomic sympathetic nervous system tone, emanating from the emotional stress of patients with a recently made diagnosis of malignancy, and non-specific physical stresses, related to diagnostic procedures, and administered chemotherapy and radiotherapy, without of course discarding the possible cardiotoxic role of the implemented therapies[6,7]. Incidentally, any reader of the present report will be interested in the details of further management of this patient with non M3 acute myeloid leukemia, whether he received more therapy, the specific chemotherapeutic regimen implemented, and the eventual outcome.

Abstract

Traditional right ventricular (RV) apical pacing has been associated with heart failure, atrial fibrillation and increased mortality. To avoid the negative consequences of RV apical pacing different strategies have been developed, among these a series of pacing algorithms designed to minimize RV pacing. These functions are particularly useful when there is not the need for continuous RV pacing: intermittent atrio-ventricular blocks and, mainly, sinus node disease. However, in order to avoid RV pacing, the operational features of these algorithms may lead to adverse (often under-appreciated) consequences in some patients. We describe a case of a patient with sinus node disease, in whom right atrial only pacing involved long atrio-ventricular delay to allow intrinsic ventricular conduction, which led to symptomatic hypotension that could be overcome only by "forcing" also right ventricular apical pacing. We subsequently discuss this case in the context of current available literature.

Key words: Right ventricular apical pacing; Pacemaker algorithms; Dyssynchrony; Pacemaker syndrome; Right atrial pacing

Core tip: Right ventricular apical pacing has been associated with worse outcome so a series of pacing algorithms have been designed to minimize it. However the operational features of these algorithms may lead to adverse consequences in some patients. We describe a case of a patient with sinus node disease, in whom right atrial only pacing involved long atrio-ventricular delay to allow intrinsic ventricular conduction, which led to symptomatic hypotension that could be overcome only by "forcing" right ventricular apical pacing. We subsequently discuss this case in the context of current available literature.

INTRODUCTION

Traditional right ventricular (RV) apical pacing has been associated with heart failure, atrial fibrillation

and increased mortality[1]. Dyssynchronous electrical activation of the heart from pacing creates deleterious myocardial fiber strain, mechanically inefficient contraction and adverse left ventricular (LV) remodeling with a progressive, dose-related, decline in pump function that is more evident in patients with an already compromised cardiac function at baseline[2]. To avoid the negative consequences of RV apical pacing different strategies have been developed. Pacing from alternative RV sites (septum, outflow tract, His bundle) is a promising option but, up to now, studies comparing apical to non-apical pacing with regard to hemodynamic, echocardiographic and long-term LV systolic function have been conflicting, failing to demonstrate a clear benefit[3,4]. Biventricular pacing can be considered in selected cases, *i.e.,* patients with atrio-ventricular (AV) block and LV ejection fraction < 35%, but it is not a first choice in the majority of patients candidates to receive a pacemaker. Contemporary pacemakers, from different manufacturers, include sophisticated algorithms designed to minimize ventricular pacing with the aim to reduce the incidence of atrial fibrillation and heart failure[5]. These functions are particularly useful when there is not the need for continuous RV pacing, that is in patients with intermittent AV blocks and, mainly, sinus node disease (SND). However, in order to avoid RV pacing, the operational features of these algorithms involve long AV delay to allow intrinsic conduction, which may lead to adverse (often under-appreciated) consequences in some patients[5,6].

We describe the case of a 85-year-old man implanted with a dual chamber pacemaker (Adapta DR Medtronic, leads positioned in right atrial appendage and RV apex) because of sinus node disease/bradi-tachi syndrome. He did not take any drug. Baseline ECG showed sinus bradycardia (35-40 beats per minute), normal *P* wave morphology, PR interval 180 msec, QRS 115 msec. Echocardiogram revealed moderate LV hypertrophy, ejection fraction 50%; diastolic pattern (pulsed wave mitral Doppler) showed abnormal relaxation with an adequate filling time in sinus rhythm. Before pacemaker implant he was symptomatic for palpitations, easy fatiguability, dizziness, vertigo, but no syncopal episode was described. Pacemaker was programmed DDDR 60-120 bm, Managed Ventricular Pacing (MVP)™ turned ON to avoid unnecessary RV pacing; ECG after implant showed atrial-based pacing with spontaneous ventricular activation (AP-VS) (Figure 1). Few days after hospital discharge the patient returned to our attention for episodes of near-syncope and falls occurring shortly after the passage from supine to upright position. We documented a symptomatic orthostatic hypotension with a sudden drop in systolic and diastolic blood pressure (SBP drop 30-40 mmHg and DBP drop 15-20 mmHg); during the episodes heart rate increased to about 80-90 beats per minute due to sensor-driven atrial pacing (with spontaneous ventricular activation). There was no obvious cause to justify these episodes, in particular different etiologies of orthostatic hypotension (neurogenic, non-neurogenic, drug/toxins effect) had been excluded; pacemaker did not show any malfunction. So we repeated an echocardiogram, recording diastolic filling during the episodes of symptomatic orthostatic hypotension: we found E/A wave fusion with a particularly short diastolic filling time (about 280 msec at 80 beats per minute) (Figure 2A). We also noticed that at ECG, during atrial-based pacing, AP-VS interval was about 280-300 msec and right atrial stimulus artifact was followed by a first deflection corresponding to right atrial depolarization (white arrow in Figure 1) and then a second deflection corresponding to left atrial depolarization (black arrow in Figure 1). We also tried to program the pacemaker in AAI mode with a fixed rate but the results were the same compared to MVP™. All these features suggested us that atrial-based pacing was responsible of an abnormal prolongation of AV interval (with E/A fusion), likely associated with intraatrial and interatrial conduction delay, with symptoms (near-syncope) and orthostatic exacerbation similar to "pacemaker syndrome". However, by definition pacemaker syndrome occurs when there is atrial systole during ventricular systole while E/A fusion seen in our case is a diastolic filling issue. So MVP™ was turned OFF and we optimized the programmed AV interval to 90 msec ("forcing" RV pacing) in order to ensure an adequate echocardiographic diastolic filling time, with a good separation of E and A waves at pulsed wave mitral Doppler (diastolic filling time 547 msec at 70 beats per minute) (Figure 2B). Since the first day after reprogramming the device, the episodes of orthostatic hypotension did not occur anymore; we tested the patient with an "orthostatic stress test" (a sudden change from supine to upright position while monitoring blood pressure, heart rate and diastolic filling pattern) and neither hypotension nor symptoms occurred during AP-VP paced rhythm.

Diastole begins soon after the end of systolic ejection (aortic valve closure) and includes LV pressure fall, rapid filling, diastasis and atrial contraction. Diastolic filling and cardiac output are strictly linked and the optimal performance of the LV depends on the alternation between a compliant chamber in diastole (LV filling from a low atrial pressure) and a stiff chamber in systole (ejection of the stroke volume at arterial pressures). When passing from supine to upright position there is a venous pooling in the lower extremities and splanchnic circulation as a result of the gravitational change. The consequent decrease of venous return to the heart leads to a transient reduction of ventricular filling, cardiac output and blood pressure. As compensatory mechanisms sympathetic tone increases and parasympathetic activity decreases: venous return, heart rate and vascular resistance they all increase with the aim of maintaining cardiac

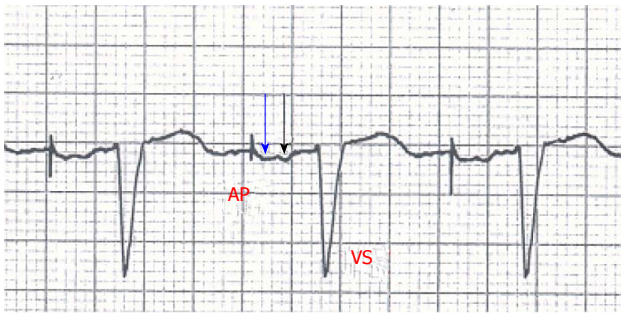

Figure 1 ECG after implant showing atrial-based pacing with spontaneous ventricular activation. AP-VS interval: 280-300 msec. Right atrial stimulus artifact is followed by a first deflection corresponding to right atrial depolarization (blue arrow) and then a second corresponding to left atrial depolarization (black arrow). AP: Atrial pacing; VS: Ventricular sensing.

output and blood pressure. When one or more of these compensatory mechanisms fail orthostatic hypotension can occur.

Several factors contribute to the clinical, ECG and echo findings in our patient. First of all pacing from right atrial appendage led to a delay in interatrial and intraatrial conduction as manifested by a "wide" P wave following stimulus artifact, with two distinct deflections corresponding to right and left atrial depolarization (Figure 1), while P wave morphology in spontaneous sinus rhythm was completely normal. As a consequence, a long AV delay occurred (AP-VS 300 msec) that was likely and mainly the consequence of inter/intra atrial conduction delay (rather than a true nodal/hisian delay, PR interval being normal during non-paced rhythm). This kind of "pseudo first degree AV block" pushed the A wave toward E wave: E/A fusion occurred so diastolic filling time was abnormally short. During orthostatic challenge the inability to fill the ventricle, because of this diastolic impairment, finally led to symptomatic hypotension with near-syncope. The only way to restore an adequate filling time was to optimize AV delay, but this involved to "force" RV pacing.

MVP™ provides an atrial-based pacing (AAI/R) with ventricular backup at an AV delay of 80 msec in absence of a ventricular sensed event following an atrial sensed or paced event. When loss of AV conduction persists (two out four non-refractory AA intervals without ventricular sensed events) the pacemaker switches to DDD/R mode at the programmed lower rate and AV delay. The algorithm, then, performs regular checks of AV conduction and switches back to AAI/R mode if possible[5]. The MVP™ tolerates markedly prolonged AV delay which can adversely affect cardiovascular hemodynamics, reducing atrial contribution to ventricular filling and favoring diastolic mitral regurgitation[5,6]. In general algorithms designed to minimize ventricular pacing operate by prolonging the AV interval with hysteresis or by switching between DDD and AAI modes; the operative features differ between manufacturers but all of them carry the risk

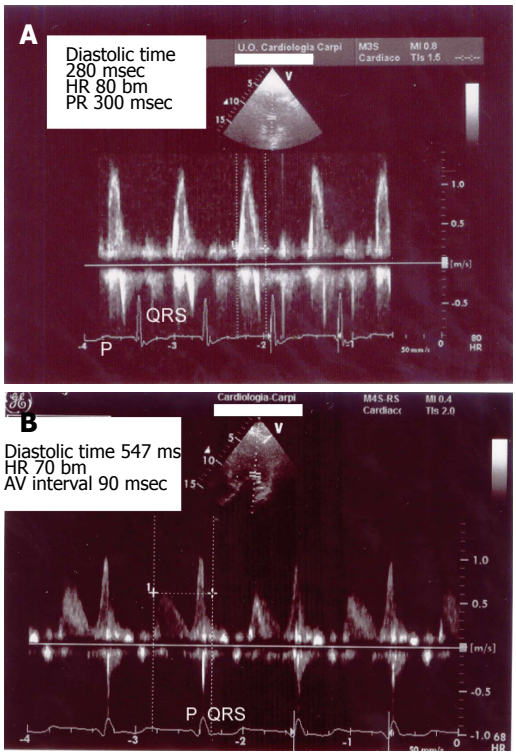

Figure 2 Pulsed wave mitral Doppler recording. A: Pulsed wave mitral Doppler recording during an episode of symptomatic orthostatic hypotension with atrial-based pacing: E/A wave fusion with a particularly short diastolic filling time (280 msec at 80 beats per minute); B: Diastolic filling after AV delay optimization at 90 msec ("forcing" RV pacing): Good separation of E and A waves at pulsed wave mitral Doppler (filling time 547 msec at 70 beats per minute).

of AV decoupling (defined as > 40% of AV intervals over 300 msec) even when baseline PR interval is normal. To prevent this adverse effect some manufactures have incorporated in their algorithms a maximum tolerated AV delay (350 msec in Ventricular Intrinsic Preference™ by St Jude Medical; 350 msec atrial sensed and 450 msec atrial paced in AAISafeR2™ by Sorin Group): if AV delay exceeds these limits, the device switches to DDD mode.

Atrial pacing "*per se*" increases AV delay: pacing from right atrial appendage can provoke marked alterations in interatrial and intraatrial impulse propagation that impairs coordinated activation and can also favor atrial fibrillation[7]. In the DANPACE trial[8], that compared AAI and DDD pacing in SND, atrial-based pacing significantly increased the risk of paroxysmal atrial fibrillation [28.4% in AAI group *vs* 23% in DDD group; hazard ratio (HR) 1.27; P = 0.024]. In a study AAI-R based pacing, in patients with SND and normal baseline PR interval, induced a clinically significant lengthening of AV conduction time, with a paradoxical increase of AV conduction during exercise in 66% of cases (that was predicted by use of antiarrhythmic class Ⅰc/Ⅲ drugs)[9]. Moreover in 23%-58% of SND patients AV conduction is already impaired at baseline, two thirds of these patients having a first degree AV block; the optimal pacing mode in these subgroup is not determined. In a

comparison study between conventional dual chamber pacing and minimal ventricular pacing mode there was no significant difference in terms of functional capacity assessed by cardiopulmonary test, quality of life and echocardiographic parameters of systolic/diastolic function; it was concluded that sequential AV pacing may be a reasonable choice for patients with SND and prolonged PR interval[10].

Alternative atrial pacing sites have also been studied: high and low interatrial septum, Bachmann bundle, lateral free wall and combinations of these sites; the concept was to improve atrial hemodynamics by reducing total atrial activation time. Although several small studies indicated that some alternative sites could help to prevent atrial fibrillation, randomized trials did not show benefit in the long term[11].

The attempt to minimize RV pacing, at expense of AV synchrony, can be particularly deleterious in patient with heart failure. In the INTRINSIC RV trial[12] patients indicated for ICD implant were randomized to dual chamber pacing with AV Search Hysteresis™ or single chamber VVI pacing 40 bpm. Patients with 10%-19% RV pacing had the most favorable outcome, while the risk of clinical events (mainly heart failure decompensation) in the 0%-9% RV pacing group was as high as the 40%-49% RV pacing group. So some ventricular pacing may be necessary, even if the optimal balance between AV synchrony and intraventricular dyssynchrony induced by RV pacing varies between patients and is not simple to define.

Abstract

Hepatitis C virus (HCV) genotypes 4, 5 and 6 are mainly present in Africa, the Middle East and Asia and they have been less extensively studied with respect to epidemiology, natural disease history and therapeutic endpoints. Response rates to a 48-wk combined peginterferon/ribavirin treatment range to 40%-69% for HCV 4, 55%-60% for HCV 5 and 60%-90% for HCV 6. Response-guided schedules are recommended to optimize the outcomes of peginterferon/ribavirin treatment in HCV 4 and, in form of preliminary data, for HCV 6, but no data are yet available to support such an individualization of therapy for HCV 5. Recently, the direct-acting antivirals (DAAs) with pan-genotypic activities simeprevir, sofosbuvir and daclatasvir have been recommended in triple regimens with peginterferon/ribavirin for the treatment of HCV genotypes 4 to 6 infections. In the future, DAA-based interferon-free therapies are awaited to drastically improve treatment outcomes in HCV. However, efforts to improve treatment outcomes with peginterferon/ribavirin should continue, as the HCV 4-6 infected population is mainly based in resource-limited settings with restricted access to the costly DAAs.

Key words: Hepatitis C virus; Genotype 4; Genotype 5; Genotype 6; Pegylated interferon; Ribavirin; Direct-acting antivirals

Core tip: Hepatitis C virus (HCV) 4, 5 and 6 are lesser known genotypes mainly encountered in Africa, the Middle East and Asia. Studies, mostly retrospective, have reported response rates to a 48-wk peginterferon/ribavirin combination ranging to 40%-69% for HCV-4, 55%-60% for HCV-5 and 60%-90% for HCV-6. Increasing evidence has supported a response-guided approach for HCV-4, whereas no robust data are yet available concerning tailoring of treatment duration for HCV-5 and HCV-6. Direct-acting antivirals may significantly improve treatment outcomes in HCV, but use of these agents in countries endemic for HCV 4-6 is currently precluded by the very high costs.

INTRODUCTION

Hepatitis C virus (HCV) remains a major health problem worldwide with over 170 million persons chronically infected and a burden of 300000 deaths annually[1,2]. Phylogenetic analyses of viral genomic sequences have identified at least 6 major HCV genotypes (and more than 70 subtypes), each with a distinct geographical distribution and sensitivity to antiviral treatment[3,4]. HCV 1, 2 and 3 are widely disseminated genotypes and have been thoroughly assessed with regard to epidemiology, natural disease history and treatment outcomes. Conversely, HCV 4, 5 and 6 have a restricted geographical distribution, mainly based in countries with limited resources and research facilities, thus epidemiological reports and treatment advances for these genotypes have been generally deficient. Prevalence of HCV genotypes 4 to 6 across different countries is summarized in Table 1. Genotype 4 is encountered throughout Middle East and Africa[5-12], whereas a spread of the infection has been described in other countries[13-15], particularly in Southern Europe[16-20]. HCV 5 is rare outside South Africa[21-23], but its sporadic presence has been reported in different parts of the world[11,15,24-28], including a pocket of the infection in Southeast Greece[29]. Lastly, HCV 6 and its subtypes are found mainly in Asia[30-35]. Crucially, due to the phenomenon of globalization, the prevalence of the HCV 4 to 6 genotypes outside of these "typical" areas is awaited to increase in forthcoming years.

During the past decade, a dual combination of pegylated interferon (PegIFN) and ribavirin (RBV) has represented the standard of care (SOC) for treating chronic hepatitis C (CHC). In 2011, introduction of first generation direct-acting antivirals (DAAs), the NS3/4A protease inhibitors (PIs) boceprevir and telaprevir, has boosted rates of sustained viral response (SVR; *i.e.*, negative HCV-RNA at 6 mo or more after cessation of treatment) in both naïve and treatment-experienced patients, although this only regarded the most difficult-to-treat CHC genotype 1[36]. Latter, in 2013, approval of the second generation DAA, NS5B polymerase inhibitor (PI) sofosbuvir, has been a further step forward due to its pangenotypic effect on HCV, better pharmacokinetics and improved resistance profiles[37]. In the light of the rapidly changing paradigm of treating CHC, new drugs were recently approved or await approval. However, in the era of DAAs, optimal treatment of HCV genotypes 4 to 6 remains, more than ever before, to be defined. Indeed, most treatment data rely on retrospective studies, extrapolations using other HCV genotypes as reference, and expert opinions.

Herein, we aimed to a concise overview on the treatment of HCV 4 to 6, including recent proposals for a response-guided treatment approach as well as the available data and future perspectives on the use of DAAs with respect to these lesser known HCV genotypes.

TREATMENT OF HEPATITIS C GENOTYPES 4 TO 6

Combination therapy with PegIFN and RBV

Hepatitis C virus genotype 4: HCV 4 has been traditionally considered a difficult to treat genotype, mainly because of the disappointing SVR rates (5%-25%) obtained in the early clinical trials using conventional interferon monotherapy[38,39]. Later introduction of RBV, used in conjunction with PegIFN, has significantly increased the efficacy of treatment, although response rates were still lower as compared to genotype 2 and 3 patients. Figure 1 summarizes results of prospective studies evaluating a fixed 48-wk treatment using standard-dose PEGIFN and RBV (PegIFNα-2a 180 μg or PegIFNα-2b 1.5 mg/kg and RBV 1-1.2 g/d) in HCV 4[40-46]. Overall, SVR rates ranged between 40% and 69%. However, a significant discrepancy could be noted between the SVR rates reported in highly endemic countries (SVR 60%-69% in studies conducted in Egypt and the Middle East)[40,42,43,47-50] and those (generally < 60%) reported in European populations infected with HCV 4; including 55% in Spain[51], 40.3% in France[52] and 43.5% in a cohort from Greece[53]. This difference has prompted the hypothesis of an impact of ethnicity on antiviral response, with 2 French analyses suggesting Egyptian (*vs* European) origin as a favorable prognostic indicator for SVR[52,54]. However, no solid pathogenetic basis has been provided for this phenomenon, although genetic or immunological ethnic-specific differences have been put forward[55,56]. Unlike the French observations, we could not identify any influence of Greek (n = 101) *vs* Egyptian (n = 76) origin on treatment outcomes[57], and only age ⩾ 45 years [odds ratio (OR) = 0.42, P = 0.01), presence of diabetes (OR = 0.23, P = 0.007), advanced liver fibrosis (Metavir F3-F4; OR = 0.39, P = 0.01) and treatment suspension (OR = 0.17, P = 0.007) were independent negative associations, in line with previous studies assessing predictors of response in HCV 4[40,42,43,52,54,58-63] (Table 2). The importance of metabolic factors has been highlighted by the observation of a beneficial effect of using an insulin-sensitizing agent, such as pioglitazone, in conjunction with antiviral treatment in patients with insulin resistance (homeostasis model assessment index > 2)[64]. Congruently, presence of hepatic steatosis, known to be a poor predictor of treatment in CHC, has been linked to host metabolic factors in HCV 4 rather than to a direct viral steatogenic effect as in the case of HCV 3 infection[65,66]. Other host factors, including the IL-28B TT genotype and high values of the interferon-c inducible protein 10 (IP-10) have been associated with a poor therapeutic outcome[59]. Interestingly, Boglione *et al*[67] have recently proposed use of the IL-28B polymorphisms upstream as a genuine basis for the identification of patients

unlikely to respond to standard dual therapy, and thus candidates for a DAA regimen. This individualized approach merit further robust assessment.

Definition of the optimal treatment duration is paramount to reduce costs and improve treatment tolerability without compromising the therapeutic efficacy. Due to the consistently lower response rates with 24 wk of therapy, a 48-wk treatment duration has been recommended as the SOC for genotype 4, similar to genotype 1[43,48,68]. A further refinement has been use of early viral responses to allow for shorter treatment durations in highly responsive patients (*i.e.*, response-guided approach). In a double-blind randomized study, Kamal *et al*[43] showed that in patients achieving a complete early viral response (EVR; defined as a negative HCV-RNA at week 12 of treatment), the SVR rate was 86% with a 36-wk therapy and 92% with 48 wk of therapy (P = 0.8), whereas PegIFN dose reductions were significantly more common in the 48-wk group. Two randomized controlled trials, one including exclusively genotype 4[69] and one including a mixture of both genotype 1 or 4 patients[70] have assessed the utility of a

Table 3 Studies reporting rates of sustained virological response to 48-wk interferon-based combination therapy in patients with hepatitis C genotype 5

Author/Country/Year	No. patients	Regimen	SVR
Legrand-Abravanel/France/2004[75]	12	Standard/Pegylated IFN plus RBV	63.60%
Delwaide/Belgium/2006[74]	6	Standard/Pegylated IFN plus RBV	83%

[1]Thirteen out of 26 patients received 24 wk of treatment due to personal, financial or medical reasons. IFN: Interferon; RBV: Ribavirin; SVR: Sustained virological response.

response-guided tailoring of treatment. Based on the results of these studies, a 24- and 36-wk treatment duration have been established as sufficient in patients with a rapid viral response (RVR, defined as negative viral load at week 4 of treatment) and EVR respectively. Contrarily, Ferenci *et al*[71] showed that a 72-wk extended-duration therapy may benefit slow responders; *i.e.*, those non achieving RVR but attaining at least a partial (*i.e.*, a $\geqslant$ 2log10 drop in serum HCV-RNA) EVR and a negative HCV-RNA at week 24. Critically, a suboptimal PegIFN alpha-2a dose (135 μg/wk after week 48) may have compromised SVR rates in this study. Patients with detectable viral load at the end of week 24 are unlike to respond to treatment, and therefore assessment based on serum HCV-RNA at this time-point may serve as a futility rule, as indicated by its 92.8% negative predictive value on SVR[53]. To date, no robust conclusions can be drawn regarding efficacy of PegIFN alpha-2a *vs* alpha-2b in patients infected with HCV 4[72].

Hepatitis C virus genotype 5: Mainly due to its low worldwide prevalence, HCV 5 probably represents the less studied HCV genotype with respect to therapeutic endpoints. Epidemiological reports from France, Belgium, Canada, Syria and Greece argue that patients infected with HCV 5 have specific epidemiological characteristics: they are predominantly females of advanced age and they are characterized by high baseline viremia and advanced hepatic fibrosis[25,29,73-75]. Despite presence of these classical negative predictors of treatment response, SVR rates have been reported to 55%-60%[29,74-81], although most of the therapeutic studies on HCV 5 (Table 3) have had inherent limitations, including the retrospective design, small sample and extreme heterogeneity with respect to treatment modalities[74-76,78] and patient sampling[79]. Currently, a fixed 48-wk course of combined PegIFN and RBV is recommended for patients with HCV 5. However, the intrinsic sensitivity of HCV to combined antiviral therapy, and thus the ideal treatment duration, remains controversial. In a retrospective study by Antaki *et al*[77], 13/26 patients were treated for 24 wk due to personal, financial or medical reasons, and no impact of treatment duration (24 wk *vs* 48 wk) was found on SVR. In support of a 24-wk treatment, some retrospective data[75,78] suggested that response of HCV is similar to that observed for genotypes 2 and 3, although this was disputed in more recent studies[76,79]. Clearly, extrapolations using other HCV genotypes as reference are not an appropriate basis for treatment standardization. In a prospective, open label, single-arm trial we have evaluated 27 patients with HCV 5 and the SVR was 63%, whereas non-response was mainly due to relapse (26.1%)[81]. To our knowledge this is the only prospective therapeutic trial using exclusively a combination of PegIFN and RBV and including only treatment-naïve patients. The most striking finding of our study was the excellent predictive value of early viral responses on SVR: the positive predictive value (PPV) of RVR was 93.8%, whereas the negative predictive value when not achieving EVR was 100%. Based on these data, a response-guided schedule may be a viable option for patients with HCV 5[82]. Thus, it merits appropriate consideration in future trials, possibly conducted on a multi-center basis.

Hepatitis C virus genotype 6: Small studies, using a combination of either standard interferon[83,84] or PegIFN[85,86] and RBV have examined treatment outcomes in HCV 6. Overall, SVR rates have ranged to 60%-90%, indicating a more favorable response in comparison to HCV 1 and comparable to that of HCV 2 and 3. Crucially, a favorable IL28B status among Asians patients may have contributed significantly to these good results[87]. Apart from baseline viral load and the degree of hepatic fibrosis, which represent classical predictors of treatment response in CHC, other host factors such as age, BMI and adherence to treatment schedule have been identified as relevant in cohorts of patients with HCV 6[88]. To date, optimal treatment duration for HCV 6 has been a matter of controversy, with studies comparing a 48- *vs* a 24-wk regimen providing equivocal results (Figure 2)[86,89-91]. Most studies investigating therapeutic outcomes in HCV 6 have applied 48-wk treatment duration[83-85].

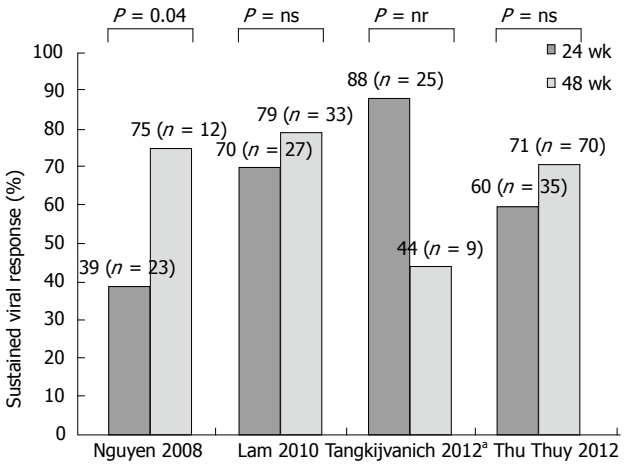

Figure 2 Studies comparing outcomes of 24 *vs* 48 wk of therapy with pegylated interferon and ribavirin in patients with hepatitis C virus genotype 6. [a]Treatment duration was tailored according to viral response at week 4: Patients with negative hepatitis C virus-RNA received 24 wk of treatment; the remainder received 48 wk. ns: Non-significant; nr: Not reported.

Moreover, in a retrospective analysis by Nguyen *et al*[86], the SVR rates were significantly lower with a 24-wk treatment schedule (39% *vs* 75%, $P = 0.044$). However, two randomized controlled trials including 60 and 105 patients have shown non-inferiority with a 24-wk (*vs* a 48-wk) regimen of PegIFN alpha/2a and RBV[89,91]. As in case of other HCV genotypes, individualization of treatment duration based on early viral dynamics may allow for reduction to drug exposure and in treatment costs. In an open-label randomized study by Thu Thuy *et al*[91], RVR occurred in about 80% of patients and had a 75%-86% PPV on SVR irrespective of treatment duration; nonetheless, among those with no RVR, even a 48-wk treatment achieved low SVR rates (8%). Efficacy of a response-guided approach based on RVR has been evaluated by Tangkijvanich *et al*[90]: in a pilot study including 34 patients with CHC genotype 6, the SVR rate in patients with RVR who underwent a 24-wk treatment was 88%. Based on these data, patients with a RVR may benefit with 24 wk of therapy. On the other hand, interruption of treatment may be the most reasonable option in patients with a detectable viral load by week 12 of therapy (non-EVR), as these patients are unlikely to respond to a 48-wk course[89,91,92] whereas there is no data to support they might benefit from longer treatment duration. Additionally to the use of early viral responses, evaluation of baseline parameters such as age, the degree of liver fibrosis, viral load and BMI may further rationalized choice of the optimum treatment duration[88]. Larger randomized trials are awaited to optimize treatment schedules for HCV 6.

Direct-acting antivirals

First generation protease inhibitors: Telaprevir and boceprevir are first generation NS3/4 PIs firstly approved in 2011 for patients infected with HCV 1. Although both drugs are not approved for HCV 4, telaprevir has shown a modest activity against this genotype. A phase Ⅱa trial (study C210) has assessed the activity of telaprevir on early viral dynamics[21]. Twenty four patients with HCV 4 were randomized to three groups: telaprevir alone; PegIFN plus RBV; and a triple regimen comprising telaprevir plus PegIFN/RBV. By day 15 of therapy telaprevir monotherapy induced only a 0.77 log10 decline in HCV-RNA levels (*vs* 4.77 log10 for HCV 1). The viral decline was more pronounced (4.32 log10) when telaprevir was administered together with PegIFN/RBV indicating a synergic effect. A descriptive subanalysis of the C210 study showed that the most frequent mutation accounting for the limited antiviral efficacy of telaprevir monotherapy was the T54A/T previously described for HCV 1[93]. Interestingly, this mutation has limited or no impact on the efficacy of subsequent treatment with dual PegIFN/RBV.

Indeed, emergence of resistant variants has generally precluded monotherapy with first generation PIs. However, use of these agents in conjunction with PegIFN/RBV still depends on interferon sensitivity, requires a high pill burden and a complex treatment algorithm. Moreover, both drugs may enhance or induce a set of considerable side effects. Anemia, neutropenia and dysgeusia are the most common side effects with boceprevir, whereas anemia, skin rash and anorectal symptoms are more frequently associated with telaprevir. Anemia, occurring in about 40%-50% of cases, may lead to discontinuation of treatment despite management with ribavirin dose adaptations, use of erythropoietin alpha or blood transfusions. Skin rush specifically related to telaprevir is generally mild and manageable using emollients and topical corticosteroids, although, in about 5% of cases, a severe life-threating cutaneous reaction may lead to treatment discontinuation[94].

Better-tolerated new generation DAAs with improved pharmacokinetics (allowing once-daily administration) and favorable resistance profiles (allowing interferon-free, all-oral regimens) were recently approved or await approval. These agents, with activities against HCV 4 to 6, will be discussed below.

Simeprevir (TMC435): It is a second generation NS3/4A PI, active against genotypes 1, 2, 4, 5 and 6. It is administered as a once-daily tablet orally and has demonstrated a favorable safety profile and limited drug-drug interactions[95]. It was approved in November 2013 by the United States Food and Drug Administration (FDA) and in Japan in September 2013.

RESTORE, a phase Ⅲ, multicenter, single-arm, open-label study, conducted in France and Belgium, evaluated simeprevir (150 mg once-daily for 12 wk in combination with PegIFN/RBV, followed by 12-36 wk of PegIFN/RBV only) in 107 patients with HCV 4, either naïve or treatment-experienced[96]. Overall, SVR

at week 12 was observed in 65.4% of patients, with rates being particularly high among treatment-naïve (82.9%) and prior-relapsers (86.4%). Both these patient groups were eligible to a shorter (totally 24 wk) treatment duration if they achieved a HCV-RNA < 25 IU/mL at week 4 and undetectable at week 12. These response-guide criteria were met by 88.6% of treatment-naïve and 90.9% of prior relapsers; among them 93.5% and 95% respectively achieved a SVR at week 12. Notably, none patient had a detectable Q80K substitution in the NS3 protease sequence at baseline, associated with decreased efficacy in patients with HCV 1a.

Overall, simeprevir has demonstrated favorable safety profile. By pooling data form phase Ⅲ clinical trials (QUEST-1, QUEST -2 and PROMISE), discontinuation of treatment due to severe adverse events occurred in 2% of patients receiving a simeprevir plus PegIFN/RBV combination[97-99]. Rates of adverse events, most commonly fatigue, influenza-like illness, headache, nausea and pruritus, were generally similar between simeprevir/PegIFN/RBV and placebo/PegIFN/RBV groups. Incidence of photosensitivity and rush has been slightly higher with simeprevir (*vs* placebo), although the vast majority of cases were graded 1/2 in severity. Transient moderate bilirubin increases were noted; however, no clinically relevant cases of hepatotoxicity were recorded.

Recent European guidelines have included a 24-48 wk simeprevir plus PegIFN/RBV combination as an option for HCV 4-related compensated liver disease (including cirrhotics), suggesting interruption of treatment if HCV-RNA levels are ⩾ 25 IU/mL at week 4, 12 or 24[100].

Sofosbuvir: This is a nucleotide inhibitor of NS5B, with a pan-genotypic effect activity and a high barrier to resistance. It is administered as an oral 400 mg tablet/day with no food effect, whereas it has been proven safe and well-tolerated in phase Ⅱ and Ⅲ clinical trial including > 2000 patients. It was approved by FDA for HCV 1 in combination with PegIFN/RBV, and in HCV 2 and 3 in interferon-free regimens in December 2013 and in Europe in January 2014.

NEUTRINO, an open-label, single-arm, phase Ⅲ trial, evaluated a 12-wk regimen, comprising sofosbuvir plus PegIFN/RBV, in 327 treatment-naïve patients with genotypes 1, 4, 5 and 6[101]. However, the vast majority (89%) of the patient population had HCV 1. Overall, 27 out of the 28 (96%) patients with HCV 4, all 6 patients with HCV 6 and the single patient with HCV 5 achieved an SVR, 12 wk after the end of treatment. Currently, a sofusbuvir-based triple combination for 12 wk appears as the most efficacious and easy-to-use interferon containing option for the treatment of HCV genotypes 4 to 6, without the risk for selecting resistant variants in case of treatment failure[100]. Critically, rates of SVR were relatively lower in cirrhotics in the NEUTRINO trial (80% *vs* 92% in patients without cirrhosis), whereas no data with this regimen has been presented in treatment-experienced patients. Thus, it remains unknown whether longer treatment duration may be required for these more difficult-to-treat patient populations.

More recently, promising data have emerged on the efficacy of an interferon-free combination of sofosbuvir plus ribavirin in patients with HCV 4. Ruane *et al*[102] randomized (1:1) 60 patients of Egyptian ancestry (treatment-naïve: 28, treatment-experienced: 32; 23% cirrhotics; 17% with the IL28B CC genotype), stratified by prior treatment status and cirrhosis, to receive 12 or 24 wk of sofosbuvir (400 mg/d) plus RBV *(*1200 mg/d). After 12 wk of treatment, SVR rates were 11/14 (79%) in treatment-naïve and 10/17 (59%) in treatment-experience patients. However, extending the duration of treatment to 24 wk resulted in higher SVR rates in both treatment-naïve (14/14; 100%) and -experienced (13/15; 87%) groups. Thus, a dual sofosbuvir/ribavirin combination given for 24 wk is currently recommended for HCV 4 patients who are interferon-intolerant or -ineligible[100].

As evident in phase Ⅲ clinical trials, sofosbuvir in combination with RBV represents a well-tolerated option with rates of treatment discontinuation as low as 1%-2%[103]. Drug-related adverse events attributable to RBV such as fatigue, insomnia and anemia were the most common, and headache was also frequent. Unsurprisingly, incidence of adverse effects commonly associated with interferon, such as influenza-like illness and depression, was significantly lower and hematological abnormalities were less prominent among patients who receive sofosbuvir/RBV than among those who receive the standard PegIFN/RBV combination[101]. Consistently, health-related quality of life and health utilities of patients have been shown to be only minimally affected by sofosbuvir/RBV irrespectively to treatment duration[104,105].

Daclatasvir: This is an HCV NS5A oral PI with a pan-genotypic activity, but a lower barrier to resistance in genotype 1a[106]. A recent phase Ⅱb double-blind, placebo-controlled study evaluated a triple combination comprising daclatasvir plus PegIFN/RBV including treatment-naïve patients with HCV 1 (n = 365) or 4 (n = 30)[107]. Patients were randomly assigned (2:2:1) to daclatasvir 20 mg or 60 mg, or placebo once daily plus PegIFN/RBV. Overall, SVR rates (week 24 post-treatment) were 8/12 (66.7%) in HCV 4 patients receiving 20 mg, 12/12 (100%) in those receiving 60 mg and 3/6 (50%) in patients receiving placebo. Patients on daclatasvir did not have adverse events beyond those typical of PegIFN/RBV.

Based on this preliminary data, a daclatasvir (dose: 60 mg/d) plus PegIFN/RBV regimen has been included as an option for the treatment of genotype 1b and 4 patients[100]. The triple combination should be administered for 12 wk. In those who do not achieve an HCV-RNA level < 25 IU/mL at week 4

and undetectable at week 10, all three drugs should be continued for an additional 12 seeks. Conversely, PegIFN/RBV should be continued alone between week 12 and 24 in those who achieve such response[100].

Other DAAs evaluated in HCV 4: Phase Ⅱ trials have evaluated other triple or quadruple drug combinations in patients infected with HCV 4. In the DAUPHINE trial, different dosing schedules of danoprevir boosted with ritonavir plus PegIFN/RBV for 12-24 wk achieved up to 100% of SVR in treatment-naïve patients with HCV 4[108]. In yet another phase Ⅱb study, 25 HCV-4 patients were assigned to asunaprevir 200 mg or placebo twice daily plus PegIFN/RBV; the SVR rates were 89% in those receiving asunaprevir *vs* 43% in the placebo group[109]. Lastly, two randomized placebo-controlled trials have evaluated use of mericitabine in combination with PegIFN/RBV including patients infected with HCV 4[110,111]. In the JUMP-C trial, a 24-wk response-guided combination of mericitabine 1000 mg twice daily plus PegIFN/RBV was well-tolerated and more effective than a standard 48-wk PegIFN/RBV combination[110].

EMERGING CHALLENGES

While standardization of dual PegIFN/RBV regimens for HCV 4 to 6 is still pending, interferon-based treatment of HCV has been superseded by the introduction of oral DAAs with pan-genotypic activities. These agents are characterized by improved antiviral efficacy and offer the perspective for short-course, all-oral and interferon-free therapies. However, as it is reasonable, most trials evaluating DAAs have focused on the more prevalent and difficult to treat HCV genotype 1. Given obvious difficulties in patient sampling, multi-centric efforts may be necessary to assess therapeutic sensitivity, optimize DAA schedules and establish cost-effective response-guided approaches for HCV 4 to 6. Crucially, the very high cost of HCV DAAs is a central barrier to their widespread use, thus interferon-based treatments are likely to continue to have a role as cost-containing options in low- or lower-middle income countries. This is particularly relevant in the case of genotypes 4 to 6 which are mainly based in resource-limited countries; but with large HCV epidemics, hence these genotypes represent > 20% of the global HCV burden. Therefore, unless low-cost DAAs become available, a large population of untreated patients will continue to spread HCV in these countries and worldwide. Furthermore, treatment with DAAs of special patient population (*e.g.*, patients with kidney disease, HIV coinfection, patients undergoing solid organ transplantation) remains a challenge, as few or no data are available.

In conclusion, it seems we need to wait for a while until arrangement of both practical and logistic issues will allow for low-cost, all-oral and interferon-free regimens, at a level to dramatically change the global epidemics of HCV 4 to 6. Until then, efforts to further rationalize the use of the traditional PegIFN/RBV treatment should continue.

Abstract

Vitiligo is a common pigmentary disorder. Many studies across decades and all over the world have attempted to illustrate the pathogenesis behind it; however, the pathogenesis of vitiligo remains elusive. This review article, we present the findings behind the most and updated theories behind this psychologically debilitating and disfiguring disease. The discussion begun with the role of genetic predisposition followed by neural theory first proposed in the 1950s. We highlight the autoimmune hypothesis, followed by the reactive oxygen species model, zinc-α2-glycoprotein deficiency hypothesis, viral theory, intrinsic theory and biochemical, molecular and cellular alterations accounting for loss of functioning melanocytes in vitiligo. Many theories were elaborated to clarify vitiligo pathogenesis. It is a multifactorial disease involving the interplay of several factors. Future research is needed to clarify the interaction of these factors for better understanding of vitiligo pathogenesis and subsequent successful treatment.

Key words: Etiopathogenesis; Pigmentary disorder; Non-segmental vitiligo; Segmental vitiligo; Vitiligo

Core tip: The pathogenesis of vitiligo elaborated by several theory. Future research needed to clarify the interaction of these factors for better understanding of vitiligo pathogenesis and subsequent successful treatment.

INTRODUCTION

The pathogenesis is complex and involves the interplay of multiple factors; however, the exact pathogenesis is not well known. Lerner *et al*[1] in the 1950s firstly proposed the neural theory, and after that, model of reactive oxygen species (ROS), the autoimmune hypothesis and the melanocytorrhagy hypothesis have appeared.

DIFFERENT PATTERNS AND PHYSICAL DISTRIBUTION OF VITILIGO

Pruritus, elevated lesions, and erythematous margins present in inflammatory vitiligo. There are 2 main types: generalized vitiligo (GV) (widespread macules with a symmetrical distribution), whereas focal vitiligo (FV) (1 or few depigmented not elevated areas at a single site). After coalescing of vitiliginous areas in GV, or becomes extensive in the body with remaining of few normal areas, thus called vitiligo universalis. Non-segmental vitiligo enrolled FV and GV, but segmental vitiligo (SV) restricted to one unilateral region[2], (Figure 1). The lesions of vitiligo are asymptomatic except in inflammatory vitiligo, which is associated with pruritus and characterized by elevated lesions, and erythematous margins.

INHERITANCE OF VITILIGO

The inheritance is polygenic[3]. Family history exists in 6.25%-38% of patients with vitiligo[4]. Those who have recessive homozygosity at 3 epistatically interacting autosomal diallelic loci will be affected by vitiligo[5].

Molecular genetics-based studies

Spritz *et al*[6] (2004) revealed different loci or alleles for GV. Autoimmune susceptibility (AIS)-1, -2 (chromosome 7) and systemic lupus erythematosus vitiligo-related gene (SLEV1) (chromosome 17) both associated loci for GV and concomitant autoimmune diseases. Of 33 tested loci, only (XBP1, TSLP, and FOXP3) were primarily concomitant with GV. FOXP3 associated with X linked recessive multiple autoimmune disease syndrome. In addition, CTLA4 had association secondarily with GV, and the autoimmune diseases[7]. However, patients with GV also linked to AIS3 locus (chromosome 8)[6].

Methylation of deoxyribunucleic acid (DNA) conducted by DNA methyltransferases (DNMT1, -3a, -3b)[8]. Monocytes in vitiliginous patients and normal volunteers showed sensitivity to alterations in methylation and revealed association between IL-10 and reactivity of autoimmune system[9,10]. In comparison with controls, methylation was increased and hypermethylation of the methylation-sensitive region in IL-10 that could alter genes expression in autoimmunity[9]. In a similar way, the role of transforming growth factor beta-receptor Ⅱ (TGFBR2), which inhibits the inflammatory pathways and lymphocyte activation was revealed[11,12].

The ultraviolet radiation resistance-associated gene (UVRAG), resists photo-damage, and plays a role in autophagy[13]. In 439 controls and 225 NSV patients, UVRAG has 2 SNPs which were significantly different[14].

Both diabetes mellitus type 1 and rheumatoid arthritis with SNPs found beside the insulin-dependent diabetes mellitus 8 locus (IDDM8)[15]. This region contains SMOC2, which enrolled in growth and development[16] and cell matrix interactions[17].

Also, melanocyte proliferating gene 1 (MYG1), is elevated in skin of both vitiliginous patients with activity, and without activity[18].

Human leukocyte antigen

Studies revealed that vitiligo associated with HLA-DRB1*07, HLA-A2, 11, 28, 31, 33, HLA-B17, 35, 40 and 44[19,20].

Susceptibility loci of vitiligo are on chromosome 6 and in the MHC[21]. A study genotyped 6623 patients with vitiligo and 10740 controls for 34 SNPs. *At 6q27, 2 SNPS* found with 3 unlinked genes. These gene include RNASET2, which responsible for ribonuclease (RNAse)[22]. The other two genes are the chemokine receptor 6 gene (*CCR6*)[21], and FGFR10P are imperative to progressing of the cycle of the cell that produce receptor of (FGF)[23]. Genes encode discoidin domain receptor 1 (DDR1)[24], and tyrosine kinase receptor play role in cell's progression and function[25], both were involved in vitiligo.

THEORIES FOR VITILIGO PATHOGENESIS

The neural theory

Early theories: The "neural theory" supposed by Lerner's (1959) was based on the fact that SV follows the course of the dermatome with exhibiting hyperhidrosis and emotional upset[1,26,27].

The sympathetic nervous system's role: Dysfunction of sympathetic nervous system's role (SNS) activity affect melanin production and lead to depigmentation. With iontophoresis and laser Doppler flowmetry level of microcirculation in lesions with vitiligo assessed to reveal SNS activity[28]. 10 subjects had facial SV, and 2 groups of controls were examined. 1 control group had 10 healthy, unaffected individuals, and the 2nd control group contained 10 non-segmental-type stable vitiligo patients. Patients were matched for gender and age. Approximately, the cutaneous blood flow was higher three times on the lesions *vs* normal skin in SV. The differences was not revealed in the non-SV.

Neuropeptide and neuronal markers: Neuropeptide Y (NPY), calcitonin gene-related peptide (CGRP), vasoactive intestinal polypeptide (VIP), and polyclonal general neuronal marker (PGP) tested for their immuno-reactivity in 12 patients with vitiligo and 7 unaffected control subjects[29]. NPY increased in the marginal areas of lesions in half of the patients *vs* normal, and associated with noradrenaline with exerting a local autonomic effect[29]. Lazarova *et al*[30] (2000) confirmed this finding; however, they found that CGRP was also non-significantly increased in vitiligo. Precipitating factor, as, stress, produce significant level of neuropeptides such as NPY that induct the disease[30,31]. A cohort study revealed

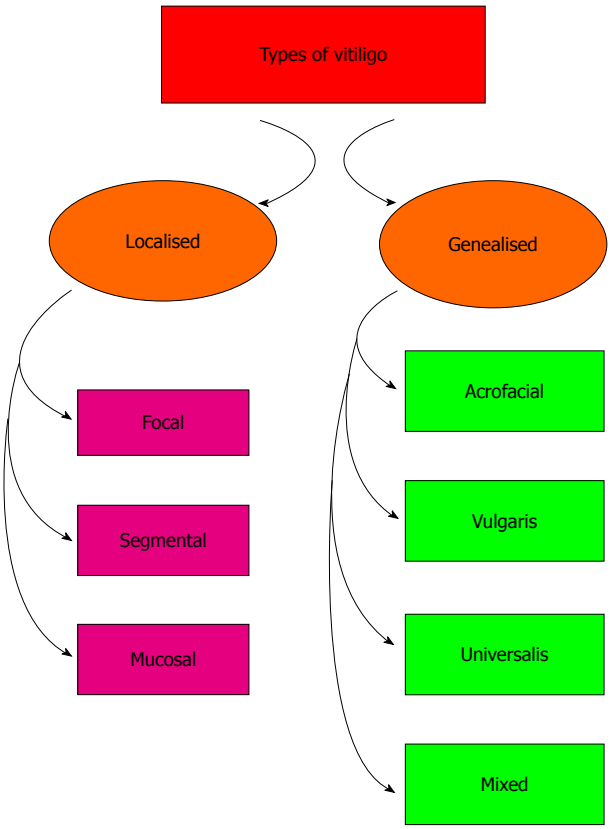

Figure 1 Types of vitiligo.

increased levels of nerve growth factor (NGF) significantly in vitiligo[32]. Stress up regulates NGF expression in hair follicles, decreases the high affinity TrkA receptor, increases production of p75NTR NGF-receptor, and increases in dorsal root ganglia the substance P neurons[33].

Catecholamine metabolite levels [homovanillic acid (HVA), vanilmandelic acid (VMA), 3-methoxytyramine (MT), normetanephrine (NMN), metanephrine (MN), 3,4-dihydroxy mandelic acid (DOMAC), and 3,4-dihydroxy phenylacetic acid (DOPAC)] were measured in 1-d urinary samples of 150 vitiliginous subjects and 50 normal subjects. HVA and VMA levels corresponded to the activity of the disease[34]. Stressors result in catecholamines discharge, which bind α-R in the mucosa and skin arteriolar wall leading to vasoconstriction, hypoxia, and overproduction of oxygen radicals that destroy melanocytes[34]. Mental stress could stimulate the hypothalamic-pituitary-adrenal axis and then secretion of catecholamines[34,35].

The autoimmune hypothesis

The etio-pathogenesis of "generalized" or non-segmental vitiligo is better explained by autoimmune mechanisms as vitiligo often has autoimmune comorbidities and it often responds to immunosuppressive treatments[36]. The reaction of immunity are cell-mediated, humoral (antibody-mediated), or through the cytokines.

The role of humoral immunity: In 2010, tyrosine hydroxylase antibodies checked with radioimmunoassay (RIA) in sera were obtained from 79 non-SV patients, 8 patients with SV, 91 subjects with other autoimmune diseases and 28 healthy subjects. TH antibodies revealed significantly in non-SV. Also, in non-SV, antibodies against MCHR1 (melanin-concentrating hormone receptor 1), tyrosinase[37] and pigment cell-surface antigens[38] were noted.

In 80% of active vitiligo patients, immunoglobulin G (IgG) and immunoglobulin M (IgM) against melanocytes were found. Low levels IgA also found in the inactive and control groups[38].

Furthermore, anti-thyroglobulin antibodies, antithyroid antibodies, anti-thyroperoxidase, and antismooth muscle antibody are present. Those are typically related to thyroid disease and other autoimmune diseases[39,40].

Melanin concentrating hormone (MCH) binds MCHR1 thus increase calcium influx and acting as an antagonist of α-melanocyte-stimulating hormone (α-MSH)[41-43].

The role of cell-mediated immunity: Immunohisto-chemical examination of the inflammatory infiltrates in perilesional vitiligo skin using single and double immunostaining for melanocytes, Langerhans cells, T-cells, and macrophages revealed higher densities of melanocytes in normal skin, *vs* non-affected skin in subjects with vitiligo. These T cell had dramatic production of (IL-2R), and increased CD8:CD4 ratio. Thus, melanocytes destruction may be cytotoxic CD8 T-cell mediated. Perilesional HLA-DR production (MHC class Ⅱ receptor) exhibited in all of the patients with vitiligo, especially along suprabasal and basal keratinocytes, due to local T cell reactivity. In addition, macrophages were numerous in vitiligo *vs* controls, whereas the CD36 subset of macrophages were higher in the later[44].

The role of cytokines in vitiligo: Beyond lymphocytes and antibodies, the immune system has a complex interplay of many cytokines. There are significantly increased expression of tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), and IL-10[45]. As IFN-γ and TNF-α are T helper cell-1 (Th1) cytokines, so vitiligo is mediated by the Th1 response[46].

IL-17 plays role with macrophages, keratinocytes, and fibroblasts. In addition, it activates the expression of others, as IL-1 and IL-6, and TNF-α[47,48]. Examination of sera and tissue of 30 vitiliginous subjects and 20 normal subjects showed significant higher levels of IL-17 toward vitiliginous subjects and disease duration[47].

The biochemical Theory- reactive oxygen species model

Oxidative stress hypothesis suggests that imbalanced redox (reduction-oxidation) state of the vitiliginous skin. This results in the dramatic production of reactive oxygen species (ROS), as H_2O_2. ROS oxidize components of the cell leading to melanocytes destruction and creating the depigmented macules[49].

The redox status of vitiligo patients: Sera of

thirty-six patients with vitiligo (18 with inactive and 18 with unstable disease), and 40 normal subjects were examined for main factors of redox status involving selenium, malondialdehyde (MDA), vitamins A and E, and glutathione peroxidase (GPx) in the erythrocyte activities, catalase (CAT) and superoxide dismutase (SOD). Superoxide radicals are scavenged and their toxicity is reduced with SOD which transforms O_2- to H_2O_2 and O_2, and catalase transforms (H_2O_2) to (H_2O) and (O_2)[50]. As MDA results from lipid peroxidation, it is a marker of oxidative stress[51,52]. Selenium is required for GPx activity and vitamins A and E are important in antioxidant activity. Serum selenium, SOD and MDA are prominent in both unstable and inactive types. By enhancing SOD activity, the H_2O_2 accumulates. In addition, GPx detoxifies H_2O_2 (downstream enzyme). Therefore, GPx levels decreased in patients with vitiligo[50,53].

Increased SOD activity in patients with vitiligo is a response to oxidative stress; thus, H_2O_2 elevate as could not be eradicated by low level of CAT[53,54].

The role of tetrahydrobiopterin recycling in vitiligo: Another cellular pathway affected by accumulating H_2O_2 involves tetrahydrobiopterin. Tyrosinase is an imperative enzyme in formation of melanin[55]. L-tyrosine synthased from L-phenylalanine by the phenylalanine hydroxylase (PAH). The 5, 6, 7, 8-tetrahydrobiopterin or 6BH4 is essential cofactor for this process is. Defective recycling of 6BH4 lead to excess 7BH4 that is an inhibitor of PAH. Uncoupled PAH and 7BH4 found in suction blister material from the skin of vitiligo patients[56]. Kowlessur *et al*[57] (1996) also found that 7BH4 production yields H_2O_2. Haase *et al*[58] (2004) studied the enzyme dihydropteridine reductase (DHPR) (imperative to end the normal 6BH4 recycling). They assessed whole blood samples from 27 untreated vitiligo subjects and 8 normal subjects. The results showed that DHPR activity decrease with high concentrations of H_2O_2 and *vice versa*.

Effect of H_2O_2 on acetylcholinesterase (AchE) decrease in patients with vitiligo *vs* healthy controls[59,60]. Thus, AchE dependent on H_2O_2 concentration levels, *i.e.*, low H_2O_2 concentrations (approximately 10-6M or mol/L) activate AchE whereas high concentrations (10-3M or mol/L) deactivate AchE[60]. Butyrylcholinesterase (BchE) mediates the hydrolysis of acetylcholine. The hydrolysis reaction is one of the rate-limiting steps in cholinergic signal transduction[61,62].

In 2008, showed that xanthine oxidase (XO) is a source of H_2O_2. High concentrations of H_2O_2 inhibit the activity of XO, and *vice versa*[63].

Briefly, there are at least 5 important pathways enrolled in H_2O_2 overproduction in vitiligo: (1) Defective recycling of 6BH4[56,64,65]; (2) Catecholamine formation increased as levels of monoamine oxidase A (MAO) increased[34,66,67]; (3) Inhibition of thioredoxin/thioredoxin reductase by calcium[68-70]; (4) NADPH oxidase activities increased by the cellular infiltrate[71]; and (5) Nitric oxide synthase (NOS) activities increased[71].

Oxidative stress affects calcium homeostasis at the cellular level[72] in melanocytes and keratinocytes in vitiliginous patients[69].

Zinc-α2-Glycoprotein deficiency hypothesis

For the first time, Bagherani *et al*[73] and Yaghoobi *et al*[74] pointed the probable association which might be present between ZAG and vitiligo[73,74]. It was suggested that the pathogenesis of vitiligo could be attributed to decrease in ZAG as follows: (1) Studies have demonstrated that ZAG is acting as a keratinocyte-derived factor influencing melanocyte proliferation and dendricity[75,76]. So, ZAG could be considered as a marker of cells differentiation and maturation[76]; (2) A chronic detachment of melanocytes is an imperative pillar in the pathogenesis of vitiligo[74,77,78]. Thus, melanocyte adhesions to the other cells in epidermis will be impaired in the lack of ZAG; (3) Topical steroids are the most safeand effective forms of treatment for vitiligo, especially for the localized one[74,79], because of their ability to increase ZAG expression[80,81]; (4) Some studies have shown that zinc can precipitate ZAG[74,82]. Thus, the effectivity of zinc in treating this disease is related to its ability to precipitate circulating ZAG at the site of vitiligo[73]; and (5) The linkage signals on chromosome 7 in patients with GV and associated autoimmune diseases have been reported[73,83]. Surprisingly, ZAG gene is located on the chromosome 7[76].

Viral theory

There is a strong association between vitiligo and chronic hepatitis C virus (HCV) infection and autoimmune hepatitis[84]. Akcan *et al*[85] in 2006 reported a low hepatitis B virus (HBV) sero-positivity in vitiliginous patients. Previous or concurrent cytomegalovirus (CMV) infections may induce the etio-pathogenesis or deterioration of vitiligo[85,86].

Furthermore, other viruses as Epstein-Barr virus, hepatitis E virus, herpes virus and the human immuno-deficiency virus (HIV) also have suspicious association with vitiligo[86,87].

Intrinsic theory

Melanocytes in vitiligo have an intrinsic defect leading to their death. They demonstrate different abnormalities, including abnormal rough endoplasmic reticulum or deficiency of unidentified melanocyte growth factors such as basic fibroblast growth factor (bFGF) and decrease in the number of melanocytes expressing the c-kit receptor in lesional skin[88,89].

Melanocytes require a constant keratinocyte-derived c-Kit stimulation for their maintenance[90], thus weak expression of keratinocyte-derived factors, as stem cell factor (SCF), may lead to passive melanocyte death and might explain the Koebner phenomenon[91].

Cellular, molecular and biochemical alterations and melanocytes loss of in vitiligo

Recently, malfunctioning melanocytes found in vitiliginous lesions[92]. Electron microscopy, reverse transcription PCR (polymerase chain reaction) and southern blotting experiments revealed sporadic survival of melanocyte in vitiliginous lesions[93,94]. Thus, this points to presence of immature melanocyte precursors/stem cells[95,96]. Now, 2 pathways have been supposed for melanocytes loss: highly programmed death by apoptosis[77,91,97,98] and accelerated cell senescence[99].

Apoptosis and accelerated cell senescence: Melanocytes from non-lesional skin of vitiligo patients have abnormalities as cytoplasm vacuolization, rough endoplasmic reticulum dilatation, DNA marginalization in the nucleus, loss of dendrites and detachment[88,99,100].

Regarding keratinocytes, apoptosis occurs at least in the traumatized vitiligo skin[101]. Thus, basal and suprabasal epidermal cells in the depigmented and normally pigmented skin show degeneration due to swelling of the membrane-bound organelles, formation of vacuoles and cytoplasm condensation[102].

As vitiligo could inducted by trauma (Koebner's phenomenon). Lee *et al*[97] revealed the lower expression levels of the antiapoptotic Bcl-2 and FLIP proteins in vitiliginous skin *vs* the normally pigmented skin. On the other hand, there was dramatic levels of the proapoptoticBax and p53 proteins and of the active forms of caspase-3, 8 and 9[97].

Apoptosis triggered by normal developmental program, UV light, H_2O_2, staurosporine and other stimuli[91,103]. *NALP1* gene that stimulates cellular apoptosis[102,104], is associated with vitiligo susceptibility[105,106].

Epidermal melanocytes from epidermal melanin unit produce growth factors (GF) for melanocytes[107]. Therefore, its damage have imperative effects on melanocyte survival[91]. Thus, low levels of GF as SCF, endothelin-1 (ET-1) or high levels of melanocyte inhibiting cytokines, as TNF-α and IL-6 may lead to keratinocyte apoptosis, and then apoptosis of melanocytes[108].

Life span of lesional keratinocytes is greatly shortened when compared to the life span of normal and non-lesional vitiligo keratinocytes. It also shows modification of proliferation and senescence marker expression (p16, p53, p21), when compared to keratinocytes from clinically noninvolved skin[98].

Although apoptosis and senescence of epidermal keratinocytes is a response to various stimuli, they also share some cellular mechanisms and controlled by similar molecular regulators[109]. Both apoptosis and aging induced by stress signals as ROS accumulation and DNA damage[110]. The paradigmatic proapoptotic factor p53[111], is also a guard keeper of DNA integrity which triggers cell cycle arrest in DNA damaged cells[109].

Melanocytorrhagy theory: Gauthier *et al*[78] in 2003 mentioned that NSV occurs due to "melanocytorrhagy", or a chronic melanocytes detachment and loss caused by trauma and other stressors include catecholamines, ROS, or autoimmune elements. This theory combined the concepts from other theories mentioned before to elaborate a single integrated explanation of vitiligo pathogenesis[78].

A study done by Tobin *et al*[92] in 2000 proposed loss of melanocytes in vitiligo. They explained these findings because of oxidative stress caused by H_2O_2. Gauthier *et al*[78] (2003) also reported that impaired cell adhesion plays a role in vitiligo pathogenesis as the synthesis of extracellular matrix components by keratinocytes may be defective, the presence of focal gaps in the basement membrane and impaired formation of basement membrane. These abnormalities weaken the basal attachment of melanocytes. Trauma could aggravate this susceptibility with subsequent chronic melanocyte loss, known as melanocytorrhagy.

Le Poole *et al*[112] mentioned that the protein tenascin may play a role in decreasing melanocytes adhesion in vitiligo. This protein was highly expressed in patients with vitiligo than the controls[112]. This can explain the development of vitiligo by Koebner phenomenon, which represent "transepidermal migration"[78,113].

Integrated theory (Conversion theory)

Despite all the mentioned theories are attractive, it is likely that vitiligo is a result of the convergence of these pathological pathways. Most experts agree that vitiligo may be a syndrome with a multi-factorial etiology rather than a single entity[114] (Figure 2).

TREATMENT

The disfigurement associated with vitiligo could cause serious emotional stress for the patient and affect his quality of life[115]. Sun protection of vitiliginous areas with sun blocks is imperative[115,116] to prevent sunburn, photodamage and occurrence of Koebner phenomenon. In addition, sun blocks decrease tanning of the uninvolved skin and thus lessen the contrast with vitiliginous lesions[117].

There is no treatment ensures complete cure of vitiligo. Therefore, there is a plethora of modalities, such as topical corticosteroids, vitamin-D derivatives, calcineurin inhibitors, photochemotherapy [psoralen plus UV-A (PUVA), psoralen with sunlight (PUVAsol)], phototherapy (UV-A, narrowband UV-B), surgical techniques[117-122], excimer laser[115,117,118-123], topical prostaglandin E (PGE2)[118], and combinations of topical therapies and light treatment[79]. Complementary and integrative therapies are also used, as ginkgo biloba[79], and levamisole[124], because of their immune-modulating properties[117].

Pseudocatalase cream with Dead Sea climatotherapy can also promote repigmentation[117]. Topical flu-

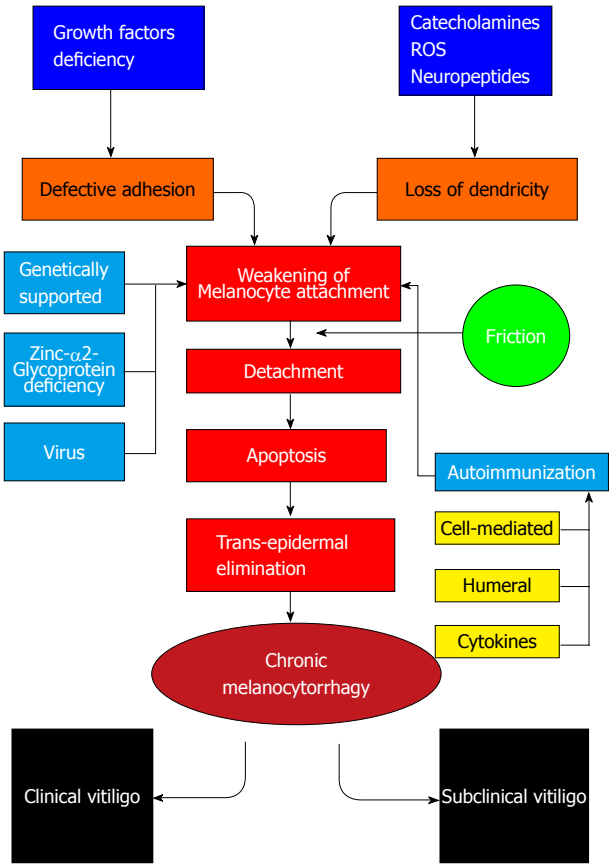

Figure 2 Pathogenesis of vitiligo.

orouracil[125], topical melagenina Ⅰ and Ⅱ, minoxidil[118], oral L-phenylalanine[117,126-129], homeopathy, ayurvedic medicine, climtologic and balneologic therapies are other therapeutic options for vitiligo[118]. Patients with widespread disease (affecting more than half of body) seeking stable matching of skin color but for whom repigmentation is not expected will be more satisfied if normal pigmented areas are depigmented with 20% monobenzyl ether of hydroquinone, twice per day for almost one year. Another helpful modality for vitiligo universalis, is combined both the topical application of 4-methoxyphenol and the Q-switched (QS) ruby laser[115]. Q-Switched ruby laser destroy the melanosomes present in melanocytes and keratinocytes by selective photothermolysis[130].

According to the impact of oxidative stress on vitiligo, α-tochopherol can be used alone or with topical corticosteroids in combinedation with psoralen plus ultraviolet A (PUVA)[131,132]. Antioxidant pool (tochopherol acetate, ubiquinone, selenomethionine, methionine) could be used in vitiligo aiming to enhance the enzymatic and the non-enzymatic antioxidant activity[131,132]. Food additives, contaminants, preservatives and cosmetic products could exacerbate vitiligo due to oxidative stress in melanocytes[133].

High consumption of omega-6 and decreased omega-3 intake produce free radicals and pro-inflammatory cytokines. On the other hand, omega-3 intake exert protection by enhancing TGF-β mRNA levels and antioxidant enzymes[134] and inhibiting pro-inflammatory cytokines as TNF-α[135].

Cell membranes enriched with omega-3 polyunsaturated fatty acids have elevated activity of glutathione peroxidase (GSH)[136]. In addition, omega-3 fatty acids contains indole-3-carbinol which activates CYP1A1 that is responsible for hydroxylation of estrogens to 2-hydroxyestrone[137]. Furthermore, omega-3 fatty acids have a vital role in the function of the central nervous system and affect the susceptibility and prognosis of depression[135]. Twenty percent of patients with vitiligo are found to have depression. This highlights the benefits of these lipids in vitiligo[137].

In conclusion, many theories were elaborated to clarify vitiligo pathogenesis. It is a multifactorial disease involving the interplay of several factors. Future research is needed to clarify the interaction of these factors for better understanding of vitiligo pathogenesis and subsequent successful treatment.

Abstract

The most common malignancy of biliary tract is gallbladder cancer (GBC) which is the third most common cancer in gastrointestinal tract. It is a lethal disease for most patients in spite of growing awareness and improved diagnostic techniques. GBC has a very poor prognosis and the 5 year survival rate is < 10%. Although etiology of the carcinoma of the gallbladder is still obscure, various factors have been implicated, cholelithiasis being the most frequent. The incidence of GBC worldwide is based on the gender, geography and ethnicity which suggest that both genetic and environmental factors can cause GBC. The major route of spread of gallbladder cancer (GC) is loco-regional rather than distant. It spreads by lymphatic, vascular, neural, intraperitoneal, and intraductal routes. Sonography is usually the most common imaging test to evaluate symptoms of biliary tract disease including suspected GC. With recent advances in imaging modalities like multi-detector computed tomography (CT) scanners, magnetic resonance imaging-positron emission tomography/CT diagnosis of gallbladder cancer has improved. Studies have also targeted molecular and genetic pathways. Treatment options have included extended and radical surgeries and adjuvant chemotherapy. This review article deals in detail with important aspects of carcinoma gallbladder and its manifestations and challenges. Role of various imaging modalities in characterization and accurate staging has been discussed. The loco-regional spread of this aggressive malignancy is dealt explicitly.

Key words: Gallbladder cancer; Loco-regional and distant spread; Cholelithiasis; Imaging; Adenocarcinoma

Core tip: Gallbladder cancer is one of the most prevalent and lethal cancer of biliary tract with multi-factorial etiology. Cholelithiasis is the most common etiological factor. Adenocarcinoma is the most common histological type with loco-regional spread in majority of cases. Sonography is used widely as an initial screening tool and primary characterization of the tumor but it has a limited role in the diagnosis of early lesions. Thus, computed tomography and magnetic

resonance imaging are used for complete morphologic characterization and staging of malignant gallbladder lesions and metastatic survey.

INTRODUCTION

Gallbladder cancer (GBC) is the most prevalent malignancy in biliary tract and third in gastrointestinal (GI) tract[1,2]. It was first described in detail in the seventies[3]. It is a lethal disease for most patients in spite of growing awareness and improved diagnostic techniques[4]. Although rare, it has high incidence in certain world populations[5]. GBC has poor prognosis and the survival rate in 5 years is less than 10%[5,6]. It affects predominantly women, four times more as compared to men[6,7]. GBC is asymptomatic in nature which makes it difficult in diagnosis and treatment. The symptoms of GBC are alike to other GI tract problems *viz.* abdominal pain, abdominal lump, anorexia, nausea, jaundice and vomiting[2]. GBC is a neoplasm which is widely known for its distinct ethnic, gender and geographical variations[8]. Precise etiology of GBC is still not known but various factors have been incriminated cholelithiasis[8], external carcinogens[9], free radicals, lipid peroxidation products, inflammatory bowel disease and secondary bile acids[10]. Congenital malformations of biliary tract (more common in Japan, China) are also observed as the risk factor for GBC. Chronic inflammatory conditions, heavy metals exposure, a high carbohydrate diet, obesity, alcohol abuse and smoking are also known as possible risk factor for GBC[11,12]. Adenocarcinoma is most prevalent histo-pathological type of GBC[8].

BACKGROUND AND EPIDEMIOLOGY

The incidence of GBC worldwide is based on the gender, geography and ethnicity which suggest that both genetic and environmental factors can cause GBC. Various epidemiological studies suggested that geographical and racial difference also affects the frequency of GBC. A high geographical variability in occurrence of GBC also correlated with the ubiquity of cholelithiasis[12]. Incidence rate of GBC is higher in South American Countries like Chile, Bolivia and Ecuador and some Asian countries like some areas of India, Pakistan, Japan, and South Korea[12]. Intermediate rate of incidence have been observed in European countries. Its rate is lower in United States but Native Americans observed to have a high incidence. Further, urban areas have less risk compared to rural region. Incidence in Chile where mortality is 5.2% is highest in the world. There, it is the most prevalent cancer affecting women and the fourth important reason of cancer deaths[5]. Marked geographical differences seen in frequency of gallbladder carcinoma suggest a possible environmental cause besides race or ethnicity. The exact etiology of GBC has not been properly known till date. It is yet to be established. But several other factors like chronic cholecystitis, gallstones, choledochal cyst, female gender, age and exposure of carcinogens have been observed to be implicated in gallbladder carcinogenesis[13,14]. Randi *et al*[5] and other studies carried out where age adjusted incidence rates of GBC in various populations based on cancer registry data were considered concluded that maximum incidence rate was found in women in Delhi, India (21.5/100000), South Karachi, Pakistan (13.8/100000) and Quito, Ecuador (12.9/100000)[5,15,16]. Another study also described a very high incidence of cancer in Northern India (1.5/100000) and Native American Indian females (14.5/100000)[17]. Therefore, there is an urgent need of early detection of GBC[18]. Gastric cancer was the main cause of death in Japan since 1999. It was reported to be the sixth leading cause of cancer related death in Japan in 2007[19]. The incidence of GBC rises with age and reaches the peak during the seventh and eighth decades of life[6]. Age-standardized incidence rates (ASIR) has been found to be high above age of 45. Delhi has been listed as having the highest ASIR with 22.08 males and 35.67 females per 10^5 persons after the age of 65 years. Studies revealed a very distinct age-related pattern among both genders[20]. Female-to-male incidence ratio was generally around 3, but ranged from 1 in Far East Asia to over 5 in Spain and Columbia[5]. The incidence was observed to be higher from the Gangetic belt, but, due to lack of cancer registries in these areas, the precise incidence cannot be known accurately. The estimated occurrence of GBC in Varanasi is around 4.4% of all types cancers and around 16% of all GI cancers[2].

PATHOLOGY

Approximately 80% GBCs follow progression from dysplastic mucosa to carcinoma in situ and invasive carcinoma[21]. Morphological and molecular changes also suggest the same[22]. Approximately 60%, 30% and 10% tumors originate in the fundus, body and neck of the GB respectively[23]. Among all the GBC, adenocarcinoma constitute about 85% in comparison to others like epidermoid carcinomas (6.5%) and adenocanthomas (4.5%). Besides these, other histologic types of GBC are small (oat) cell carcinomas[24], carcinoid tumors and anaplastic carcinomas[8]. Glandular, medullary, scirrhous, papillary, and colloid type are the parts of adenocarcinoma with incidence rate of 35.3%, 23.2%, 15.7% 14.5% and 11.3%

respectively[25]. Infiltrative, papillary and combined papillary-infiltrative forms are the different forms of GC[26]. Thickening and induration of GB wall occurred in infiltrating tumors which invades the subserosal plane and gallbladder wall into liver and neighboring structures. Papillary carcinoma shows a polypoid cauliflower like appearance which fills the GB lumen with very low wall invasion as it has the best prognosis. Recent researches also divide GC into metaplastic and non-metaplastic types[27]. Pseudopyloric and intestinal are two types of metaplastic variety. They are associated with chronic inflammation and cholelithiasis. Intestinal variety is associated with increasing age[28].

MOLECULAR AND GENETICS RELATED TO GBC

Different epidemiological studies and diversity in incidence of GBC studies also suggest an association of gene in its etiopathogenesis. Few facts are available about genetic changes in GBC. *K-ras* gene mutations have been found in 39%-59% of GBC, whereas *p53* mutations have been reported in 35%-92% of patients having GBC[6,29]. Shukla *et al*[30] reported that telomerase activity was significantly raised in gall bladder cancer tissue. Telomerase activity was mainly concentrated in poorly-differentiated adenocarcinomas (83.33%) and increased expression was present in advanced stages. The presence of telomerase may serve as a molecular marker for the diagnosis of gall bladder carcinoma and may have prognostic and therapeutic implications in the treatment of patients[30]. It has been reported in various studies that genetic alterations in k-ras, p53 and p16 take a significant part in gallbladder carcinogenesis[31-36]. Inactivation of tumor suppressor genes involves the different genetic mutational events which lead to the one allele and allelic loss of the other allele. This is the main and complex mechanism associated with it. This allelic loss is known as loss of heterozygosity (LOH) which can be detected by using microsatellite markers. Recurrent LOH has also been detected in GC at different chromosomal locations like 1p, 3p, 5q, 8p, 9q, 13q and 17p[37]. Other reports also suggested in their study that many chromosomal regions have important tumor suppressor genes which are also detected in this neoplasm. 3p (20% to 52%); 5q21 (*APCMCC* gene, 6% to 66 %); 8p22-24 (22% to 44%); 13q14 (*RB* gene, 20% to 30%); and 18q (*DCC* gene, 18% to 31%) are the some gene locations other that the *TP53* and *CDKN* gene[37]. In all the cholecystitis and adenoma patients Retinoblastoma (*Rb*) gene have been detected; however, *Rb* gene is deleted in 18%-67% of carcinoma of the gallbladder patients[38,39]. The precise molecular abnormality which causes neoplastic transformation in the gallbladder epithelium still unclear. An accurate pathway related to molecular changes which further result in neoplastic transformation in gallbladder epithelium has not fully understood. This more understanding of molecular changes events will give better tools to detect GBC in early stage.

ROUTES OF SPREAD: LOCO-REGIONAL AND DISTANT

Vascular, lymphatic, intraperitoneal, neural and intraductal routes are the leading routes of spread. Intraductal spread in GBC has a better prognosis[40]. Invasion of liver and lymph nodes has been reported in 69% and 45% of patients respectively in 984 patients from nine series[8]. Loco regional spread in GC is more common than distant metastasis. Metastases usually occur in liver (Figures 1A-B), lymph nodes, adjacent organs and peritoneum. Lymph nodes are usually found in about 60% of cases while metastasis in liver is about 76%-86% cases. Intraperitoneal spread is common with ascites, omental nodules and peritoneal implants[41-43]. 76.8%, 71% and 24.6% cases had liver, lymph node involvement and peritoneal deposits respectively in a study consists of 69 patients which undergo exploratory laparotomy[1]. Lymphatic drainage from the gallbladder occurs in a predictive fashion and correlates with the pattern of lymph node metastasis seen in GBC. Initially, cystic duct and pericholedochal nodes are involved, followed by more distant metastasis to posterior nodes to the head of the pancreas and then to interaortocaval lymph nodes. This primary route is called cholecysto-retropancreatic pathway. Secondary route of lymphatic drainage includes the retroportal and right celiac lymph nodes through the gastrohepatic ligament, called cholecysto-celiac pathway. The third one is called cholecysto-mesenteric route consisting of a pathway from the posterior of gallbladder to the aortocaval lymph nodes *via* pancreas[44]. It is common for GBC spread directly into the liver and porta hepatis which lead to narrowing or obstruction of the common hepatic or right hepatic duct. Surgical specimens from 48 patients who had undergone radical/extended cholecystectomies were examined in 5-mm stepwise tissue sections in one large surgical series[45]. Zero to three score was given to nodal spread (0: no metastases; 1: cystic, paradochal, hilar; 2: peripancreatic head, portal, hepatic artery; 3: celiac, periduodenal, perimesenteric). Out of 48 patients, 8 (17%), 7 (14.5%) and 9 (18.8%) were found to have group 1 and 3 nodes respectively. Out of 16 patients with group 2 or 3 nodes, only 3 were considered for curative resection. Such studies recommend a possible niche for regional radiation therapy where more distant nodal groups are commonly comprised for pancreatic cancer and cholangiocarcinoma (CC). Some studies also described that GBC have a greater risk for synchronous distant metastatic spread than in CC as GBC usually have a regional pattern of spread.

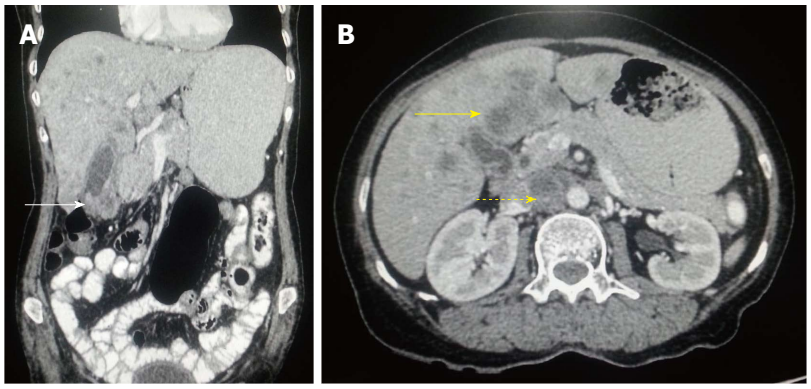

Figure 1 Carcinoma gallbladder: Nodal and hepatic metastasis. A: Coronal contrast-enhanced computed tomography (CECT) abdominal section shows relatively defined heterogenous mass involving fundus of gall bladder (arrow) with loss of fat plane with adjacent hepatic segment; B: Axial CECT abdominal section shows multiple hepatic metastasis (arrow) along with interaortocaval lymph nodal metastasis (dashed arrow).

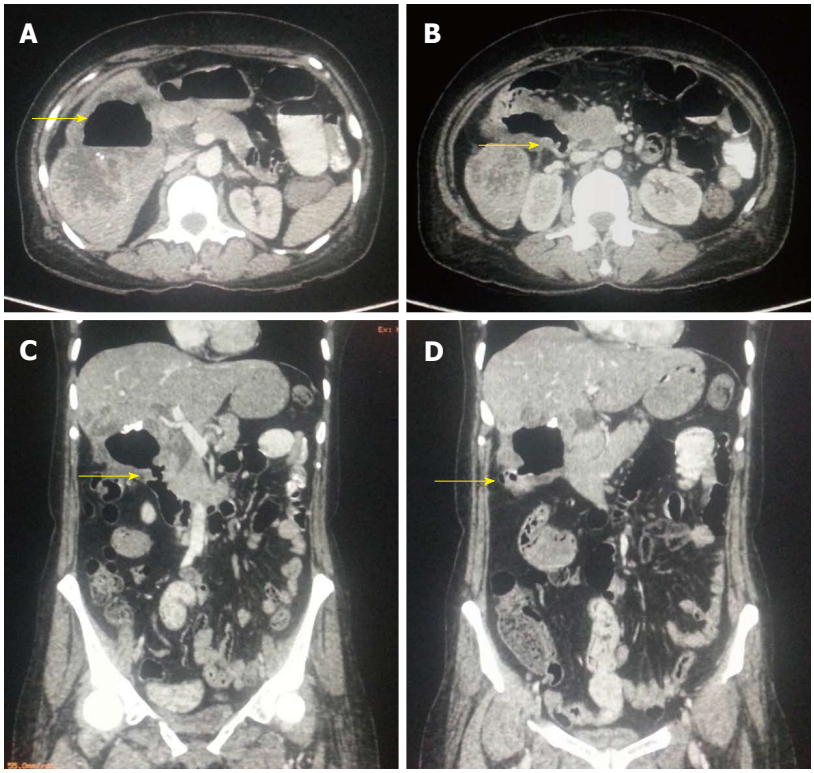

Figure 2 Aggressive gallbladder cancer and entero-biliary fistula. A: Axial contrast-enhanced computed tomography (CECT) abdominal section shows predominantly hypodense mass lesion replacing gall bladder fossa with presence of air (arrow) raising suspicion of fistula formation. Adjacent hepatic segments are also infiltrated by the mass; B and C: Axial and Coronal CECT abdominal sections clearly reveal the fistulous communication with D2 segment of duodenum (arrow); D: Coronal CECT abdominal section also show coexisting cholecysto-colonic fistula with hepatic flexure of colon (arrow).

Ninety-seven patients of GBC and 76 patients of hilar CC were included in a study who were subjected to potentially curative resection and analyzed for patterns of initial disease recurrence[46]. GBC patients had a significantly lesser time to recurrence (11.5 mo for GBC, *vs* 20.3 mo; *P* = 007) than hilar CC patients. In addition, GBC patients were far more likely to have a distant site involved at the initial period of recurrence (85% for GBC, *vs* 41%; *P* = 001). They summarized in their study that patients of GBC were having less chances to benefit from locoregional therapy given the high rate of synchronous distant disease. Such conflicting results have made difficult to recommend chemo radiation. Spontaneous biliary-enteric fistulas are developed by gallstones (90%), peptic ulcer disease (6%) and malignancy or trauma (4%). Cholecysto-duodenal type (61% to 77%) is the most common communication, followed by cholecysto-colonic (14% to 17%) and cholecysto-gastric (6%)[47] (Figures 2-5). Contrast cholangiographic studies were used in the diagnosis of gallbladder and biliary tract diseases before the emergence of USG and computed tomography (CT). Involvement of hepatic flexure and mesocolon has been observed in 33.3% of cases which was demonstrated by eccentric or circumferential wall thickening. A gallbladder mass lesion closely abutting hepatic flexure with no obvious eccentric wall thickening was observed in 2.3% cases[48]. According to Arminski[49] metastases occur to every organ including liver, lymph nodes, adrenal, kidney, spleen, brain, breast, thyroid, heart and uterus, those to the skeletal system are least frequent. Adrenal metastases (Figures 6 and 7) and venous occlusion due to tumor thrombus are unusual in newly diagnosed gallbladder carcinoma patients. Incidence of vascular metastasis is rare, but can occur. Portal vein invasion or tumor thrombus can be seen in aggressive or late cases. Vascular invasion leads to the localized involvement of

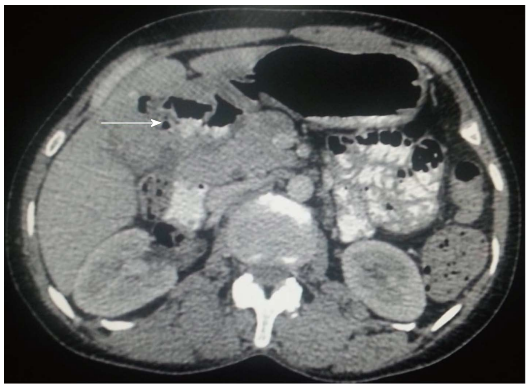

Figure 3 Axial contrast-enhanced computed tomography abdominal section shows ill-defined heterogenous mass replacing gall bladder fossa with loss of fat plane with adjacent hepatic segments. Cholecystoduodenal and cholecysto-gastric fistulas are seen with D1 segment of duodenum and antropyloric region of stomach (arrow).

Figure 4 Axial contrast-enhanced computed tomography abdominal section shows ill-defined mass replacing gall bladder fossa with direct infiltration of hepatic segment V. Cholecystoduodenal fistula (arrow) is noted along with retroperitoneal lymph nodal metastasis (dashed arrow).

Figure 5 Axial contrast-enhanced computed tomography abdominal section shows ill-defined heterogenous mass replacing gall bladder fossa with direct infiltration of hepatic segments. Cholecystoduodenal fistula (arrow) is noted along with multiple hepatic metastasis (dashed arrow).

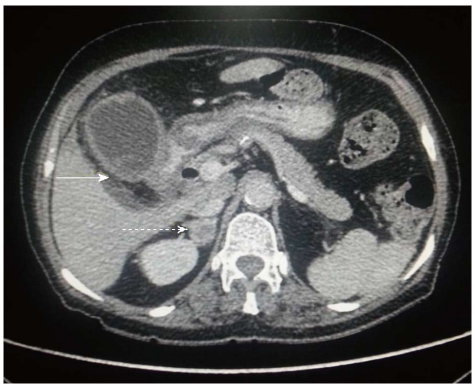

Figure 6 Axial contrast-enhanced computed tomography abdominal section shows diffuse irregular nodular enhancing wall thickening of gall bladder (arrow) along with circumferential wall thickening of distal stomach and proximal duodenum. Associated right adrenal metastasis is also seen (dashed arrow).

Figure 7 Axial contrast-enhanced computed tomography abdominal section shows ill-defined heterogenous mass replacing gall bladder fossa with direct infiltration of adjacent hepatic segments. Associated left adrenal lesion is also seen (dashed arrow) raising suspicion of adrenal metastasis.

the liver in the neighboring primary lesion preferably than disseminated multiple nodules[50]. Disseminated metastases appear in the late stage of the disease and caused due to retroperitoneal veins invasion. Median survival rate in patients of carcinoma gallbladder with distant metastases is only 3 to 4 mo and these patients may not be offered any intervention[42] Indian studies suggest that cases from this geographic belt are more aggressive[51]. Accuracy rate of preoperative staging by using multislice CT has an overall range from 83% to 86%[52,53]. GBC can have myriad of manifestations and spread[54]. The rarity of bony metastases from primary carcinoma has been documented by other authors[49,55-57]. In cases of skeletal metastases of the carcinoma of the gall bladder, 90% are purely osteolytic, 10% are mixed lytic and blastic type with purely osteoblastic lesions being unknown[58] (Figures 8). GC have non-specific laboratory finding. Most common laboratory finding are liver function abnormality. Serum alkaline phosphatase (ALP), direct bilirubin (conjugated bilirubin), and aspartate aminotransferase (AST) concentrations are usually deranged in more than 50% of cases. The patient is mildly hypoalbuminemic and hemoglobin level is

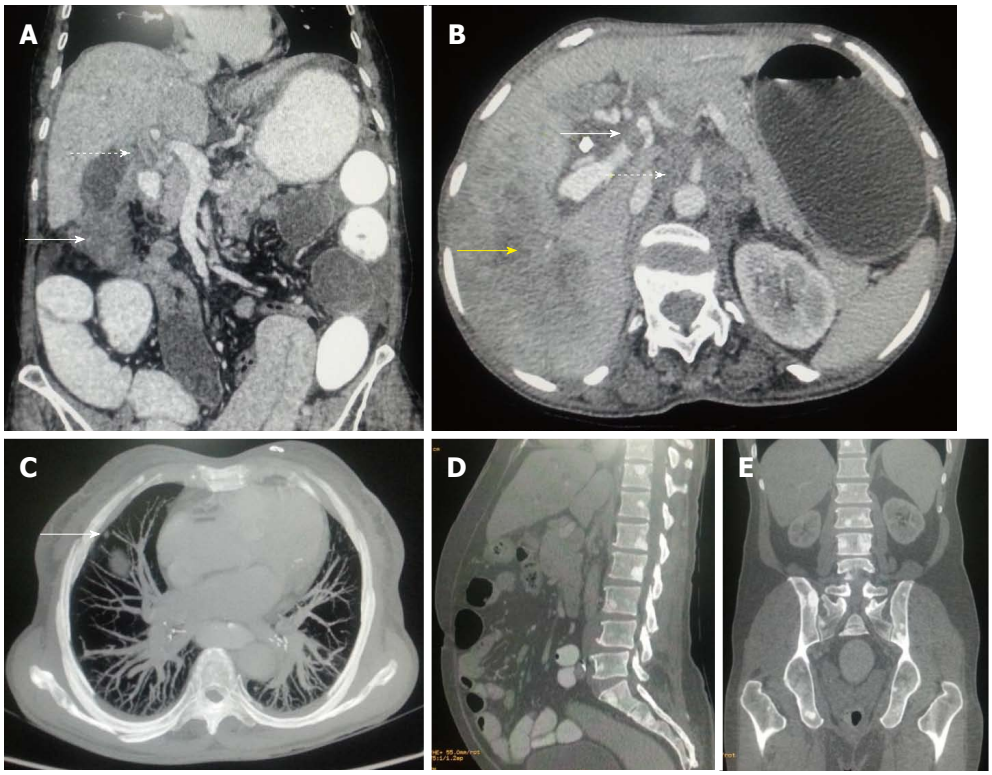

Figure 8 Gallbladder carcinoma: regional and distant metastasis. A: Axial contrast-enhanced computed tomography abdominal section shows heterogenous mass lesion involving fundus of gall bladder fossa (arrow) with associated circumferential enhancing wall thickening of CBD (dashed arrow) indicating cholangitis or intraductal spread of malignancy; B: Axial CECT abdominal section shows hypodense filling defect in left branch of portal vein indicating thrombus formation (arrow). Hepatic infiltration is seen in segment VII (yellow arrow) with retroperitoneal lymph nodal metastasis (dashed arrow); C: MIP axial CT imaging shows soft tissue nodule in anterior segment of right lung indicating pulmonary metastasis (arrow); D and E: Sagittal and coronal CECT abdominal sections (bone window) show multiple osteoblastic skeletal metastatic lesions. CBD: Corticobasal degeneration; CECT: Contrast-enhanced computed tomography.

usually less than 11 g/dL in 10% of patients[59].

STAGING

Staging is the main part for the management and reporting of GBC. Gallbladder carcinoma is staged primarily at the time of surgery. Pathologic staging is decided at the time of surgery when the resection has been performed. Resection area (R) should be reported as it acts as the most important prognostic factor for GBC[60]. American Joint Committee on Cancer has given a TNM Staging System which usually determined by the depth of invasion, expansion of GC into adjacent structures, lymph node involvement and metastatic spread[61,62] The primary stage of GC which decides the treatment is the "T" stage. Surgery is usually performed for T1/T2 (tumor confined to GB wall) if metastasis is absent. Tumors extending beyond the GB wall are considered T3 and T4. T3 tumors can be resected but with en bloc resection of adjacent organs while T4 tumors are unresectable[17]. But a simple cholecystectomy cannot be used to completely remove a T2 stage tumor as there is no serosa on the GB on the side from where it is attached to liver[60]. A minimum presence of three regional lymph nodes is required for accurate "N" staging. Hilar, celiac, periduodenal, peripancreatic and superior mesenteric nodes as well as nodes along the pancreatic head are included in the regional lymph nodes. Lymph nodes outside the hepato-duodenal ligament are regarded as metastatic disease[17]. Metastasis to liver and peritoneum is common and occasionally to the lungs and pleura. Direct tumor invasion to the liver should not be regarded as distant metastasis[60].

IMAGING MODALITIES

Abdominal ultrasound

The most prominent imaging modality to assess symptoms of biliary tract disease along with suspected GC is Ultrasound (US). It can differentiate between carcinoma and chronic cholecystitis with a sensitivity of 44% in early stages of disease[63]. Sensitivity differs for different types as reported by a retrospective study using US in early GC[64]. Ultrasound can easily detect invasion of liver parenchyma and loss of normal tissue interface. The sensitivity and accuracy of US in advanced GC are 85% and 80% respectively[65]. Bach *et al*[66] in their study reported the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) in non-resectable carcinoma. The gallbladder wall is not visualized or poorly visualized as a thin echogenic line on ultrasound. An echogenic double-rim effect is produced when the gallbladder wall

becomes thickened from wall edema in inflammatory diseases[67]. Increase in gallbladder wall thickness can be seen in association with many conditions including chronic cholecystitis and neoplasia[68]. Sonography is often the first requested imaging technique in suspicion of gallbladder diseases due to cost effectiveness and easy availability[69-71]. CT and MRI are preferred over US for detection of early lesions and accurate staging and characterization[69,71,72]. US should be used along with other modalities as a complementary tool[73]. Hederström *et al*[63] in their study concluded that US had poor sensitivity to differentiate GBC from chronic cholecystitis. There is significant chance of missing a malignancy. A cholecystectomy in such cases is useful. Another study reported that 6 were correctly diagnosed by surgery or autopsy out of 11 ultrasonographically proved GC. It concluded that sonography can suggest the diagnosis of gallbladder carcinoma, but inflammatory changes in the gallbladder may simulate or mask the signs of malignancy[74]. A study by Wibbenmeyer *et al*[75] suggested that several sonographic findings were more common in patients with GBC in comparison to patients with benign gallbladder pathologies. Evaluation of these signs may be helpful in such conditions[75]. Doppler US has been found to be useful in detecting invasion of GC into the liver, the portal vein, and the bile ducts, but it has limitation in detection of lymph node and peritoneal metastases[66]. Contrast enhanced US may be helpful in improving the diagnosis of GC. The usefulness of contrast enhanced US for differential diagnosis of polypoid GB lesions has been described by Hattori *et al*[76]. Classification of contrast enhanced patterns were described as linear, scattered, and diffuse or branched. It had a sensitivity of 100%, specificity of 76.9% and accuracy of 84.5% in case of diffuse or branched type pattern[76]. US guided fine needle aspiration cytology (FNAC) has been routinely for tissue diagnosis. It has an accuracy of 95% without major complications[77]. FNAC has been reported to have a sensitivity of 88%, specificity of 100%, PPV of 100% and NPV of 52%[78].

Endoscopic ultrasonography

Endoscopic ultrasonography (EUS) has been widely used for peri-operative staging of GC. It looks as a hypoechoic mass with or without GB wall calcifications[79]. The overall accuracy rate of 91.9% has been reported in differentiating neoplastic from non-neoplastic masses[80]. Mitake *et al*[81] also demonstrated the effectiveness of EUS in determination of the extent of tumor invasion and GC diagnosis. They reported an overall accuracy rate for tumor invasion depth to be 76.5% and differentiation between early and advanced stage tumors was possible in 79.5%. Furthermore, the usefulness of EUS has increased by the development of contrast agents. The depth of GC invasion was accurately assessed in 11 of 14 cases (78.6%) by conventional EUS, and in 13 of 14 cases (92.9%) by contrast enhanced EUS in a comparative study. If we compare the conventional ultrasonography to endoscopic ultrasonography, the endoscopic ultrasonography has been observed to be more precise for staging[82,83] A combination of diagnostic methods and biopsies may bring down the incidence of explorative laparotomies performed for GC[71]. Other aids like percutaneous liver biopsies, cholecystocentesis and culture of bile have been suggested in diagnosis of equivocal cases[84]. Use of EUS alone or in combination with EUS-guided FNA of gallbladder can improve the diagnosis of GC[85,86]. EUS-guided FNA is a safe and reliable modality for carcinoma gallbladder[79] .

CT

CT is a common imaging modality for the identification of primary tumor and tumor staging. Hepatic parenchyma is the most commonly invaded site, followed by the bile duct and neighboring organs. CT scan can also accurately determine peritoneal and lymphatic metastasis[87]. Pericholedochal nodes and cystic nodes are commonly involved[88]. Kim *et al*[89] using preoperative CT reported a precision of 71%. Helical CT was suggested to evaluate the spread and depth invasion of GC to assess resectability[90]. There are many advantages of helical CT over conventional CT[52]. In a retrospective study diagnostic precision for T staging was reported to be 83%-86% in comparison to conventional CT[52]. In another study overall accuracy of CT for staging GC was 71% and 79% for T1 and T2 tumors, 46% for T3 tumors, and 73% for T4 tumors. There was statistically significant difference between thickened wall and intraluminal mass type of tumors ($P < 0.05$). The accuracy was (89%) for the intraluminal mass type, (83%) for massive type, whiles it was 54% in the thickened wall type[89]. Another prospective Japanese study using spiral CT reported affectability, specificity, PPV, NPP and the general exactness to be 88%, 87%, 88%, 87%, and 87%, respectively[91]. Although CT is not routinely used to explore patients with gallbladder disease symptoms, it is an important examination for suspected cases of gallbladder carcinoma. The most widely recognized CT finding in gallbladder carcinoma is a mass that fills the greater part of an irregular and distorted gallbladder[92] (Figure 9). Gallbladder carcinoma appears as a symmetric or asymmetric gallbladder wall thickening that may be hard to distinguish from the scarred gallbladder seen in chronic cholecystitis. Non-specific gallbladder wall thickening can be seen in acute and chronic cholecystitis, xanthogranulomatous cholecystitis, adenomyomatosis, diffuse hepatic or systemic disorders like hepatitis, portal hypertension, and congestive heart failure[46,93]. Yun *et al*[87] used dual phase CT to assess thickness as well as enhancement pattern of gallbladder wall seen in gallbladder melanoma as well as chronic cholecystitis in arterial and venous phase. They reported a difference in enhancement patterns of malignancy as compared to chronic cholecystitis using

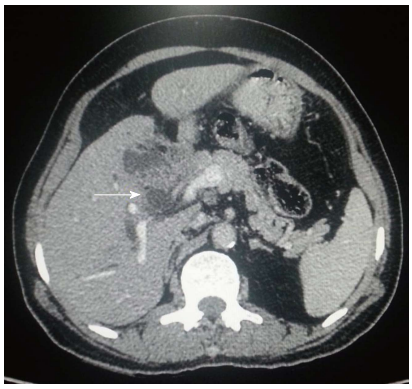

Figure 9 Axial contrast-enhanced computed tomography abdominal section shows heterogenous mass involving gall bladder fossa and leading to obstruction of biliary system due to intraductal spread (arrow).

dual phase CT. Kim *et al*[89] assessed the enhancement pattern of abnormal GB wall thickening using MDCT to differentiate between carcinoma and inflammatory diseases. They concluded that there is a distinct pattern of enhancement of inner wall compared to non-enhancing surface covering. Different signs of gallbladder carcinoma can be found due to biliary obstruction and liver involvement[53]. CT was found to be 85% precise in evaluation loco-regional spread of gallbladder malignancy[94]. It can be useful in guiding aspiration/biopsy from gallbladder in few cases[95]. It is prudent to correlate CT scan findings with clinical and laboratory findings in elderly individuals, particularly women presenting with acute cholecystitis and abnormal liver function. Imaging findings suspicious of carcinoma are diffuse irregular gallbladder wall thickening, intraluminal mass along with enlarged local lymph nodes[96]. Lee *et al*[97] compared the efficacy of ultrasound (US) and CT in cases of intraluminal and infiltrating gallbladder carcinoma with and without gallstones. They found CT to be superior than US. Some authors suggest that combination of CT with ultrasound increases the diagnostic accuracy of gallbladder carcinoma associated with cholecystitis[98].

Magnetic resonance imaging

Initially due to disadvantage of poor spatial and contrast resolution, magnetic resonance imaging (MRI) was not widely used to evaluate GB disease[18]. Nonetheless, with recent advances and introduction of dynamic techniques after the administration of paramagnetic contrast, MR cholangiopancreatography (MRCP) and MR angiography (MRA), have been utilized for tumor staging[70]. Primary GC appears hypodense on T1 weighted images and hyperdense on T2 images with sensitivity of 67%-100% and specificity of 89%-100%[95]. The detection rate of lymph node metastasis was only (57%). The sensitivity and specificity for vascular invasion can be increased by combining MR cholangiography with three-dimensional MR angiography[99,100].

Positron emission tomography

18F-2fluoro-2-deoxy- D-glucose (FDG) uptake by tumor cells gives positron emission tomography (PET) imaging the combined benefit of utilizing metabolic activity and imaging features together. The main drawback of FDG-PET is that it is not yet generally accessible for routine clinical use and the low pervasiveness of GC. Till date, there is little data on the feasible contribution of these techniques in the useful imaging diagnosis of GC. In a recent prospective cohort study in patients presenting with radiologically suspicious gallbladder lesions[101] a staging diagnostic pre-surgical FDG-PET study was performed. Total diagnostic precision was 83.33% for the finding of the primary lesion, 88.89% for the assessment of involvement of lymph node and 85.1% for the assessment of metastatic spread. Karim *et al*[102] examined the efficiency of different imaging techniques employed in GBC diagnosis.

Preoperative evaluation and staging

MDCT is widely available nowadays and has a reported precision of up to 84% in determining the T stage of primary gallbladder carcinoma[103] and 85% in foreseeing resectability due to its capacity to depict hepatic and vascular invasion, lymph nodal and distant metastases[104]. MDCT is commonly performed as unenhanced and contrast-enhanced dual phase, from which multiplanar and 3D volume-rendered reconstruction images are generated to provide complete anatomic information. Additional coronal oblique images may be acquired for surgical management[104]. Kim *et al*[89] claimed that the all-in-one standard protocol of using MR cholangio-pancreatography and contrast enhanced MR angiography may yield a sensitivity of up to 100% with regard to bile duct and vascular invasion. However it is only 67% with regard to hepatic involvement and 56% with regard to lymph node metastases. PET/CT may have a promising role in the diagnosis associated with unsuspected metastases, which might change staging and treatment[105,106]. To date, potential research which specifically assess CT, MRI, and PET/CT in their capabilities to detect and stage gallbladder carcinoma are yet to be executed. The particular spread of gallbladder carcinoma to the liver parenchyma in addition to surrounding internal organs is possibly due to lack of muscularis mucosa in addition to submucosa inside the gallbladder wall structure and primary venous drainage with the liver parenchyma on the hepatic abnormal veins. As per the sixth release of American Joint Committee on Cancer staging manual for gallbladder carcinoma[107] primary gallbladder carcinoma can be delegated T1, kept to the lamina propria or the muscle layer of the gallbladder (T1a and T1b, separately); T2, stretching out to the serosa; T3, puncturing the serosa or directly invading the liver or one other contiguous structure (stomach, duodenum,

colon, pancreas, omentum, extrahepatic bile channels); or T4, invading the primary portal vein, the hepatic artery, or numerous extrahepatic organs. Lymphatic spread is present in more than half of patients at initial finding and first reaches cystic, pericholedochal, hilar, periduodenal, peripancreatic, and predominant mesenteric nodes, which are viewed as regional or N1 nodes. Portacaval, inter-aortocaval, and more distant nodes are viewed as distant or M1 disease. Gallbladder carcinoma can spread through intraductal route along the cystic duct, hematogenous route and neural pathways, and intraperitoneal "drop" metastases[70]. T1 or T2 involvement without nodal metastasis are termed as stage ⅠA or ⅠB respectively. T3 disease without nodal spread are stage ⅡA. T1, T2, or T3 disease with N1 lymph node involvement is characterized as stage ⅡB. A T4 disease without distant metastasis is considered as stage Ⅲ. Any patient with distant disease comes in to the category of stage Ⅳ.

Cytology

A carcinoma at an early stage can be ignored, and the diagnosis can only be made after microscopic examination of paraffin-embedded tissue. Imprint cytology of the gallbladder mucosa is a simple, quick, and excellent method for the detection of GBC[108]. Ultrasound-guided fine-needle aspiration cytology is likewise a safe diagnostic method for GBC[109]. Endoscopic retrograde cholangio-pancreaticography of biliary tree and GBC can also be considered for assessment of clinically suspicious carcinoma[110].

Tumor markers

Nowadays, tumor markers have a significant role in the detection and assessment of GBC. Investigation of CA242, CA15-3, CA19-9, and CA125 are genuinely proficient markers for segregating patients of carcinoma of the gallbladder from cholelithiasis. CA242 and CA125 when utilized together accomplished best sensitivity and specificity. Serum markers appear to be less effective when utilized independently, however it can be a useful complementary tool in combination[111]. No biochemical markers are useful in early detection of GC. Cholestasis and hyperbilirubinemia indicate late stage disease. Carcinoembryonic antigen (CEA) more than 4 ng/mL has a sensitivity of 50% and specificity of 93%[112]. Presence of CA19-9 suggest poor prognosis. A value more than 20 IU/mL has a specificity of 79%. CA19-9 is frequently increased in the presence of biliary obstruction therefore it is less specific in patients of jaundice[112]. Incresed levels of serum alpha fetoprotein (AFP) have been seen in few patients but have little significance[113].

Electrophoretic pattern of proteins

Electrophoretic examination of serum protein has demonstrated protein bands in patients of carcinoma of the gallbladder in comparison to electrophoretic pattern in cholelithiasis[114].

Gallbladder membrane lipids

Fourier enhance infrared (FTIR) spectroscopy is usually very sensitive for the molecular composition of tissues, and has the potential to distinguish premalignant tissues. Lipids have been elevated inside the plasma tissue layer of GBC. This proportion associated with high intensity might be a marker to help in identification of cancer through FTIR[115].

TREATMENT OPTIONS

The only likely curative treatments intended for gallbladder carcinoma is usually surgical resection. Unfortunately, most patients with GBC have unresectable disease. Only 10%-30% of patients can be considered for surgery on presentation[29]. The surgical alternatives for the treatment of GBC have evolved over the years. The methods range from a simple cholecystectomy to a radical or extended cholecystectomy, which incorporates the gallbladder in addition to 2 cm of liver tissue from the gallbladder bed. The radical cholecystectomy has been further modified to incorporate more significant liver resections, like segmentectomies (4b/5), right hepatectomies and trisectionectomy. Extended procedures additionally incorporate regional lymphadenectomy of the porta hepatis and periduodenal and pancreatic stations. Few surgeons incorporate a resection of the bile duct to clear the lymphatics in the porta hepatis. A few specialists now incorporate periaortic lymph node dissection for staging purposes and if the tumor is distal or includes the head of the pancreas, a pancreatico-duodenectomy is added to accomplish R0 resection status[116,117]. Incidental GBC is found during cholecystectomy in 1%-2% of the cases. GBC should be suspected in the event of a tough gallbladder dissection or if there is presence of regional lymphadenopathy. A simple cholecystectomy is definitely an adequate treatment for Tis and T1 stage. Five-year survival for patients with T1 tumors is more than 85% with simple cholecystectomy[117,118]. For the T1 stage patients, the estimation of radical resection depends upon whether it is a T1a tumor or T1b tumor. In a study, the authors compared treatment of simple cholecystectomy and radical resection of T1a patients; however they didn't find any variation in survival or recurrence in the two groups[119]. Additionally, no positive lymph nodes were found in the sampled 147 lymph nodes in 12 patients who underwent radical resection. Simple cholecystectomy is needed for T1a GBC. For T1b (muscle invasion), there is proof that a more aggressive surgical methodology is needed. T1b tumors had lymph node metastases in 15% of cases, though only 2.5% of T1a tumors are accounted to have lymph node association[117]. Extrahepatic biliary resection is advocated for the management of T3 and T4 tumors[120]. The authors propose that the limit for extrahepatic

biliary resection ought to be decreased in patients with penetration of GBC through the subserosa[120]. Adjuvant combination chemotherapy and molecular targeted therapy are emerging as powerful therapeutics choices in those with advanced GBC. These days, adjuvant combination chemotherapy and molecular targeted therapy are regularly utilized as viable treatment for advanced GBC[121,122]. Adjuvant radiation treatment is utilized in locally advanced GBC or gallbladder disease with regional disease and has better survival rate[123,124]. It has been found that chemotherapy did not give effective treatment to unresectable GBC. Different regimens are already studied which include mixtures of 5-FU, leucovorin, mitomycin, adriamycin, in addition to nitrosoureas. A study observed a 64% reaction rate to gemcitabine with or without cisplatin to patients with stage 4 GBCs during phase Ⅱ trial. Average time to development was 28 wk and the average general survival was 42 wk[125]. In other phase Ⅱ trial utilizing a combination of gemcitabine and carboplatin in 20 patients with unresectable GBC, the reaction rate was 37%, average time to development was 34 wk, and the 1-year survival rate was 43%. The study concluded that chemotherapy with mixture of gemcitabine and carboplatin is viable in the treatment of advanced gallbladder carcinoma[126]. Palliative treatment may be done if GBC is found to be unresectable at the time of surgical investigation. The particular rate of biliary obstruction within affected individuals by GBC is higher than 60%[117]. A study concluded that combination of gemcitabin and oxaliplatin works well in inoperable GBC with overall response rate of more than 20%. It depicted that it may even incite complete pathological reaction. One year survival was found in more than 20% patients[127]. Other phase Ⅲ study predicts that survival rate has been found higher in those patients who receive combination of gemcitabine and cisplatin in comparison to gemcitabine alone. Different studies are in process of clinical trials for molecular targeted agents which restrain angiogenesis and EGFR pathways[128]. New effective treatment and drugs are an urgent need for GBC. Recently a new study has been done in which the authors look at the effects of triptolide on GBC cells to identify its anticancer effects. They concluded in their study that triptolide induce apoptosis in gallbladder cells and thus can be used as a potential drug for treatment of GBC[129].

CONCLUSION

The clinical and radiologic diagnosis of gallbladder carcinoma at an early stage is challenging. It is crucial for radiologists to examine the gallbladder in its entirety, especially in patients who are at a greater risk of developing GBC, for important morphologic abnormalities that may suggest carcinoma. Identification of characteristic imaging appearances of primary GBC and comprehension of its pathways of spread and staging criteria will help in formulating appropriate treatment regimens.

Abstract

Percutaneous nephrolithotomy is a very commonly done procedure for management of renal calculus disease. Establishing a good access is the first and probably the most crucial step of this procedure. A proper access is the gateway to success. However, this crucial step has the steepest learning curve for, in a fluoroscopy guided access, it involves visualizing a three dimensional anatomy on a two dimensional fluoroscopy screen. This review describes the anatomical basis of the renal access. It provides a literature review of all aspects of percutaneous renal access along with the advances that have taken place in this field over the years. The article describes a technique to determine the site of skin puncture, the angle and depth of puncture using a simple mathematical principle. It also reviews the common problems faced during the process of puncture and dilatation and describes the ways to overcome them. The aim of this article is to provide the reader a step by step guide for percutaneous renal access.

Key words: Fluoroscopy; Percutaneous renal access; Percutaneous nephrolithotomy; Learning curve; Kidney

Core tip: This article is a review of the various fluoroscopic guided renal access techniques. It provides an in depth description of the technique with the aim that the urologist can have a step by step guide of the procedure. It gives an anatomical basis of percutaneous renal access and gives description of determining the skin site, angle and depth of puncture. It also describes the difficulties faced and incorporates suggestions to prevent and overcome them.

INTRODUCTION

Rupel and Brown first reported Percutaneous nephrolithotomy in 1941[1]. Goodwin *et al*[2] described percutaneous trocar nephrostomy in a hydronephrotic kidney in 1955. The technique gained popularity especially after the description by Fernstrom and Johansson in 1976[3-5]. The improvement in endourological equipment and the advancement in techniques resulted in percutaneous nephrolithotomy (PCNL) getting accepted as the gold standard for the treatment of patients with renal stones larger than 20 mm in diameter[6]. Its popularity and acceptance amongst urologists and patients is largely due to the fact that it is minimally invasive and is associated with low morbidity[7]. Initially the procedure was done only in prone position using fluoroscopy guidance. However, in the last couple of decades use of ultrasonography alone or along with fluoroscopy has been used for percutaneous renal access[8]. Various modifications in the position of patient have also been described to overcome some limitations and drawbacks of the percutaneous renal access in prone position[9]. Despite these changes fluoroscopy guided access in prone position is still the most commonly used technique for PCNL[10]. The prone position is associated with a significantly shorter nephrostomy tract length and more potential access sites, which may improve ease and safety of percutaneous renal access[11]. In European countries, urologist establishes their own percutaneous renal access, but in the United States, access is often performed by interventional radiologists. Studies have shown lower stone free rate and a higher complication rate in radiologist performed renal access[12-14]. Despite these facts and the documented safety and efficacy of urologist acquired percutaneous renal access, as few as 11% of urologists who perform PCNL achieve access[15]. This low success rate is attributed to probably a lack of skill[16]. This is probably due to the difficulty in visualizing and mentally imbibing the three dimensional anatomy of the pelvicalyceal system on the two dimensional fluoroscopy screen[17]. The purpose of this review is to describe the various aspects of the technique of fluoroscopy guided percutaneous renal access in prone position. It is the attempt of the authors to provide a step by step guide of all aspects of the technique. Finally, the authors describe their technique in detail and the rationale behind it.

INSERTION OF URETERIC CATHETER

At the beginning of the procedure, a 5 Fr or 6 Fr ureteric catheter is inserted in the collecting system either using a rigid cystoscope (with the patient in lithotomy position) or a flexible cystoscope (with the patient prone). This is used to instill contrast to opacify the system. Also it can be used to flush saline so as to distend the system, flush small gravels during the process of stone fragmentation and at times to pass a glide wire for insertion of a double J (DJ) stent, at the end of the procedure. A Foley catheter is also passed by the side of the ureteric catheter. Both the catheters are secured with each other to prevent inadvertent slipping out of the ureteric catheter.

PRONE POSITIONING

This is an important maneuver which, if not done properly, can result in potentially serious injury to the patient. The ideal way would be to have the patient supine, have a separate trolley by the side of the operating table, shift the patient in supine position to the side trolley, remove the monitoring devices and then make the patient prone on the operating table and immediately connect the devices which have been disengaged or removed. These maneuvers should be done with adequate staff and with proper co-ordination between the anesthesiologist managing the airway, endotracheal tube and neck and the staff managing the chest and torso. Although cervical spine injury during prone positioning under anesthesia is rare, it has been reported with both over flexion and over extension during prolonged procedures[18]. Patients with cervical spine pathology, Down's syndrome or rheumatoid arthritis or patients with myelopathic syndromes are at the greatest risk. Post operative visual loss is an uncommon (0.2% of spinal surgeries in one review) but grave complication of prone surgery[19]. The ability to maintain good ventilation along with the hemodynamic stability throughout the procedure is the challenge which the anesthesiologists face. For a healthy, adequately anesthetized patient, these may be clinically insignificant; however, for those with associated co morbidities, it can be very precarious. Hence, irrespective of whether the procedure is done under general or regional anesthesia, constant vigilant monitoring during the procedure is a must. Anesthesia for PCNL cannot and should not be taken lightly.

POSITION OF PATIENT

Care should be taken to ensure that the pressure points are properly padded and limbs are positioned in a way that undue stretch, especially of the joints is avoided. This would prevent inadvertent injury and stretch of the nerves. The chest and abdomen is supported in a way to ensure free movements for the pulmonary capacity is greater in the prone compared to the supine position[18]. After positioning the flank is properly prepared and the unsterile areas covered with drapes (Figure 1).

ARRANGEMENT OF TROLLEYS

This is as shown in the figure. This helps to have a clear view of the fluoroscopy and endo camera monitors (Figure 2).

Figure 1 Position of patient.

INSTILLATION OF CONTRAST

Contrast is instilled *via* the ureteric catheter to opacify the pelvicalyceal system and identify the calyx which should be punctured. The contrast should be diluted in ratio of 1:3. The ureteric catheter, if placed in the upper pole, should be pulled down a bit so that it is in the pelvis. This helps in proper filling of all the calyces. The contrast should be instilled slowly to prevent extravasation. There should be continuous fluoroscopy monitoring so that which calyces are filled earlier and which later can be seen and this helps to identify the posterior calyx.

WHICH POLE TO PUNCTURE?

The creation of a proper percutaneous renal access is the gateway to success or disaster in PCNL[10,20,21]. A basic understanding of anatomy is needed to plan this. The kidneys lie on the posterior abdominal wall against the psoas muscle with their longitudinal axis parallel to the oblique course of the psoas at an angle of 13° to 30° to the midline. Also, as the psoas major muscle is cone shaped, the kidneys, in their longitudinal axis have a dorsal tilt with the superior poles being more medial and more posterior than the inferior poles. As the hilar region is rotated anteriorly on the psoas muscle, the kidneys are rotated about 30° posteriorly and hence the lateral aspect of the kidney is posterior to the medial aspect. The kidneys are also angled 30°-50° behind the frontal (coronal) plane with the lower pole anterior to the upper pole[22]. In prone position, the pelvis tends to fall anteriorly on the psoas muscle; hence the lower pole, pelvis and the proximal end of the ureter are placed more anteriorly than the upper pole[23,24]. The calyceal drainage of poles of the kidneys is also very important. Sampaio found that, in the cases he studied, the superior pole was drained by only one midline calyceal infundibulum in 98.6% of cases; the inferior pole was drained by paired calyces arranged in two rows in 58% and by a single mid line calyceal infundibulum in 42% of cases and the mid pole was drained by paired calyces arranged in two rows (anterior and posterior) in 96% of cases[22]. This

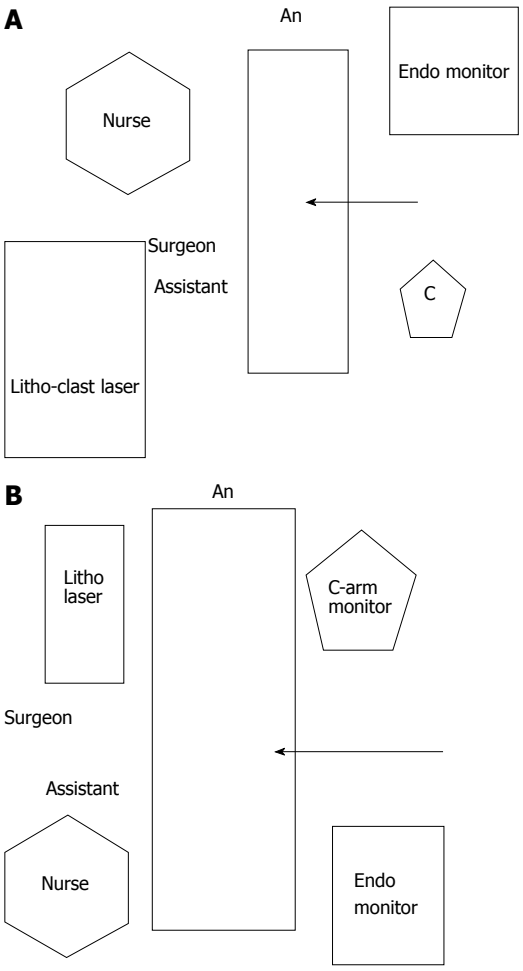

Figure 2 Arrangement of trolleys. A: Arrangement for lower pole puncture; B: Arrangement for upper pole puncture.

has important implications for percutaneous renal access as it will be easier to access endoscopically a polar region drained by a single infundibulum, which usually has suitable diameter, rather than a polar region drained by paired calyces. He also found that for best access to the pelvic-ureteric junction (PUJ) one should choose a pole whose calyx forms an angle of 90° or more with the PUJ[22].

The planning for puncture begins preoperatively by proper assessment of the imaging studies. Traditionally intravenous urography was used for functional and anatomical assessment of the collecting system. Nowadays, CT urography with coronal reconstruction is getting popular[25]. The advantages of the CT scan over intravenous urography is the ability to assess the spatial relationship of the kidney relative to the stone, depict the calyceal anatomy in 3D format to choose the access site, assess risk of pleural or bowel injury and even predict success of a sub costal fluoroscopic access for upper pole puncture. The preoperative detection of heptaosplenomegaly or the presence of retro renal colon allows serious complications related to tract placement to be avoided[26-29]. These advantages are offset by the slightly higher cost and lack of widespread availability of multiplanar CT scans in

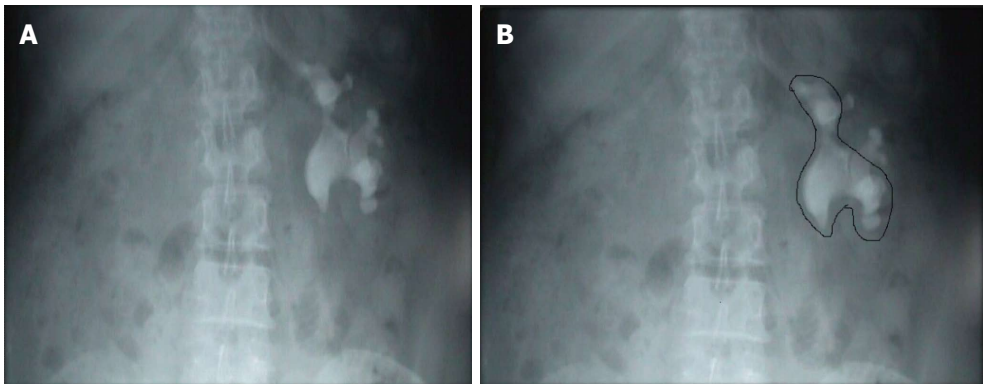

Figure 3 Outline-o-gram. A: KUB showing a Left staghorn calculus; B: Outline-o-gram suggests that most of the calculus can be cleared by the lower puncture and a separate puncture may be needed for the residual fragment.

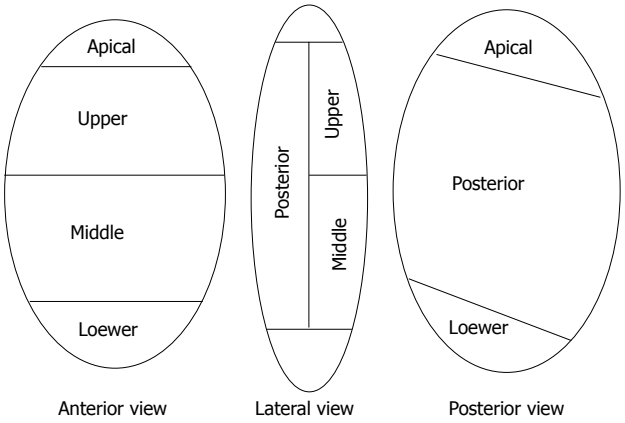

Figure 4 Arterial blood supply of kidney.

developing countries.

Whichever imaging modality is used the urologist has to select a pole for puncture which provides the straightest path along the stone axis and would provide maximum or complete stone clearance. A useful adjunct to make this decision would be to make an "outline-o-gram". As shown in Figure 3A there is a complete stag horn calculus. The "outline-o-gram" as shown in Figure 3B indicates that most of the calculus can be cleared by a lower pole puncture. The mid pole calculus would need a separate puncture or use of a flexible nephroscope. Thus an "outline-o-gram" can serve as a guide to determine which pole to puncture and also to decide whether multiple tracts will be needed.

WHICH CALYX TO PUNCTURE?

The literature is clear about the fact that it should always be the posterior calyx which should be punctured for a safe and complication free access[20,21].

WHY TO PUNCTURE THE POSTERIOR CALYX?

A good understanding of the renal anatomy provides answer to this question. The kidney gets its blood supply from the renal artery which divides into the anterior and posterior branch. These further divide into segmental arteries which supply specific areas of the kidney as shown in the figure (Figure 4). As these arteries are end arteries, there is a zone of relative avascularity between these two divisions, called as the Brodel's line of bloodless incision. The potential for bleeding complications is the least in this area. Due to the renal rotation, the posterior calices are usually oriented with their long axis pointing towards the Brodel's line. Hence puncture of a posterior calyx will traverse this relatively avascular zone[30]. Also, as the patient is prone, it will provide the direct path to the renal pelvis. If an anterior calyx is punctured, there is increased risk of bleeding as it does not traverse through the Brodel's line. More parenchyma is traversed to reach the calyx, resulting in more renal damage. Also, as there will be an acute angle between the line of puncture and the infundibulum, entry in the renal pelvis will be difficult, associated with more torque and thus increased bleeding and damage to the renal parenchyma[20,21].

CALYCEAL ORIENTATION-WHICH CALYX IS THE POSTERIOR CALYX?

The renal papillae drain into the minor calyces which may be simple or compound. There are three drainage zones, upper, middle and the lower pole. Compound calyces are the rule in upper pole, are common in the lower pole and are rare in the middle pole.

Investigators have attempted to differentiate calyces as anterior or posterior solely on the basis of their medial or lateral orientation as seen on IVU. The available anatomical references on this aspect are contradictory, confusing and incomplete. In 1901, Brodel studied corrosion casts of 70 cadaveric kidneys. He depicted the anterior calyces as medial and posterior as lateral[31]. Hodson, in 1972, described exactly the opposite, *i.e.,* the anterior calyces located laterally and posterior calyces located medially[32]. Then, in 1984,

Kaye and Reinke[33] measured calyceal angles from the axial CT images. They concluded that the Brodel pattern is seen in 69% of right kidneys while 70% of left kidneys have a Hodson pattern[33]. Sampaio *et al*[34,35] studied 140 endocasts and found that the anterior calyces are lateral in 28%, posterior calyces are lateral in 19%, and in 53% endocasts the anterior and posterior calyces had varied positions, superimposed or alternately distributed (in one region the most lateral were the anterior calyces and in another the posterior calyces)[34,35]. He found that the calyceal orientation was region dependent. The typical anterior and posterior pattern of the calyces is seen only in the middle pole[22]. The lower pole has this arrangement in only 58% cases while the upper pole almost uniformly has a compound calyceal system[22]. This implies that in the lower and upper pole the calyces are dominantly oriented in the direction of their respective poles. This has been further studied by 3D CT renderings which have also looked at the primary plane of the calyceal group. Miller *et al*[17] found that in the upper pole the primary plane of the calyces in the upper pole was Medial/Lateral and generally neutral relative to the anteroposterior axis of the kidney. As the upper pole is more posterior in the prone position, access *via* any calyx would provide a working tract that parallels the longitudinal axis of the kidney. This would mean access *via* an angle which would allow rigid instruments to reach most of the calyces in the kidney[17]. However, preferably the lateral most calyx should be punctured in the upper pole as puncturing a medial calyx is associated with significant risk of causing injury to the posterior segmental artery[36]. Eisner *et al*[37] studied the lower pole anatomy by CT scans in 101 units. They found that if there were two calices in the lower pole, the medial calyx was anterior in 95% of units while the lateral calyx was posterior in 93% of units. If there were 3 calices in the lower pole, than the medial most calyx was anterior in 93 of units. In such renal units the lateral to most medial, *i.e.,* the second calyx was posterior in 70% of units while the lateral most calyx was anterior in 71% of units. In 31% of cases, no calyx was truly posterior. In these kidneys, though both the calices were anterior, one of the calices was less anterior than the other. Their study showed that regardless of the number of lower pole calices, the most medial calyx on two dimensional imaging is anteriorly facing 94% of times. They recommended that the calyx, just lateral to the medial calyx, the second calyx, is statistically the most likely to be posterior facing and the most posterior positioned calyx[37].

HOW TO IDENTIFY THE POSTERIOR CALYX ON FLUOROSCOPY?

On account of the unreliability of the antero-posterior radiography to determine the optimal posterior calyx for entry additional maneuvers are needed[35]. With the patient in prone position, diluted contrast when instilled will fill the dependent anterior calices first. Thus the posterior calices will be filled later and would appear less dense[21]. Injection of 5-10 mL of air *via* the ureteric catheter also helps to identify the posterior calices as air will preferentially enter these calices when the patient is prone[21,38]. Despite these maneuvers if there is dilemma in indentifying the posterior calyx, movement of the C arm can help to identify the posterior calyx. In the prone position, the posterior calyces move in the opposite direction to the image intensifier on the C arm. If the C arm is rotated towards the surgeon then the posterior calices move away and shorten. *Vice versa*, if the C arm is rotated away from the surgeon then the posterior calices appear elongated. Thus by moving the C arm way from the surgeon one can identify the laterally placed calices as posterior and by moving the C arm towards the surgeon the posterior calices appear more medially placed and appear end on[9].

NEEDLE USED FOR PUNCTURE

A diamond tip needle and not a bevel tip needle should be used for puncture. A diamond tip needle has symmetrical tip which exerts equal force in all directions on the tissue. Hence the tissue is cut in the moving direction of the needle tip. A bevel-tip needle exerts forces asymmetrically so cutting of the tissue occurs at an offset angle depending on the bevel angle, needle flexibility and tissue properties[39]. The size of the needle used for puncture is a matter of debate. The options are a 21 gauge needle (which allows a 0.018 inch guide wire) or an 18 gauge needle (which allows a 0.035 inch guide wire). The 18 gauge needle is stiffer but more traumatic. The 21 gauge needle is less traumatic but less stiff and hence cannot maintain the trajectory adequately. Also, the 0.018 inch guide wire that passes through the 21 gauge needle must be exchanged for a standard 0.035 inch guide wire for subsequent tract dilatation. This requires an extra step, which adds to the complexity of the procedure and increases the risk of loss of access. Weighing the pros and cons of both it would be rational to use the 21 gauge needle when the surgeon is less experienced or if minimizing trauma is the need of the moment. The 18 gauge needle should be used by an experienced surgeon who is confident of attaining access with minimum attempts[40].

WHAT SHOULD BE THE TRAJECTORY OF THE NEEDLE?

Renal pelvis should not be punctured directly as there is very high risk of injuring a retro pelvic vessel (artery and/or vein). Studies by Sampaio have proved beyond doubt that puncture through the infundibulum of a calyx is associated with a significant risk of significant

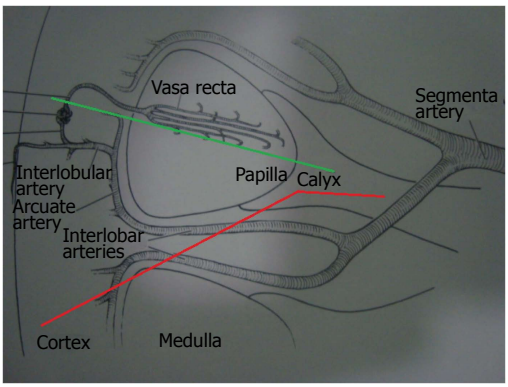

Figure 5 Trajectory of needle during puncture.

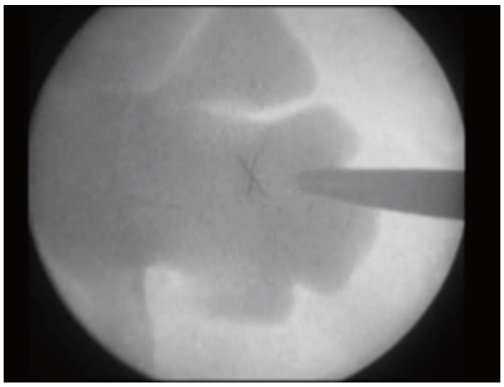

Figure 6 Bull's eye appearance of the needle.

bleeding from interlobar vessels. There is an added risk of through and through puncture of the collecting system. The risk of injury to a major arterial vessel is maximum in the upper pole where puncture of the upper pole infundibulum puncture may cause damage to posterior segmental artery, which is related to the posterior surface of upper pole infundibulum in 57% of cases. Damage to this artery may lead to loss of upto 50% of the renal parenchyma as well as serious hemorrhage[30,35].

The trajectory of the needle during puncture should be such that it aims at the fornix and not at the infundibula (Figure 5). In other words we should aim for the center of the calyx posterolaterally *via* the renal parenchyma. When puncture is made through a fornix, no arterial injury occurs and venous injury occurs in less than 8% cases[30].

CRITERIA FOR A GOOD PUNCTURE

Percutaneous renal access through a calyx must meet five conditions that guarantee safe access and avoids complications[41]: (1) Access should be performed from a posterolateral aspect; (2) Access should be through the renal parenchyma; (3) Access should be towards the center of a calyx posterolaterally; (4) Access should be towards the center of the renal pelvis and as a result of these four conditions; and (5) The trajectory does not damage any major blood vessels.

TYPES OF FLUOROSCOPY GUIDED PUNCTURE

There are two types of fluoroscopy guided puncture techniques-the Bull's eye and the Triangulation Technique. Besides these two there are a number of variations described[42].

BULL'S EYE TECHNIQUE

It is also called the Eye of the Needle technique[20]. The target calyx is identified with the C arm at 0° in the axial plane. Then the C arm is rotated 30° towards the surgeon and the calyx to be punctured would appear end on the fluoroscopy screen. A tilt of 5°-10° in the caudal direction for the lower pole or in the cranial direction for the upper pole may be necessitated to have a circular end on appearance of the target posterior calyx[21]. The position on the skin overlying the selected calyx is then marked and the puncture initiated. The needle is advanced at the end of full-expiration. It is seen as a Bull's eye (as a dot) on the fluoroscopy screen. If a longitudinal segment of needle is seen then it indicates that the trajectory is not correct and adjustment needs to be made accordingly. The C arm may be rotated by few degrees away from the surgeon to get a proper perspective of the depth of the puncture. The needle will now be seen in profile. It is then advanced to puncture the calyx. Free efflux of urine confirms the position in the collecting system[20,21,41,42]. To minimize radiation to the hands, the needle could be held with hemostat, sponge forceps or a purpose-built radiolucent needle holder (Figure 6).

Modifications of the bull's eye technique

Bilen *et al*[43], described the use of an in-line laser pointer to guide renal access in which the laser was attached within the field of the receiving head of the C-arm fluoroscopy unit. Ko *et al*[44] described a further modification using a C arm mounted laser positioning device where the laser beam is focused on the hub of the needle continuously so that the correct alignment is maintained during the puncture without the use of fluoroscopy. This approach may reduce fluoroscopic exposure early in the learning curve. As experience increased the muscle memory leads to maintenance of the correct needle alignment[42].

TRIANGULATION TECHNIQUE

Triangulation technique is the technique of using two known points of reference to locate a third unknown point. It is guided by biplanar fluoroscopy. The medial and lateral plane is assessed with the C arm at 0°. The depth is assessed by rotating the C arm in the

cranial or caudal direction by 30°. The target calyx is identified with the C arm at 0°. Then the line of puncture is aligned with the infundibulum. With the C arm at 0° the needle is introduced through the skin incision. The left and right, *i.e.,* the mediolateral adjustments are made and the needle is aligned with calyx. Then the C arm is rotated 30°, towards the head end for lower pole punctures and towards the foot end for upper pole punctures. The needle is then oriented in the up and down, *i.e.*, the cephalo-caudal position so that the orientation is again towards the desired calyx. When making the adjustments in one plane it is necessary to maintain the orientation of the needle in the other plane. The needle is then advanced with the C arm tilted 30° to give an idea regarding the depth and the respiration suspended at end expiration. After advancing the needle for several centimeters shift the C arm to 0° to see that the trajectory of the needle is still properly aligned to the target calyx in the mediolateral plane. If necessary the needle trajectory can be readjusted to maintain proper targeting. It is imperative that to minimize trauma to the renal parenchyma, the adjustment of the needle plane should be done when the needle is outside the renal capsule and not when the needle is in the parenchyma. A slight jiggle of the needle causing indentation of the desired calyx is a further sign that the trajectory of the needle is correct. If the needle position in the medial-lateral and cephalo-caudal planes is maintained, the needle should enter the targeted calyx[20,24,39-41]. It is preferable to use the 18-gauge rather than a 21-gauge needle with the triangulation technique, as its stiffness provides better stability to help maintain angle of entry[39].

Comparison of Bull's eye and Triangulation technique

In the Triangulation technique, the puncture is along the stone axis, *i.e,* in alignment with the infundibulum. This decreases the need for excessive torque on the renal parenchyma by the rigid instruments, which may cause renal trauma and bleeding[20]. Tepeler *et al*[10] did a comparison of the Bulls' eye and the Triangulation techniques and found no difference between the two as regards operation time, fluoroscopy screening time, duration of hospitalization and blood transfusion rate. They found a slightly greater drop in hematocrit and complication rate in the group undergoing access by the Bull's eye technique as compared to the Triangulation technique. However, the difference was not statistically different.

The advantage of the triangulation technique over the eye-of-the-needle" technique is that the needle cannot be passed too deeply because the depth of advancement is monitored continuously[39]. Also, the triangulation technique alone fulfills the five criteria of a successful puncture[41]. The disadvantage of the triangulation technique is that maintaining both the medial-lateral and cephalo-caudal planes are difficult because both are not being monitored at the same time as in the "eye-of-the-needle" technique. Complex visual spatial skills are required in performing this task when using a C-arm fluoroscopy unit, especially by the novice surgeon[44]. It is at this juncture that multiple attempts are needed by the urologists and excessive use of fluoroscopy occurs especially by a beginner. This is also the aspect which has the steepest learning curve for an urologist getting trained in percutaneous nephrolithotomy[45]. Usually, during the learning curve the problem comes in the assessment of depth with the C arm in the oblique position. Whether the needle is superficial or deep to the calyx has to be ascertained by the surgeon and adjustments made accordingly[46]. The easiest way to determine this would be to place another needle on the skin surface over the target calyx. If the calyx is between the two needles than the puncture needle is deep and should be adjusted superficially. If the target calyx is below the two needles, then the puncture needle is superficial and should be adjusted towards the depth.

Modifications of triangulation technique

Several new approaches and refinements have been described to improve access and reduce the learning curve of the surgeon. Mues *et al*[47] described a geometric model to create a plane of coincidence between the C arm and the needle, each at the same angle of 20°-30° from the targeted calyx, but in opposite directions. For lower pole access, the C arm is rotated cranially 30° from the vertical plane and a needle is advanced from a position distal to the calyx, rotated caudally 30° from the vertical plane. For mid pole and upper pole calyceal access the C arm is rotated 20° away from the surgeon and the needle is advanced from a position lateral to the calyx at an angle of 20° towards the surgeon from the vertical plane. During the procedure the C arm remains fixed and the needle is advanced till the point of coincidence between the calyx and the needle tip is reached. This technique avoids the need for C arm manipulation and thus potentially reduces time need to achieve the puncture[41]. This technique, however, requires a plumb, protractor and ruler to calculate, and confirm the necessary measurements. Also, it presumes that the angle of convergence would be 30° at the lower pole and 20° at the other poles. Considering the wide variations in the structure of the kidney that occurs with the varying degrees of hydronephrosis that occurs, this may not necessarily be always true. Liatsikos *et al*[48] described a technique to take advantage of the ability of triangulation technique to target a calyx from a preselected puncture site. After clearing the calculus from the initial puncture site, the sheath is withdrawn and additional calices which need to be approached for complete stone clearance are punctured from the initial puncture site. A single nephrostomy tube can be left despite multiple entries through the single incision[42,48]. The tracts are from a single site but in

different directions. This does not reduce the chance of complications. Moreover, attempt of maneuvering the rigid nephroscope may increase the torque on the renal parenchyma with resultant increase in bleeding. Mozer *et al*[49] have described a computer generated system which can be used to project the ultrasound nephrostomy tract onto fluoroscopic images virtually. The surgeon, thus, has the benefit of having preview to a three dimensional anatomy while doing the procedure instead of the usual two dimensional fluoroscopy picture. Though exciting, it requires a special system which is not routinely available. Newer C arms utilizing softwares to provide a three dimensional picture have also been used to obtain renal access in animal models[50]. Robot assistance for fluoroscopic percutaneous renal access has also been studied and is under evaluation[51,52]. These futuristic techniques have not gained widespread acceptance A study comparing robot assisted renal access with standard manual access showed that though the mean number of access attempts was comparable, the robot took lesser time to achieve puncture (10.4 min *vs* 15.1 min). However, conversion to manual access was needed in 3 cases where the robot was unsuccessful[53]. A stereotactic localization system with specially designed instruments have been described by Li *et al*[54]. It uses the Pythagoras principle of right angle triangle to calculate the depth of puncture. Then using specifically designed and patented instruments the puncture is made with precalculated depth and angle of puncture. The same instrument is then used for dilatation of the tract. The authors found that their technique is associated with higher efficiency, better stone clearance and lower morbidity, which they attribute to the greater accuracy of the puncture. This technique was not found to be useful when the puncture angle was less than 30°, because the buttocks of the operator would be in the way. Also the authors generally selected the puncture point with the same distance vertically and horizontally, which means at 45° from the skin to the stone. This again makes the principle of puncturing quite rigid as the variations in the pelvicalyceal anatomy may preclude adherence to such rigid principles. Recently, Hatipoglu *et al*[55] described a monoplanar access technique. The chosen calyx is marked with a clamp. For the lower pole puncture the needle is placed 1 cm below and medial to the 12th rib. The needle is placed with a 30° angle to the sagittal plane and is directed toward the desired calyx. If puncture fails, the needle is retracted approximately 1 cm intracorporeally, and its angle of entry adjusted on the same vertical plane and reinserted. For the mid and upper pole puncture the needle is held perpendicular to the spinal column and at a nearly 30° to the horizontal plane to access targeted middle and upper calyces to reach the pelvis and lower poles. The authors proposed that as the C arm is fixed in an anteroposterior position and thus rotation is avoided, the operative time needed for puncture is less[55]. However, there were no upper pole punctures in this study. In the initial learning curve a surgeon would find this technique difficult to master. Also, using a pre fixed puncture point on the skin for all lower pole punctures and directing the needle at a fixed angle of 30° to the sagittal plane may not always be a correct approach especially considering the variation in the position and direction of the lower pole calyces.

Hybrid technique

Rationale thinking suggests that the three most important things needed to achieve a successful percutaneous renal puncture are the site of skin entry, the angle of entry and the depth at which the puncture is achieved. Determining the correct point of skin puncture is important in the triangulation technique because a skin puncture that is too medial or lateral to the desired optimum point of entry would result in a tract of variable length and angle of entry in the calyx. This would interfere with proper access and would cause excessive torque on the parenchyma during maneuvering of the rigid nephroscope in the pelvicalyceal system. The literature does provide guidelines when it comes to determining the site of skin puncture. To avoid injury to the colon, the puncture should be medial to the posterior axillary line but not too medial as it would traverse the paraspinal muscle causing increased postoperative pain and would probably be directly on the renal pelvis without traversing the renal parenchyma. The puncture that is too close to the rib may injure the intercostal nerve and vessels and hence is to be avoided. For lower-pole access, the skin puncture should be 1 cm inferior and 1 cm medial to the tipoff the 12th rib[20,55-57].

We have described the technique of determining the site of skin puncture, which amalgamates the advantages of both the bull's eye and triangulation technique and hence is called as the hybrid technique[41,57]. With the C arm at 0°, the site of skin corresponding to the target calyx is marked as point A. The C arm is then rotated 30° towards the surgeon. The point on the skin corresponding to the target calyx and forming a bull's eye with the needle is marked as point B. In The Bull's eye technique we take a puncture at the point B. However in the Triangulation technique, the puncture is along the stone axis in alignment with the infundibulum. If we take the target calyx as the center of a sphere, then we have an imaginary circle on the skin where the point A is the center of the circle. The distance from point A to B will be the radius of the circle. The radius remains the same irrespective of the direction in which it is measured from the center of the circle. Thus, when we take a line along the stone axis where we intend to take a puncture-the site of skin puncture is marked using this principle. This means that the point B1 is marked on the skin such that the distance from point A to B1 is equal to the distance between A to B, *i.e.*, the radius of a circle with the target calyx being its center. This is how we determine site of skin puncture in triangulation technique[57]

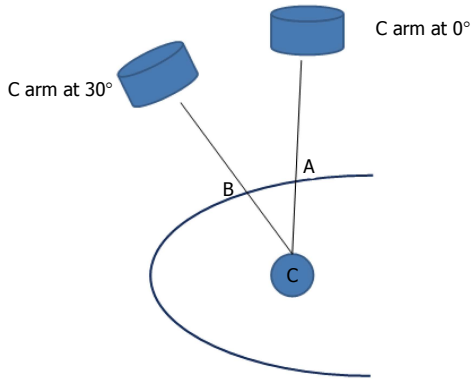

Figure 7 Hybrid technique. Point C is the calyx to be punctured. Point A corresponds to the Point C with the C arm at 0°. Point B corresponds to the point C with the Carm rotated towards the surgeon by 30°. The needle held at Point A or B is seen as a Bull's eye effect on the Carm monitor. The distance between points A and B is measured.

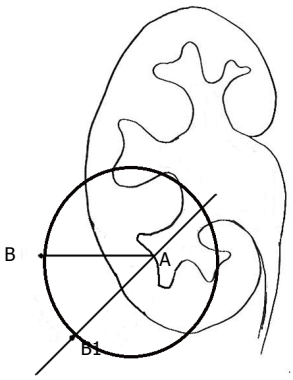

Figure 8 Hybrid technique. "A" is the point on the skin which corresponds to the targeted calyx with the C arm at 0 degree and is the center of an imaginary circle. The distance between "A" to "B1" is equal to the distance between the "A" to "B", *i.e.*, the radius of the circle.

(Figures 7 and 8).

Once the site of puncture is determined the next critical step is to access the centre of a posterior calyx with the needle directed at an appropriate angle. This step of hitting the calyx at the depth often requires maneuvering the C arm in different directions, either towards the surgeon (in bull's eye technique) or in an oblique cephalo-caudal direction (for the triangulation technique) and requires understanding a three dimensional anatomy on a two dimensional fluoroscopy monitor. This step requires maintenance of the needle in one plane while making the adjustments in the other plane and not surprisingly, multiple attempts are needed and excessive use of fluoroscopy occurs, at this step, especially by a beginner[20,45]. Maintenance of needle orientation in one plane while making the adjustment in the other plane is critical for a proper puncture. This is also the aspect which has the steepest learning curve for an urologist getting trained in percutaneous nephrolithotomy[45].

We describe our technique of using a simple mathematical principle to determine the angle and depth of puncture in fluoroscopy guided percutaneous renal access in prone position. We have used it in > 150 cases for lower, mid and upper pole punctures with > 95% success in first attempt and no pleural, visceral or hemorrhagic complications. This has recently been accepted for publication.

In the Bull's eye technique, the angle at which the needle is seen as a dot is the angle at which the puncture is made. Our Hybrid technique utilizes this principle. With the needle at point B and the C arm rotated 30° towards the surgeon and the needle forming the Bull's eye; the angle that the needle makes with the skin surface is measured using a protractor (Figure 9). One needs to take care that the protractor is held parallel to the operating table. Using the principle of sphere and circle as described earlier; if we are hitting the calyx by using the triangulation technique from the point B1-the angle of puncture

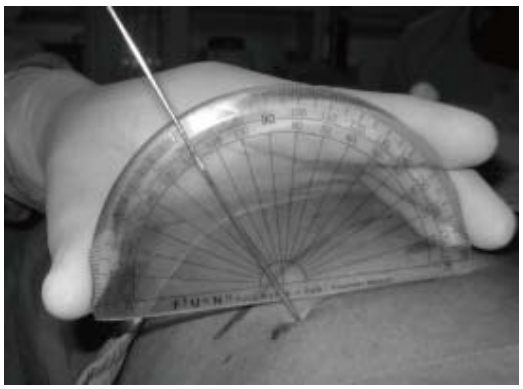

Figure 9 Hybrid technique. The angle which the needle makes with the skin surface is measured using a protractor.

would be the same with probably variations of 1-2 degrees due to the not so perfectly flat contours of the body surface. The third component of the hybrid technique is to determine the depth of puncture. What we have till now is an imaginary triangle (Figure 9) where we know: (1) One side - the distance between point A to B which is marked on the skin; (2) One angle - which is 90° with the C arm at 0°; and (3) Another angle- which is measured using the protractor at the point B.

With this information; by using the Universal triangle solver application from Google play store we can determine the depth. In this application, if we put the two angles and one side then, by the law of sines, it calculates the other two sides and the angle. For example, if the distance AB is 4 cm and the angle calculated by the protractor is 65° and with the other angle always being 90°- by universal triangle solver- the depth will be 9.5 cm.

The same principle can be applied in the triangulation technique. The C arm is brought to 0°. The line of puncture is determined in alignment with infundibulum from point A. On this line the point B1 is marked. From the Point B1 access can be obtained

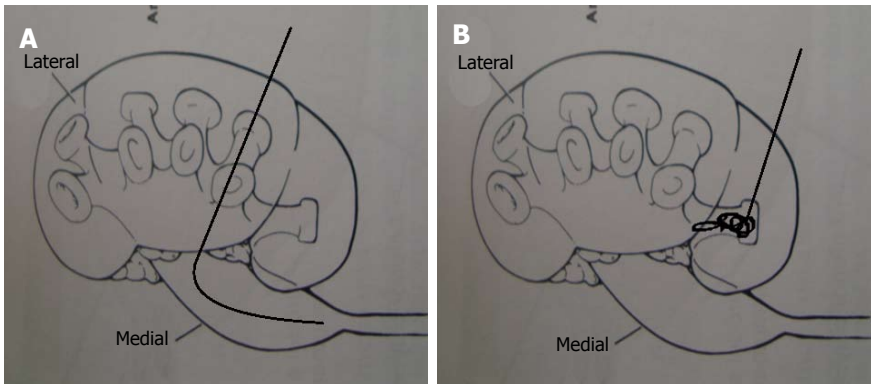

Figure 10 Calyceal puncture. A: If the posterior calyx is punctured than the glide wire passes easily in the pelvis; B: if the anterior calyx is punctured than the glide wire gets coiled in the calyx before it makes its way to the pelvis.

using the triangulation technique (Figure 8). The angle of puncture is as determined by the protractor earlier using the bull's eye principle. The depth of puncture is the same as calculated earlier. As the angle of entry is known and the depth pre calculated, the needle is advanced with the C arm 0° position only (without the need to take it in oblique position) and the puncture is made.

In the technique described by us we have assumed the target calyx as the centre of a sphere. If we have to hit the centre of a sphere from the surface, the distance traversed from any point on the surface to the centre would be the same. Hence once we have marked the point B on the skin surface using the bull's eye technique and then mark point B1 for the skin entry using the triangulation technique; then the distance from C to B or from C to B1 will be the same, *i.e.*, the radius of the sphere. Also the angle of entry from B or from B1 towards point C would be nearly the same, with only minor difference, because of the not so perfectly flat contours of the body.

But, this minimal difference would not cause any major hindrance in achieving access by the technique described because the angle of puncture and thus the trajectory of the needle would not have much variation. This was seen by us in our study. The difference between the calculated and the actual depth ranged from 0-3 mm. Also, as the angle of entry is known the fluoroscopy screening time and the time needed to achieve puncture decreases as multiple movements of the C arm are not required.

The technique described by us is applicable for both the bull's eye and the triangulation method. It describes the three most important things needed to achieve a successful percutaneous renal puncture: the site of skin entry, the angle of entry and the depth at which the puncture is achieved. It relies on simple tools. There could be some errors which could creep in especially if the protractor is not held parallel to the operating table, but this could be overcome easily with minimal experience (and the assistant telling that the protractor is parallel to the table or not). But so far this technique has not been compared with other techniques. The applicability and validation of this technique in the hands of others is yet to be ascertained. This would need a controlled prospective study involving many surgeons of equal experience and comparison with the traditional technique. It would then ascertain whether this technique is associated with a lesser fluoroscopy time, more accuracy and lesser learning curve as proposed by us. The grade of hydronephrosis can affect the puncture with the access being relatively easier for higher grades of hydronephrosis. However, if the angle, *i.e.*, the trajectory of puncture is correct, as described by this technique, the puncture would be easier and precise even in lesser grades of hydronephrosis.

CONFIRMATION OF PUNCTURE OF POSTERIOR CALYX

If air has been instilled during opacification of the pelvi calyceal system, air will be aspirated followed by a free flow saline especially if it is instilled through the ureteric catheter. After this when the glide wire is passed, while maintaining the angle of the needle, in enters the pelvis easily. No manipulation is needed. On the contrary if the anterior calyx has been punctured than the glide wire will be coiled in the calyx, will not enter the pelvis easily or will do so only after much manipulation (Figure 10).

PASSAGE OF GLIDE/GUIDE WIRE

If a 21G needle has been used for puncture than a 0.018 inch guide wire is passed initially which has to be exchanged later for a 0.035 inch guide wire. If a 18 G needle has been used than 0.035 inch glide wire can be passed. Initially a J tip Teflon coated guide wire was used. Nowadays the use of an angled tip hydrophilic glide wire is increasing. The maneuverability, resistance to kinking and ease with which it can be negotiated in the ureter across an impacted calculus or be coiled in a distant calyx are the distant benefits of this wire.

But the slippery nature of the hydrophilic wire makes it prone to displacement. Hence, it should be replaced with a stiffer wire such as a 0.035 inch Zebra or an Amplatz super stiff guide wire[21,41]. Another caution which needs to be exercised in passing the hydrophilic glide wire is to keep it wet. The dried tip can be stiff and cause inadvertent perforation of the collecting system.

INCISING SKIN AND FASCIA

The skin should be incised adequately so that the dilators and desired size of Amplatz sheath can be introduced easily. The correct way of incising the fascia would be to use the knife along the needle under fluoroscopic guidance as a lumbotome. The fascia should be incised in two planes at right angles to each other. This is especially important in patients who have scarring as a result of previous surgery. One may use an 18 G coaxial fascial incising needle (Cook) taking care to avoid lacerating the nearby sub costal or intercostal neurovascular bundle on the inferior rib margin[21].

GUIDE WIRE AND SAFETY WIRE

Traditional teaching gave much emphasis on the placement of a safety guide wire to access the tract in the event of the inadvertent slipping out of the working guide wire[20]. Many surgeons nowadays do not find it necessary to place a second safety wire especially if the guide wire is passed all the way in the bladder and more so it is a super stiff guide wire[21]. However during the learning curve it is prudent to have a safety wire. This can be introduced alongside the initial wire using a dual lumen catheter or 8/10Fr coaxial dilator of the dilatation canula (Karl Storz)[20,21,41]. Dilatation should be done over the stiff wire and not over the slippery hydrophilic wire.

TRACK DILATATION

The dilatation of the tract for creation of the nephrostomy access is an integral step of PCNL. Tract dilatation is performed to increase the size of the percutaneous wire access so that working instruments can be inserted in the pelvi-calyceal system (PCS). The size of the tract should be increased to 24 or 30 Fr size in most cases with the use of specialized dilators. The function of the dilator is to enlarge the tract in a noninvasive manner and to make renal access easier. The dilated tract is then maintained by placement of an Amplatz sheath.

Tract dilatation can be acute or chronic[58]. Chronic dilatation is done by placement of a percutaneous nephrostomy tube, which is gradually dilated over few days by sequentially replacing it by larger tubes. Acute dilatation is done just before the therapeutic procedure. The tract is dilated either by sequential (Amplatz dilators) or telescopic coaxial dilators (Alken dilators). These are rigid dilators. Balloon dilators are also in vogue and have results similar to rigid dilators. The chronic dilatation approach was once the conventional method by which renal access surgery such as PCNL were done; however, in recent years one stage acute dilatation method has become preferred due to its low risks of patient morbidity and decreased time, which allows less room for complications.

Alkens dilators

These are rigid metal dilators that are introduced over a central guide rod. Progressively enlarging coaxial stainless steel dilators help to dilate the tract from the 8 Fr guide rod up to 30 Fr. The guide rod has a round bulbous end prevents the sequential dilators from over-shooting. The advantages of the Alkens dilator system are that it is reusable, hence inexpensive and importantly is able to dilate even when there is dense perinephric scarring[59]. The disadvantage is that the same characteristics that make the Alkens dilator so effective are also the reasons why the rigid metal dilators can do considerable damage.

Amplatz dilators

These are semi rigid plastic dilators that are passed over an 8-Fr PTFE guiding catheter that fits over a 0.035-inch guide wire. They can also be passed over a guide rod. The dilators are passed one after the other, not coaxially like the rigid metal dilators but progressively, by advancing one dilator, removing it, advancing the next larger dilator, and so on until the final tract diameter is achieved. Finally, the working sheath is passed over the final dilator and then the dilator and 8-Fr catheter are removed, leaving the working wire and sheath in place. The dilators are made in increments of 2 Fr, but if the tissue being dilated is soft, then not every dilator needs to be used.

The advantages of Amplatz dilators are that trauma experienced by the collecting system is theoretically less probable than the trauma experienced by the collecting system using rigid metal dilators, but the disadvantage is that bleeding can happen each time a dilator is withdrawn. As these are disposable dilators, they are more expensive than the Alkens dilators.

There have been many comparative studies[59-63] between the two dilator systems but experienced urologists have found no difference between the two systems in terms of safety. Alkens dilators may be preferred in patients who have tight fitting staghorn calculi, as Amplatz dilators need some space in the calyx for dilatation. In calyces that have no space, the dilatation may remain short due to tapered end of the dilator.

Balloon dilators

Here a pressure balloon is used for rapid tract

making[64]. The Amplatz sheath is back loaded on the balloon and is placed once the balloon is adequately distended. The balloon dilator is expensive and may be difficult to use in patients with densely scarred tissue. The dilators may have an advantage when operating on a hyper mobile kidney. As it is a single step dilatation that causes tamponade, the bleeding is expected to be less, but not all studies have documented less bleeding and transfusion as compared to the Alkens and Amplatz dilators[59,65-67].

In an effort to make tract making rapid, easy, and blood less, multiple single step techniques have been described. The simplest is using the largest Amplatz dilators without the initial smaller dilators. In difficult situations where scar tissue is present around the kidney, collings knife or plasma vaporization has been used for tract making[68]. Two new dilatation systems described have been a radially expanding single step dilator system[69] and the 5pang system[70]. Both the systems of the advantage of not removing the needle and hence the dilatation is over s rigid system resulting in less chances of kinking of guide wire. Also the dilatation would be faster. However, so far it has been a single center experience and multi center experience with these two systems has not been described.

The important principles of tract dilatation are: (1) A proper planning of the procedure and correct choice of the calyx of entry is vital for the success of PCNL. This needs a study the radiologic images prior to the procedure; (2) The tract should be dilated only till the minor calyx. If over-dilatation happens, it can traumatize the infundibulum, renal pelvis or uretero-pelvic junction. Trauma to the anterior wall of the PCS can cause significant bleeding that may be difficult to control. It is always better to under dilate than to over dilate and cause trauma; (3) The success of tract making is dependent on maintaining the angle, depth, and the direction of the dilatation; (4) Every step of dilatation should be monitored on fluoroscopy; (5) The collecting system should be kept distended during dilatation by instilling in the system either contrast or saline. This is instilled by the OR assistant through the ureteric catheter; and (6) Adequate lumbotomy is important for safe dilatation.

AMPLATZ SHEATH

The use of an Amplatz Sheath during percutaneous renal procedures has become standard. No matter the type of dilator used, rigid or balloon, or the technique of track dilation, one-step or multi-stepped, an Amplatz sheath is always used. The Amplatz sheath serves many purposes: (1) Amplatz sheath maintains the tract during procedure; (2) It causes tamponade of the tract and reduces bleeding. The beveled end of the Amplatz sheath can be used to tamponade a part of renal parenchyma that is actively bleeding[71]; (3) It protects the renal parenchyma from injury by the instruments used in renal procedures; (4) The use of Amplatz sheath maintains a low-pressure system and reduces fluid intravasation. Maintaining a low-pressure system would be important in patients with infected calculi as the risk of sepsis would reduce; and (5) Amplatz sheath helps in removal of calculi and prevents parenchymal injury by broken ragged stone edges.

WHEN TO DO MULTIPLE PUNCTURES?

The amount of bleeding, parenchymal damage, morbidity as well as the risk to the patient increases with increase in the number of punctures[72]. It is important to plan the first puncture in a way that multiple punctures are avoided. Use of flexible nephroscopy and flexible ureteroscopy would also reduce the need for multiple punctures[73].

Multiple accesses may be needed when treating large and complex stones and staghorn calculi. In this situation the first tract is made in a way that most stone bulk can be removed through it. The accessory tracts can be mini-PCNL tracts for peripheral small calculi. In this situation, upper calyx has an advantage as it affords a direct access to the upper calyx, renal pelvis, all components of the lower calyx and the upper ureter[74]. In selected situations where the calculi are smaller than the neck of the calyx, percutaneous calyceal lavage can be done to flush the calculi in the renal pelvis so that they can be picked up through the primary tract. If necessary, multiple tracts can be safely made in experienced hands with the intent of complete stone clearance[75].

In a complex situation, the plan of management would be as follows: Make the primary tract in a way to clear maximum stone bulk. If access to a flexible nephroscopy with holmium laser is available, use this to prevent additional tracts. If these facilities are not available, percutaneous calyceal lavage, mini-tracts or accessory tracts can be made.

HOW TO MAKE A SAFE SECOND TRACT?

The second or multiple tracts tend to bleed more than the primary tract because when the second tract is made, it is not possible to opacify the system. The puncture is more often directed to the stone and not to the calyx. Also the bleeding and fluid extravasation through the first tract can alter the anatomy. To prevent this, if a second tract is anticipated, it is better to place the guide wires in the calyces where the second tract is expected before the first tract is dilated. The advantage of a pre-placed guide wire is that the proper placement of the tract is possible but the disadvantage is that in some patients this wire may not need to be dilated. The advantages of a proper placed tract far outweigh the risk of a tract made

aiming for the stones.

HOW TO MINIMIZE RADIATION?

The risk of radiation is quite high in patients with stone disease during their evaluation and treatment. Recently, two centers have studied the radiation dose in a patient with a primary acute stone event over a 1 year period. They found average radiation to which these patients were exposed was 29.7 mSv, and 20% of the patients were exposed to > 50 mSv[76]. This dose exceeds the International Commission on Radiological Protection recommendation on limits for occupational exposure to radiation, which is 20 mSv averaged over a 5-year period with not nore than > 50mSv in any single year. In comparison, a typical CT of the abdomen and pelvis without contrast exposes patients to a median of 15 mSv[77]. Fluoroscopy during percutaneous nephrolithotomy is associated with radiation exposure not only to the patient but also to the surgeon and the operation theatre staff[78]. High Body Mass Index, high stone burden, and increasing number of access tracts are associated with an increased radiation exposure. Branched stones and the presence of hydronephrosis are associated with decreased radiation exposure[79,80]. Proper planning of the procedure by an experienced surgeon is very important for reduction of radiation exposure[81]. It is the duty of the surgeon to reduce this health hazard for all concerned. Following steps can be taken to minimize radiation during PNL: (1) The surgeon and the staff must always wear radiation protection gowns, thyroid guards and radiation protection gloves[82]; (2) It is important to limit the time of exposure to minimum necessary. Using short bursts of fluoroscopy and using the "last image hold" feature of the fluoroscopy unit reduces radiation exposure[83]; (3) The image intensifier should be placed as close to the patient as possible, fluoroscopy beam should come from under the table, be focused on the area of interest and a pulsed fluoroscopy mode should be used[25]. The use of air instead of iodinated contrast may further reduce the radiation exposure[84]; (4) Keeping the fluoroscopy unit foot pedal with the surgeon and thinking during and after screening are other small precautions which can decrease the radiation; (5) For lower pole punctures using triangulation technique tilt the C arm cephalad and *vice versa* for upper pole puncture; and (6) Hold the needle in a way that the hands get minimal radiation exposure. Use of an instrument to achieve this would reduce radiation exposure. Needles and dilators that have distance marked on them can help in reducing radiation as the fluoroscopy can be used once the needle-tip is near the kidney[40,85].

PREVENTING VISCERAL INJURY DURING PCNL

Any abdominal organ close to the kidney can be injured during percutaneous renal surgery including the colon, duodenum, jejunum, spleen, liver, and biliary system. Such injury is always an accident and an effort is needed in preventing them. If it happens, early identification and treatment is very vital.

Colonic injury

Colonic injury happens in about 1% percutaneous renal procedures in prone position. It is thought to be due to retro-renal position of the colon. It is more common on the left side when a lower calyx access is attempted[86]. Thin patients, elderly age group, dilated colon, prior colon surgery or disease, and the presence of a horseshoe kidney are additional risk factors[40,87]. It can also happen in patients who undergo significant weight loss in a short time like patients after bariatric surgery, ileal diseases and resections. A recent hypothesis proposed retro-renal colon to be an acquired anomaly[88]. Five patients developed colonic injury in the 2nd stage PCNL. All these patients had a long-standing large hydronephrosis that was initially drained by either a nephrostomy or a DJ stent. They proposed that the colonic mesocolon lengthens over the gradually dilating obstructed kidney. Once the kidney is de-obstructed, the kidney reduces in size but the long mesocolon persists. The colon with the long mesocolon drops posterior to kidney forming a retro renal colon.

Prevention of colonic injury is very difficult. In patients who are predisposed to colonic injury, a pre-operative CT scan in prone position could help identify the position of colon in relation to the proposed tract. Awareness of the colonic gas bubble on fluoroscopy at the time of making access and monitoring any changes in the bubble could help prevent this injury. It would be possible to identify the overlying colon if a sonography guided puncture is attempted.

Liver and splenic injury

Injury to normal sized liver and spleen are very rare during PCNL and are likely to occur if the puncture is above the 10th rib[89,90]. In patients with significant splenomegaly and hepatomegaly pre-operative CT scan could be used to decide a safe access. In rare situations, CT guided access could be made. Pre-operative awareness and planning is the only way to prevent these injuries.

Pleural injury

Pleural injury is a definite risk associated with supra-costal access. All supra costal tracts traverse the diaphragm and hence there is risk of damage to the pleura and lung. The surgeon should be aware of this risk while undertaking Supracostal puncture[91]. The risk increases as the tract moves higher on the intercostal space. The risk that is about 4% in supra 12th rib access increases to nearly 20% in supra 11 rib access[92] .

To understand pleural injury during PCNL, it is

important to understand the pleural anatomy. The parietal pleura crosses the 12th rib such that the medial half is covered by the pleura while the lateral half of the rib is not covered by the pleura. In the mid scapular line, while the parietal pleura is at the level of the 12th rib and the visceral pleura is at the level of the 10th rib,. The parietal and visceral pleura ascend cranially and laterally on the ribs, and further rise in deep expiration[91,93].

To prevent pleural violation[91]: (1) Make the Tract lateral to the mid scapular line; (2) As far as feasible, stay below the 10th rib; (3) Tract making should be performed in deep expiration; and (4) Tract should be kept to the minimum necessary size.

Based on the above mentioned anatomical caveats it would be rational to suggest that tracts below the 11th rib made lateral to the mid scapular line would miss not only the visceral pleura but mal also miss the parietal pleura. Tracts made through the parietal pleura may not be of clinical significance. Use of an Amplatz sheath would further mitigate major complications by preventing leakage of the irrigation fluid in the pleural space.

An anesthetist who understands the procedure and is involved during the procedure is important, as he would maintain the patient in deep expiration when the tract is being made. If the individual case demands higher tract, there is no harm in making it. Use of thoracosopy control would make this safer[94]. The pleural fluid collection, if occurs, can be easily managed by placing a chest drain at end of the procedure. It is vital to check the costo-phrenic angle at the end of the supra-costal access. A clear costo phrenic angle on fluoroscopy at the end of the procedure is a proof that pleura have not been violated[95].

PROBLEMS DURING ACCESS

Failure to opacify the system

Cause: This uncommon occurrence can occur either due to the ureteric catheter slipping out or a tightly impacted calculus preventing passage of contrast across it. Prevention: The ureteric catheter needs to be fixed to the per urethral catheter inserted initially so that it does not slip out while making the patient prone. Using a hydrophilic glide wire also helps in negotiating the wire and then the ureteric catheter across the calculus.

Remedy: For a tightly impacted calculus, where the contrast does not go across it. Keeping the patient in "head-low" position or reducing the concentration of the contrast (increase the dilution) may help some contrast go beyond the blocking calculus. If this does not work, then either an ultrasound guided puncture can be attempted or one can use a Chiba needle to opacify the system. Chiba needle is a much finer needle as compared to the initial puncture needle hence is likely to be less traumatic[96]. The needle is introduced around 2 cm lateral to the vertebral transverse process at L1-2 level. At this site it is likely to hit the renal pelvis. The CT scan images could help in identification of exact site of renal pelvis. Once the PCS is entered with a Chiba needle (confirmed by aspiration of urine from PCS), opacify the system and make the standard tract through the chosen calyx.

Extravasation of contrast

Cause: Extravasation of the contrast is an unfortunate problem. It is important to avoid this situation, as extravasation would happen before the main procedure begins, and would complicate the further access making. The extravasated contrast would make the tract making difficult and also hamper the radiologic confirmation of stone clearance post procedure. The most common cause is when an enthusiastic assistant instills a large volume of contrast under high pressure. Rarely, the contrast may extravasate from an improperly placed ureteric catheter. This would be more common in patients with large impacted ureteric calculi with infection. It may also happen intra-op when the first attempt at needle insertion is not satisfactory and the contrast leaks from the needle puncture site that is made in the collecting system.

Prevention: To prevent extravasation of contrast, inject diluted contrast slowly while keeping the ureteric catheter in the pelvis so that sudden distension of the system with consequent extravasation does not occur. It is extremely important to instruct the assistant to instill a small amount of contrast gradually at a very low pressure. The volume of the normal collecting system is 5-8 mL; hence gradual instillation of small volume is vital.

Remedy: The problem can be salvaged in multiple ways: (1) Give diuretic and wait for the contrast to get absorbed. The concentration of the extravasated contrast would significantly reduce if you wait for about 15 minutes after a frusemide injection; (2) Use concentrated contrast that would help in identification of the PCS through the dilute extravasated contrast. The tract needs to be made fast before the concentrated contrast extravasates and compounds the problem; (3) Use of air-pyelogram to identify the PCS. The similar problem of air extravasation can happen through the needle hole in the cortex; (4) Ultrasound guided percutaneous access is a good option. However, even this technique would be difficult after contrast extravasates. Do not attempt air pyelogram, if you want to do an ultrasonography; (5) Very rarely, it may be desirable to stage the procedure and re-attempt access after 48 h; (6) Grasso *et al*[97] initially described ureteroscopically assisted percutaneous renal access as a salvage procedure in difficult cases. This can be utilized in cases where significant extravasation has occurred. The major hindrance is the availability of a flexible scope, which is not the case in many

developing countries; and (7) Giannakopoulos *et al*[98] have described the use of an angiographic catheter to salvage such situation. A 0.038-inch guide wire is passed through open-end ureteral catheter which is then removed and an angled- tip angiographic catheter is passed. The radiopaque tip of the angiographic catheter is easily seen on the fluoroscopy despite significant extravasation of contrast. A guide wire is then passed through the angiographic catheter. It is manipulated and brought in a calyx which is to be punctured. The angiographic catheter is then brought till the calyx and the puncture is made aiming at the tip of the catheter. The intravenous urogram film or an initial normal fluoroscopic image before extravasation, which is captured on the second monitor of the fluoroscopy unit is very helpful in manipulating the guide wire and catheter in the proper calyx. The correct position of the catheter in a posterior calyx can also be confirmed by rotating the C-arm[98].

Inability to puncture

Cause: Inability to puncture is often a technical problem .This happens either due to the inexperience of the operator or due to technical difficulty commonly while attempting puncture of a non-dilated system. This could be related to incorrect choice of the calyx for puncture.

Prevention: In the initial learning phase, presence of a more experienced colleague goes a long way in minimizing the learning curve and overcoming difficulties during the procedure. It is important to keep the PCS adequately filled for ease of puncture. Ask the assistant to continuously flush fluid in the ureteric catheter so that the system remains distended. If despite multiple attempts it is still difficult, reassess the pre-operative radiological studies and re-plan the puncture. Add a drop of methylene blue or betadine solution to the contrast; aspiration of the colored fluid (blue or brown) from kidney would give confidence of correct puncture[99].

Remedy: In a non-dilated system, fluoroscopy guided puncture is usually feasible using the techniques described above. If the surgeon is worried about trauma to the kidney, then it is prudent to use a 21 G needle for initial puncture and pass a 0.018 inch guide wire, which can be exchanged for a 0.035 inch stiffer guide wire[40]. If these attempts fail, take the help of a senior colleague from the department. An interventional radiologist may help with difficult punctures. Re-planning the procedure under CT scan guidance or ultrasonography guidance may rarely be needed[100] Puncture would also be difficult in a patient who has a very thin renal cortex. The renal cortex tends to move away from the needle or to get tented by the needle rather than getting punctured. Forcefully pushing the needle in, once near the cortex, can help the needle enter the PCS. Forceful insertion would be safe as in this patient with thin renal cortex the PCS is likely to be hugely dilated. Proper care of the wire once inserted is very important in these patients. It is also important to keep a safety wire if possible. If there were a tract loss, it would be very difficult to get inside these deflated hydronephrotic sacs. Puncture will also be awkward in very thin patients. As there is no perirenal fat pad, the kidney tends to get pushed by the needle. A bolster kept below the kidney can hold the kidney in place so that puncture can be made.

Blood at tip of needle and not urine

Cause: It is not uncommon to have made a puncture and after removing the trocar and aspiration have blood and not urine. This happens if the needle is in a blood vessel or needle is in renal parenchyma instead of in the pelvicalyceal system. It can also occur if multiple attempts have been made to achieve access.

Prevention: Avoid trauma by making multiple attempts of puncture using a 18 G needle, instead use a 21 G needle. Follow a proper puncture technique so that we aim at the calyx through the fornix.

Remedy: If after injecting saline through the ureteric catheter, the efflux clears then it suggests that the needle tip is in the collecting system and glide wire can be passed in the collecting system. If the efflux or the aspirated fluid is frank blood then the needle's position should be readjusted. This entails with drawing the needle and adjusting the medio-lateral and anteroposterior position. It is usually the depth of the needle which needs to be adjusted. Either the needle is superficial or deep to the desired calyx. This adjustment is best made after withdrawing the needle outside the parenchyma. Manipulations within the parenchyma cause trauma and should be avoided. The 3 finger technique described by Shergill *et al*[46] is an attempt to help the junior trainee to overcome this difficulty. The tip of the needle should be towards the desired calyx with the C arm in the anteroposterior position or tilted towards or away from the surgeon or tilted in cephalo caudal direction. The surgeon should remember the medio-lateral adjustments should be made with the C arm at 0^0 and the depth adjustment should be made after tilting the C arm towards or away from the surgeon, as in Bull's eye technique or tilting it in the cephalo-caudal direction, as in the triangulation technique. An easy way to determine the depth would be to place another needle on the skin surface over the target calyx. If the calyx is between the two needles than the puncture needle is deep and should be adjusted superficially. If the target calyx is below the two needles, then the puncture needle is superficial and should be adjusted towards the depth. Use of the Hybrid Technique described above minimizes these problems.

Inability to park the guide wire

Cause: This occurs either if the glide wire is outside

the collecting system or if the calyx is completely occupied by a calculus. Rarely, inadvertent puncture of a renal cyst and aspiration of clear fluid can cause a mistaken assumption of a good puncture. But the glide wire does not enter the collecting system in such cases. If an anterior calyx s punctured then also the glide wire will not enter the pelvis easily (Figure 10B).

Prevention: Free flow of urine from the needle usually is a sure shot sign of a correct puncture. A hydrophilic glide wire usually passes easily in the pelvis even across an impacted calculus. As regards inadvertent cyst puncture, the ultrasound findings and the intravenous urogram or the CT scan picture should alert the surgeon regarding such a possibility.

Remedy: Re puncture or re-insert the glide wire if one suspects that the glide wire is outside the system. Injecting diluted contrast or diluted methylene blue can also confirm that the needle is properly positioned in the desired calyx. There may be a calculus blocking the passage of the wire down the ureter, in this situation, the second best place to park the wire would be a distant calyx. If the wire does not coil in distant calyx then keep as much length as possible of the wire in the punctured calyx[99].

Kinking of guide wire

Cause: This usually occurs due to forceful dilatation in the wrong direction and/or against resistance of the initial dilator. Once the guide rod is in place this problem cannot occur.

Prevention: The wire usually kinks at the level of the thoracolumbar fascia. Hence the fascia needs to be incised well before starting the dilatation. Use of super stiff wire is recommended due to its properties to resist kinking more than the PTFE guide wire[101]. The dilatation should be in the correct direction and with adequate force. A simple rule would be to achieve the 2/3 of the progress of the dilator by rotational screwing movements and 1/3 by force. If there is doubt regarding the correct direction then moving the glide wire gives a good indication. If the wire moves freely then it indicates that the direction and trajectory is correct. *Vice versa*, if the glide wire does not move freely then the direction and trajectory needs to be adjusted. This simple friction test can be of immense help in the initial learning of percutaneous renal access. Use of the 5 part PANG needle system largely avoids this problem[70].

Remedy: If a kink has occurred then the initial dilator should be advanced close to the kink and it should be pulled inside the dilator. The correct direction should then be ascertained and further dilation should be done. At times a re-puncture is needed. If a safety wire has been inserted then it can be used for dilatation. Recently Lezrek *et al*[102] have described a use of bi prong forceps to overcome renal mobility and prevent guide wire kinking during tract dilatation.

Under dilatation

Cause: Under dilatation is a condition when the wire was initially well placed but during dilatation the dilators and the Amplatz sheath remained short of the PCS. This usually occurs early during the learning curve. Use of Amplatz dilators is also associated with this as the terminal taper end of the dilator enters the calyx but the amplatz sheath introduced over it does not enter the calyx and remains outside the collecting system. This may cause brisk bleeding as there is a portion of parenchyma that has been partially dilated, which does not have the tamponade effects of the Amplatz sheath. This situation needs rapid management.

Prevention: Flushing saline from the ureteric catheter during the process of dilatation helps in confirming that the dilator/ dilators are within the collecting system by seeing the efflux of saline form the dilators. Small frequent bursts of screening on the C arm confirm the correct position of the dilators.

Remedy: The treatment would depend on the position of the wire. If the wire is still inside the PCS, thread the guide rod on the wire so that the bulbous end of the rod is fluoroscopically positioned in the PCS. Using the flexible guide rod may be easy in this situation. Once the guide rod is placed, use Amplatz dilators to dilate the remaining non dilated tract and the reposition the Amplatz sheath in the collecting system. If the wire has also slipped out and the nephroscope is outside the parenchyma in the perirenal fat, it is important to find the hole in the renal capsule through which partial dilatation had been done. This can be identified as a site of bleeding in the parenchyma. To identify this site one may need to reduce the irrigation pressure of the nephroscope so that venous bleeding is visible. Once the site is identified, place the guide rod through the capsular hole and confirm its position on the fluoroscopy. A guide wire may be placed through the rod to make the access secure. Once this is done, the remaining dilatation could continue with Amplatz dilators. If no bleeding site is identified, for identifying the capsular hole some colored fluid will be needed. Methylene blue or betadine solution can be used. The methylene blue solution should be very dilute. Add just 1-2 drops of methylene blue in 10 cc normal saline. For betadine solution, undiluted betadine or betadine with one-in-one dilution could be used. Flush either solution through the ureteric catheter. Watch for egress of colored solution. Once identified, place a guide rod through that site and continue with the remaining dilatation. If despite colored solution, puncture site cannot be identified, attempts re-puncture and repeat

tract making. This may be difficult as the contrast may extravasate or the calyx may not fill due to leakage of contrast. Choosing an access through another calyx or sonography guided puncture may help. In a rare situation, it may be needed to stage the procedure. The puncture site seals in 48-72 h and a repeat procedure can be done after that time.

Overdilatation

Cause: Over dilatation is a state when the dilators have traversed the opposite wall of the PCS and the Amplatz sheath is now placed anterior to the kidney. Forceful dilatation is the usual reason for this problem.

Prevention: Hold the guide rod firmly and dilate 2/3 by rotation and 1/3 by force. Attempt should be to dilate till the calyx and not till the calculus. It is better to under dilate than to over dilate.

Remedy: The problem with this complication is that when the Amplatz sheath is withdrawn back to get it in the PCS, the dilated anterior wall will not have any tamponade effect and is likely to bleed briskly. Also, the irrigation fluid would leak through the hole in anterior wall. Further Nephroscopy would become difficult as the PCS may collapse due to fluid leakage. The fluid that extravasates would cause significant fluid overload. Even the stone or stone fragments can migrate outside the PCS through the hole in the anterior wall. The Amplatz sheath needs to be withdrawn gradually till the sheath is back in PCS. The further plan after this would depend on the size of perforation and the amount of bleeding. If over dilatation has resulted in a small pelvic perforation than one can get back properly in the system and quickly finish the procedure without causing much extravasation. However if there is a large perforation or significant bleeding than it is prudent to insert a nephrostomy tube, abandon the procedure and live to fight another day. Always a keep a large bore nephrostomy tube during such situations. The second procedure can be staged after 3-4 d, as the perforation usually heals within this period[103].

Loss of tract

Cause: Loss of tract means initially that the tract was well made but during Nephroscopy or lithotripsy, the Amplatz sheath has slipped out of the PCS. This happens when the glide wire slips out before the dilatation is completed. At times during the fragmentation of the calculus, the guide wire comes out and if the amplatz is not held properly then it too can come out of the collecting system.

Prevention: To prevent loss of tract, the guide wire should be adequately parked in the collecting system or passed till the bladder. Use of a safety wire is another maneuver which can prevent a complete loss of tract. Also using a super stiff guide wire instead of a slippery hydrophilic glide wire prevents complete loss of tract.

Remedy: The treatment depends on the position of the guide wire. If either the guide wire or the safety wire is well placed, it is possible to follow the wire endoscopically till the nephroscope is positioned in the PCS; the Amplatz sheath can be threaded over the nephroscope once the scope is well placed. If there is no wire, the steps are same as for under-dilatation. Look for the bleeding site or look for egress of the colored fluid. One important concern of the lost tract is that calculi or calculi fragments may extrude and can get misplaced in the perirenal fat. These calculi can be a source of persistent infection. If possible, an attempt should be made to remove all calculi. During endoscopic exploration of the perirenal space, reduce the irrigation pressure so that patient does not land in fluid overload. If despite care, the extruded calculi are misplaced in the perirenal fat, it is important to document that the radio-opaque shadows seen on post-op imaging are outside PCS. They would cause apprehension to the patient hence proper explanation to the patient is vital.

CONCLUSION

"Good results of surgery are results of good surgery". This adage is most appropriate for a percutaneous renal access, for a correct access decides to a large extent the success of PCNL. More innovations would come in the management of renal calculus and technology would make percutaneous access easier in future; but adherence to the understanding of renal anatomy would still be the base on which a percutaneous renal access would be based.

Abstract

Robotic surgery is increasingly being employed to overcome the disadvantages associated with use of conventional techniques such as laparoscopy. However, despite significant promise, there are some clear disadvantages and robust evidence base supporting the use of robotic assistance remains lacking. In this paper, the advantages and drivers for robotics will be discussed, its drawbacks and its future role in surgery.

Key words: Robotics; Surgery; Simulation; Patient safety

Core tip: Robotic technology is increasingly being employed in surgery to overcome the disadvantages associated with use of conventional techniques such as laparoscopy. However, despite significant promise, robust evidence base supporting the use of robotic assistance remains lacking. Prospective, multicentre randomised controlled trials to evaluate efficacy, long-term outcomes, safety and cost are the next steps before widespread uptake of this technology to treat patients. Moreover, with the unprecedented need for patient safety, it is imperative that adequate training and assessment strategies are in place to bridge the gap between conventional techniques and robotic surgery without harm to patients.

INTRODUCTION

Robotic surgery is increasingly being implemented to overcome drawbacks associated with the use of conventional techniques such as laparoscopy, especially in complex procedures. However, despite holding significant promise, robotic surgery is associated with some clear disadvantages and robust evidence base supporting robotic assistance remains lacking[1].

The introduction of minimally invasive techniques to general surgery has been described as "the most dramatic change in surgery since the introduction of anaesthesia"[2]. This has led to many procedures being performed exclusively *via* the laparoscopic approach, such as a cholecystectomy. Reasons include reduced blood loss and post-operative pain, reduced risk of infection, reduced length of hospital stay and faster return to daily activities[3]. However, these superior

results are only when the initial learning curve has been taken into account.

Laparoscopic surgery is associated with several challenges. Disadvantages and complications have been well documented[4]. Long, rigid instruments amplify tremor, reduce range of motion and degrees of freedom. This is exacerbated by the fulcrum effect whereby instrument tips move in a direction opposite to those of surgeon's hands[5]. Loss of 3-dimentional (3D) vision and having to view a 2-dimentional image, not directly under the control of surgeon, enhances these difficulties by leading to loss of traditional eye-hand target axis[6]. The laparoscopic technique is associated with poor ergonomics and health problems in surgeons such as nerve injuries[7]. Robotic systems, such as the da Vinci, have thus emerged to overcome few of these limitations.

The 3D, high-definition imaging of robotic technology facilitates stereotactic vision of the operation field and makes depth perception possible[8]. The camera is surgeon-controlled and the area of interest can be magnified up to 10 times. The surgeon's hand movements can be scaled (5:1, 3:1, or 1:1) so that large hand movements are translated into smaller movements inside the patient[9]. Combined with tremor abolition, this facilitates precise surgical manoeuvres. Endowrist instrumentation provides 7 degrees of freedom and improves range of motion, enhancing dexterity, comparable to that attained in open procedures[10]. The surgeon's comfort is increased by the ergonomic sitting position, reducing fatigue (both physical and cognitive) due to exhausting positions or movements often observed in conventional laparoscopy[11]. The intuitive movements in robotic surgery can potentially shorten the learning curve compared to conventional laparoscopy[12]. Thus, less experienced laparoscopic surgeons may acquire skills to conduct robotic surgeries in a relatively shorter time period compared to attaining corresponding proficiency in conventional laparoscopy. Significant progress in robotic applications has been in procedures that cannot be performed by a laparoscopic approach, *i.e.,* cardiac and endovascular surgery.

CARDIAC SURGERY

A Total Endoscopic Coronary Artery Bypass (TECAB) can now be performed using the robotic slave system, da Vinci, from the Left Internal Mammary Artery to the Left Anterior Descending artery without the need for a strenotomy[13]. Successful results have been reported by several groups as a result of reduced post-operative pain, better cosmesis and faster healing due to lack of a strenotomy incision[14]. Procedures requiring extreme precision or fine visualisation, such as coronary anastomosis are facilitated by the high magnification and tremor-free, precise microinstrumentation[15]. Greater patient satisfaction is also reported[16]. Off-pump procedures (*i.e.,* on a beating heart) avoid complications of cardiopulmonary bypass and are associated with a lower incidence of atrial fibrillation, stroke and death in the elderly[17]. Robotic surgery is also useful for mitral valve reconstruction. 3D visualisation allows good view of the ventricle needed for suturing in chordal reconstruction[18]. Greater range of motion facilitates the complex cutting and needle loading angles in the confined space of the left atrium[18].

However, there are disadvantages. Robot-assisted TECAB is a technically demanding and time-consuming procedure. It is associated with a significant learning curve[19]. Nevertheless, it represents a feasible alternative to conventional coronary artery bypass[20].

ENDOVASCULAR SURGERY

Another emerging domain of robotic surgery is that of endovascular robotics. The conventional endovascular catheters present several limitations within the vascular tree. These include their small range of shapes and sizes, difficulty in maneuvering the tip with the lack of stability[21]. Hence, interventionalists have to frequently change catheters and this presents a major risk of vessel trauma or distal embolization as a result of alteration of guidewire position[21]. This is especially critical in the aortic arch, where stroke, as a result of cerebral embolisation, may occur[21].

Riga *et al*[22] demonstrated that Endovascular Aneurysm Repair using a robotically steerable catheter system is feasible and may improve catheter maneuverability, stability and precision. Pre-shaped conventional catheters can rotate around one axis only, presenting a major drawback when fine and controlled movements are required in multiple planes[22]. Conversely, a steerable multidirectional catheter may overcome this hurdle and may be especially useful with regards to anatomically difficult cannulation in fenestrated stent-grafting[23]. This system also minimises operator radiation exposure, as the workstation is located outside the endovascular suite and away from the radiation source. Robotic endovascular catheters may lead to improved accuracy, reduce time and minimise radiation exposure in complex vascular procedures in particular[23]. Moreover, robotic endovascular catheters have been demonstrated to lead to a statistically significant faster skill acquisition in novice surgeons[24]. Hence, there is a potential to shorten the learning curve so that trainees can attempt more complex endovascular procedures earlier and with a greater degree of safety[24]. Yet, transferability of these findings to the operating room (OR) is debatable.

DRAWBACKS AND THE FUTURE

Despite the numerous advantages, robotics in surgery has drawbacks that hinder the widespread

Table 1 Drawbacks associated with robotic surgery

Drawback	Discussion
Cost	The da Vinci system costs approximately $1.5 million with maintenance fees of about $150000 per year[43,44]. Likewise, robotic endovascular catheter systems are expensive, have high maintenance costs, with the additional cost of disposable catheters. However, there is no conclusive data regarding the cost-effectiveness of these robotic systems. Moreover, an economic model, with quality of life adjustment, has not been performed for any of the robotic systems[44]
Evidence	Currently, the evidence for robotic surgery's efficacy and safety is largely from retrospective studies often with small sample sizes or from an institution's initial cases/experiences, where the surgeon may be at the start of his/her learning curve[44]. Hence, conclusions about safety and efficacy must be interpreted with caution
Preparation, floor space and emergencies	The Theatre team must also be trained with the device set-up including troubleshooting problems that may arise during operations. Hence, the robotic surgery venture is likely a time, cost and resource-intensive process[45]. Moreover, considerable floor space is needed, with bulky instruments; this may be problematic and considerable cost may be incurred for renovations before robotic surgery can be employed. Furthermore, in an emergency, there may be a delay in converting to an open procedure since the bulky instruments cannot be as easily removed as in conventional laparoscopy[44]
Unproven efficacy	Current evidence base for efficacy of robotic surgery is mainly from small, retrospective studies. Prospective, multicentre randomized clinical trials to evaluate safety, efficacy, long term outcomes and cost analysis are required to prove that robotic assistance is indeed superior to conventional techniques before its widespread use

Table 2 Definitions of validity and reliability

Type	Definition
Face Validity	Extent to which the simulator resembles real life scenarios
Content Validity	Extent to which the domain that is being measured is being measured by the simulator/assessment tool
Construct Validity	Extent to which a simulator measures the trait it purports to measure
Concurrent Validity	Extent to which the results of the assessment tool correlate with the gold standard for that domain
Predictive Validity	Ability of the simulator to predict future performance
Test-Retest Reliability	Measure of a test to generate similar results when applied at two different points
Inter-Rater Reliability	Measure of agreement between two or more observers when rating an individual's performance

implementation of its usage (Table 1). In particular, the evidence base supporting robotic assistance remains lacking[1]. This extends beyond the examples provided above. A robotic prostatectomy is now the standard of care in many centres; despite only one RCT and substantial publication and selection bias, the results have showed no significant improvement in patient morbidity compared with conventional laparoscopy[25]. Likewise, a Cochrane review showed no differences in safety and efficacy for benign gynaecological robotic surgery compared to conventional laparoscopy[26].

Results from high quality, prospective, multi-centre randomized clinical trials (RCTs) are urgently required to evaluate the true efficacy of robotic surgery. Enhanced patient care may justify any higher costs. For surgeons uncomfortable with advanced conventional techniques, robotic surgery may reduce the time for them to reach procedure proficiency. For experienced surgeons, robotic surgery may enhance precision and decrease physical and mental workload.

With an unprecedented need for patient safety[27], it is imperative that adequate training and assessment strategies are in place to bridge the gap between conventional techniques and robotic surgery without harm to patients. This is especially important now with reduced working hours and training opportunities following calmanisation and introduction of the European Working Time Directive[28]. Possible avenues include: (1) Virtual Reality (VR) simulation; (2) Use of dual consoles; and (3) Training courses.

VR SIMULATION

VR simulation has been well established for conventional laparoscopy and has shown to improve skill transfer to the operating room[29,30]. However, its effectiveness in robotic surgery is less clear[31]. Before a simulator is used, it must fulfil a criterion with regards to validity and reliability (Table 2)[31]. Indeed, a study by Hung *et al*[32,33] showed that the da Vinci Skills Simulator demonstrated content, face and construct validity. The performance of the expert group was superior to intermediate/novice group when evaluating parameters such as overall score, motion economy and time to completion[32]. Specific proficiency-based curricula need to be developed in order to provide structured training with in built measures of assessment. However, while VR simulation for Robotic Surgical Training is a promising tool, data on skills transfer to the operating room is still lacking and further work is required before we can draw any firm conclusions about its efficacy in training. Another promising strategy is use of a dual console.

DUAL CONSOLE

The dual console allows collaboration between the trainee and an experienced mentor[31]. There are two

collaborative modes: (1) "Swap mode" enables the experienced surgeon and the trainee to operate in parallel and switch control of the robotic arms; this facilitates parts of the operation requiring multiple hands, for example vessel isolation[31,33]; and (2) "Nudge mode" enables trainee and mentor to share the two robotic arms which is useful during key parts of the operation whereby the mentor can guide the hands of the trainee[31,33,34]. Marengo *et al*[35] suggested that use of dual consoles might shorten the learning curve and increase trainees' confidence in performing procedures. However, the data for the efficacy of dual consoles is scarce and prospective, RCTs are required to evaluate their true efficacy in surgical training[31].

TRAINING COURSES

Training courses, using animal, inanimate or cadaveric models have shown promise[31]. Assessment parameters include time to setup and operate, complications, errors and quality as determined by the Objective Structured Assessment of Technical Skills score[34,36]. Dulan *et al*[37] have developed a proficiency-based robotic training program that demonstrates construct and content validity as well as feasibility. Further validation of such curricula should be encouraged since we know that for conventional laparoscopy, achieving proficiency ascertains whether a surgeon has the aptitude to perform a procedure; this is not related to the length of training[38]. Aggarwal *et al*[39] demonstrated that a proficiency-based curriculum for laparoscopic cholecystectomy could shorten the learning curve resulting in faster skill acquisition. Moreover, such curricula for robotic surgery may provide the opportunity to exercise deliberate practice that has been regarded as a key practice to enhance and acquire "expert performance"[40,41]. And crucially, proficiency-based curricula may allow standardisation in training and assessment[39].

Finally, future development and innovation in more advanced technology for procedures that are challenging to perform with conventional as well as current robotic technology is warranted with the ultimate aim of improving patient outcome. The new imaging-sensing-navigated, kinematically enhanced robot, a flexible-access robot with integrated multimodal and multi-scale sensing, can enable the surgeon to guide tools into regions of the body that are difficult to access with the current technology[42]. It has already shown promising results *in vivo*, with clinical translation planned in the next couple of years[42].

CONCLUSION

Like when laparoscopic surgery was introduced, establishing the role of robotic surgery will take time and to ascertain which patients are most likely to benefit from it. Prospective, multicentre randomised controlled trials to evaluate efficacy, long-term outcomes, safety and cost are the next steps before widespread uptake of this technology to treat patients.

Abstract

Different orbital and transcranial approaches are performed in order to manage orbital tumors, depending on the location and size of the lesion within the orbit. These approaches provide a satisfactory view of the superior and lateral aspects of the orbit and the optic canal but involve risks associated with their invasiveness because they require significant displacement of orbital structures. In addition, external approaches to intraconal lesions may also require deinsertion of extraocular muscles, with subsequent impact on extraocular mobility. Recently, minimally invasive techniques have been proposed as valid alternative to external approaches for selected orbital lesions. Among them, transnasal endoscopic approaches, "pure" or combined with external approaches, have been reported, especially for intraconal lesions located inferiorly and medially to the optic nerve. The avoidance of muscle detachment and the shortness of the surgical intraorbital trajectory makes endoscopic approach less invasive, thus minimizing tissue damage. Endoscopic surgery decreases the recovery time and improves the cosmetic outcome not requiring skin incisions. The purpose of this study is to review and discuss the current surgical techniques for orbital tumors removal, focusing on endoscopic approaches to the orbit and outlining the key anatomic principles to follow for safe tumor resection.

INTRODUCTION

Orbital tumors encompass a broad spectrum of benign and malignant lesions intrinsic to the orbit, like cavernous hemangiomas, schwannomas, hemangiopericytomas, and tumors starting from the skin, sinuses, nose, cranial bones and cerebral parenchima with secondary orbital invasion. Cavernous hemangiomas are the most frequent intraorbital primary tumors in adults, representing 4% of all orbital tumors and 9%-13% of all intracranial cavernous hemangiomas[1].

Exact location within the orbital cavity and size of tumors are crucial elements involved in the surgical planning.

External surgical approaches to the orbit have already extensively been described. Lateral orbitotomy or the transconjunctival approach are usually performed for the removal of small tumors located on the temporal compartment or on the orbital base; supraorbital approach allows the resection of lesions located dorsolaterally; transcranial approaches, like pterional approach, are indicated for large tumors even located medially to the optic nerve.

Recently, minimally invasive techniques have been proposed as valid alternative to external approaches for selected orbital lesions. Norris and Cleasby firstly described the use of the endoscope in orbital surgery in 1981[2]. Endoscopic management of orbital lesions was initially reported in 1985 by Norris *et al*[3]. Thereafter different endoscopic approaches have been described for orbital tumors removal with the aim of reducing the morbidity rate related to a more significant tissue manipulation while preserving cosmesis. Transnasal endoscopic approaches are also well established for different non-tumoral conditions like Graves' ophthalmopathy[4], medial wall fracture[5] and traumatic optic neuropathy unresponsive to steroids[6].

Several authors have reported on different transnasal endoscopic approaches for orbital tumors removal, especially for intraconal lesions located inferiorly and medially to the optic nerve. Most surgeons performed "pure" endonasal approaches; some others described combined "open" orbital and endoscopic surgery[7]. Mir-Salim *et al*[8] removed an intraconal cavernous hemangioma through an endonasal transethmoidal route with the aid of microscope. The expanded endonasal approach allows the removal of all types of skull base tumors, including posterior and medial orbital lesions[9].

Very recently, direct transorbital endoscopic approaches have been described for posterior lateral orbital tumors removal[10].

The aim of the present study is to review and discuss the current surgical techniques for orbital tumors removal, focusing on endoscopic approaches to the orbit.

OPERATIVE TECHNIQUES

External approaches

Lateral orbitotomy, providing a wide exposure of the lateral orbital compartment, is universally indicated for extra- and intraconal lesions situated therein, such as pleomorphic adenomas and cavernous hemangiomas[11-15].

The transconjunctival approach is restricted to smaller basal and medial intra- and extraconal tumors, such as cavernous hemangiomas, schwannomas, hemangiopericytomas, and isolated neurofibromas[15,16]. This approach implies incision of the conjunctiva inferiorly along the corneal edge and caudal opening of the flap[17,18].

The supraorbital approach *via* eyebrow incision is indicated for lesions located superiorly to the optic nerve[19]. This approach is more suited to large extraconal lesions in which added exposure is needed[15].

The pterional approach offers excellent exposure of the posterior orbit and wide visualization of the superior orbital fissure and the anterior temporal fossa, also allowing access to the upper part of the medial orbit[19,20]. The contralateral pterional was considered suitable for lesions located medially and inferiorly to the optic nerve in the posterior intraconal space[20].

Endonasal microsurgical approach

Mir-Salim *et al*[8] described an endonasal transethmoidal approach performed with the aid of microscope in order to remove a cavernous hemangioma. They performed ethmoidectomy and then resected the lamina papyracea between the sphenoid sinus wall, skull base and ethmoid. After mobilization of the medial rectus muscle, the cavernoma was removed under microscopic control.

Endonasal endoscopic approaches

Transnasal endoscopic approach is indicated for intraconal lesions located inferiorly and medially to the optic nerve, especially cavernous hemangiomas, which can be easily manipulated with low risk of rupture thus resulting ideal for the transnasal management[21].

Usually sphenoethmoidectomy is performed by means of a 0° optic with a 18 cm rigid endoscope followed by a maxillary antrostomy to gain access to the floor of the orbit. Then with a 45° optic the bony medial part of lamina papyracea and the floor of the orbit are identified and removed. After careful dissection from the overlying bone, the periorbita is sharply opened with sickle knife and endoscopic microscissors. Then the tumor become visible and is removed after dissection from the periorbital fat.

For intraconal lesions located inferiorly and medially, the dissection corridor is between the medial and inferior rectus muscles. They are identified and

isolated with vessel loop as they insert on the globe and then retracted. Once the intraconal corridor is developed, the tumor is identified and removed with limited bipolar cautery and extensive sharp dissection.

Combined approaches

Campbell *et al*[7] described a combined transcaruncular and a transnasal endoscopic cryo-assisted approach to remove a cavernous hemangioma. The Cryo-probe allowed freezing both at the tumor capsule surface and within the stroma, thus facilitating the endoscopic removal of the fluid-filled lesion.

Tsirbas *et al*[22] performed, through an inferior transconjunctival orbitotomy, an orbital floor dissection subperiosteal to the posterior orbit to identify the anterior limit of the cavernous hemangioma. Then, by means of a transantral endoscopic approach, they removed the posterior orbital floor and gained the posterior orbital periosteum overlying the lesion, which was incised.

Transorbital endoscopic approach

A transconjunctival transorbital endoscopic approach was recently described by Rivkin *et al*[10] for the resection of a pleomorphic adenoma located in the posterior lateral orbit. The authors performed a lateral conjunctival incision, posterior to the lateral rectus muscle. No bone removal, craniotomy, or skin incision were required. Then, under the vision of a 0° endoscope, they made an incision in the periosteum and the tumor was delivered into the periosteal pocket.

The endoscope is a useful adjunct also for the treatment of selected orbital roof lesions, such as cholesterol granulomas, orbital dermoids and Langerhans cell histiocytosis involving the anterior portion of the orbital roof. In these cases bone removal is often needed for adequate visualization behind the superior orbital rim[23].

Table 1 summarizes the hallmarks of aforementioned surgical approaches.

DISCUSSION

Posterior orbit harbors pivotal neurovascular structures like the optic nerve, the ophthalmic artery and vein, and the ocular muscles and their nerves all crowded in a very narrow cone-shaped surgical field[22]. Thus the surgical approach planning is extremely challenging.

The location of the lesion inside the orbit is the most relevant parameter to consider in choosing the surgical approach. The approach is also decided on the basis of the extension and the type of the tumor[20]. The experience of the surgeon especially in endoscopic sinus surgery has also a role in the surgical planning process.

Traditional external orbital and cranial approaches involve risks associated with their invasiveness because they implies manipulation of delicate orbital structures like extraocular muscles, which in some case need to be deinserted, with subsequent impact on extraocular mobility[9].

Moreover lateral orbitotomy and supraorbital approach carry the disadvantage of postoperative scar. At the other hand the transconjunctival approach, which implies incision of the conjunctiva inferiorly along the corneal edge, without bone removal or skin incision, carry the disadvantage of a limited view; thus it is not suitable for large lesions.

The pterional approach offers an optimal view of the posterior orbit and of the upper part of the medial orbit thus providing good control of the optic canal, the superior orbital fissure and the anterior temporal fossa[24]. Extensive tissue manipulation connected with this approach can lead to the risk of injuring the frontal lobe along with intraorbital bleeding, cerebral edema and seizure.

The endonasal microscopic approach to the retrobulbar region described by Mir-Salim *et al*[8] provides a limited view compared with the narrowness and deepness of the surgical field.

Different transnasal endoscopic approaches have been reported on for the treatment of orbital tumors, especially for intraconal lesions located inferiorly and medially to the optic nerve and the extraconal lesions adjacent to the paranasal sinuses.

A safe resection of orbital tumors through an endonasal endoscopic approach requires the respect of some key anatomic principles[9]. First, it is critical to avoid crossing the optic nerve. Thus, tumors that are localized to the superior/lateral orbit are contraindicated for an endonasal approach. Second, entering through the lamina papyracea below the level of the ethmoidal foramina allows sparing of the ethmoidal arteries thus reducing the risk of retrobulbar hemorrhage and vision disturbances. Finally, the dissection should occur between muscle groups rather than through individual muscles for preservation of function.

The avoidance of muscle detachment and the shortness of the surgical intraorbital trajectory makes endoscopic approach less invasive, thus minimizing tissue damage[25,26]. Endoscopic approach carries also the advantage to decrease the recovery time and to improve the cosmetic outcome not requiring skin incisions[26].

Orbital surgery carries the risk of damaging the intraorbital structures because of a local increase of intraorbital pressure. In transnasal procedures, the removal of the lamina papyracea allows partial displacement of orbital content, otherwise collapsed in a not distensible space[25].

The endoscopic surgery also carries some risks and distinct disadvantages. The first one is the lack of three-dimensional vision. However, moving the endoscope actively, thereby providing some sense of depth, can simulate a three-dimensional perception.

Table 1 Hallmarks of the surgical approaches to the orbit

Approach		Ref.	Location	Size	Contraindication	Advantages	Disadvantages
Lateral orbitotomy		Arai *et al*[14] Carta *et al*[11]	Lateral, dorsal and basal to the ON	All	Medial location	Good view	Cosmetic scar
Transconjunctival		Cheng *et al*[16]	Basal and medial intra-extraconal tumors	Small	Medium size and large tumors	Minimally invasive	Limited view
Supraorbital		Maus *et al*[19]	Superior, lateral and medial	All	Basal location	Good view	Cosmetic scar
Pterional		Schick *et al*[24]	Superior and medial	All	Basal location	Good view	Invasive
Contralateral pterional		Hassler *et al*[20]	Superior and medial	All	Basal location	Good view	Invasive
Endonasal microsurgical		Mir-Salim *et al*[8]	Intraconal lesions	All	Lateral location	Three-dimensional view	Long approach distance and limited view
Endonasal endoscopic		Castelnuovo *et al*[25]	Inferior and medial to the ON, paranasal sinuses	Medium	Lateral location	Minimally invasive, better cosmetic outcome, short recovery time	Two visual dimensions, Small operative field
Combined	Transcaruncular and transnasal endoscopic cryo-assisted	Campbell *et al*[7]	Orbital apex	All	Solid consistency	To ablate vascular tumors	Cosmetic scar
	Inferior transconjunct, orbitotomy and transantral endoscopic	Tsirbas *et al*[22]	Posterior orbit, orbital apex	All	Medial location	Improved visualization and limited manipulation within the orbit	Cosmetic scar
Transorbital endoscopic		Rivkin *et al*[10]	Posterior lateral	All	Medial location	Decreased surgical morbidity, improved cosmesis	Two-dimensional view, learning curve

ON: Optic nerve.

Furthermore, the endoscopic sinus surgery allows a limited degree of space for instruments. Considering that the hemostasis could be difficult and risky in a small operative field, the endoscopic transnasal approach should be restricted mostly to benign tumors or inflammatory processes and not be used for highly vascularized tumors[27].

Muscatello *et al*[21] noted that the consistency of cavernous hemangioma is ideal for the transnasal approach, because these lesion maintain their shape and can be easily manipulated without excessive risk of rupture. Moreover, unlike cerebral ones, which are not encapsulated, orbital cavernous hemangiomas are well encapsulated, probably by a specific reaction of the orbital fatty tissue[28] and the extracapsular dissection can be easily performed[23]. Furthermore, they consist of endothelium-lined dilated spaces with a low blood flow; this condition allows the surgeon to manipulate and to remove the lesion piecemeal when this procedure is necessary.

While endoscopic endonasal surgery is limited to intraconal lesions located inferiorly and medially to the optic nerve and to extraconal ones adjacent to the paranasal sinuses, tumors located in the lateral portion of the orbit can alternatively be managed using a transconjunctival transorbital endoscopic approach, as recently described by Rivkin *et al*[10]. Comparing with external approaches, this technique proved to share the same advantages of the endonasal corridor such as decreased morbidity and post-operative pain, reduced hospitalization and improved cosmesis. Similarly, the technique has the limit of a two-dimensional view and the learning curve that may be required for surgeons less familiar with this surgery. Larger tumors or masses with bone involvement may still require standard open approaches.

CONCLUSION

Endoscopic endonasal approach allows a useful and safe route to reach and manage orbital lesions located medially to the optic nerve. More traditional surgical approaches are still widely preferred but imply major surgical morbidity and invasiveness, so they can be avoided whenever an endoscopic endonasal approach should be performed. A multidisciplinary team with expertise in endoscopic techniques is mandatory.

Abstract

Gluten is one of the most abundant and widely distributed components of food in many areas. It can be included in wheat, barley, rye, and grains such as oats, barley, spelt, kamut, and triticale. Gluten-containing grains are widely consumed; in particular, wheat is one of the world's primary sources of food, providing up to 50% of the caloric intake in both industrialized and developing countries. Until two decades ago, celiac disease (CD) and other gluten-related disorders were believed to be exceedingly rare outside of Europe and were relatively ignored by health professionals and the global media. In recent years, however, the discovery of important diagnostic and pathogenic milestones led CD from obscurity to global prominence. In addition, interestingly, people feeding themselves with gluten-free products greatly outnumber patients affected by CD, fuelling a global consumption of gluten-free foods with approximately $2.5 billion in United States sales each year. The acknowledgment of other medical conditions related to gluten that has arisen as health problems, providing a wide spectrum of gluten-related disorders. In February 2011, a new nomenclature for gluten-related disorders was created at a consensus conference in London. In this review, we analyse innovations in the field of research that emerged after the creation of the new classification, with particular attention to the new European Society for Paediatric Gastroenterology, Hepatology and Nutrition guidelines for CD and the most recent research about non-celiac gluten sensitivity.

Key words: Celiac disease; Wheat allergy; Gluten sensitivity; Non-celiac gluten sensitivity; Gluten-free diet; Gluten; Anti-gliadin antibodies

Core tip: In recent years, there has been a widespread diffusion of gluten-associated symptoms. Current reactions to gluten include, but are not restricted to, celiac disease. This review analyses this interesting epidemiological worldwide phenomenon by discussing the spectrum of gluten-related disorders and focusing on their clinical features and diagnostic criteria. In particular, this paper will cover the most important news from European Society for Paediatric Gastroenterology,

Hepatology and Nutrition guidelines for celiac disease and the state of the art of non-celiac gluten sensitivity.

INTRODUCTION

In recent years, the prevalence of a wide spectrum of gluten-related disorders (GRDs) has increased. This can be attributed to changes in global dietary habits; many countries are experiencing a progressive westernization of diet as well as worldwide diffusion of the Mediterranean diet, which is based on a large number of foods that incorporate gluten (including wheat)[1]. In particular, consumption of wheat is progressively replacing consumption of rice in many countries in North Africa, the Middle East, and Asia[2]. Corn is still the most consumed cereal in the United States; however, a trend toward an increase in consumption of wheat is clearly evident, with an average of $132.50 spent on wheat products per person[3].

In addition, current wheat varieties have an higher content in gluten compared to the past due to changes directed by both technology and nutritional reasons.

Types of wheat cultivated for thousands of years, such as Triticum monococcum and Triticum dicoccum, contained smaller quantities of the highly toxic peptide 33-mer gliadin[4].

The toxic effects of gluten are mediated in humans primarily by immunologic reactions; however, the absence of proper adaptation of gastrointestinal reactions can also play a role[2]. The mechanization of agriculture and the increasing use of industrial pesticides have encouraged the development of new types of wheat with a higher content of toxic peptides of gluten, constituting a further element in the increasing prevalence of GRDs[1]. Furthermore, bread and bakery products currently contain a higher portion of gluten than in the past because of the reduced time of dough fermentation[5].

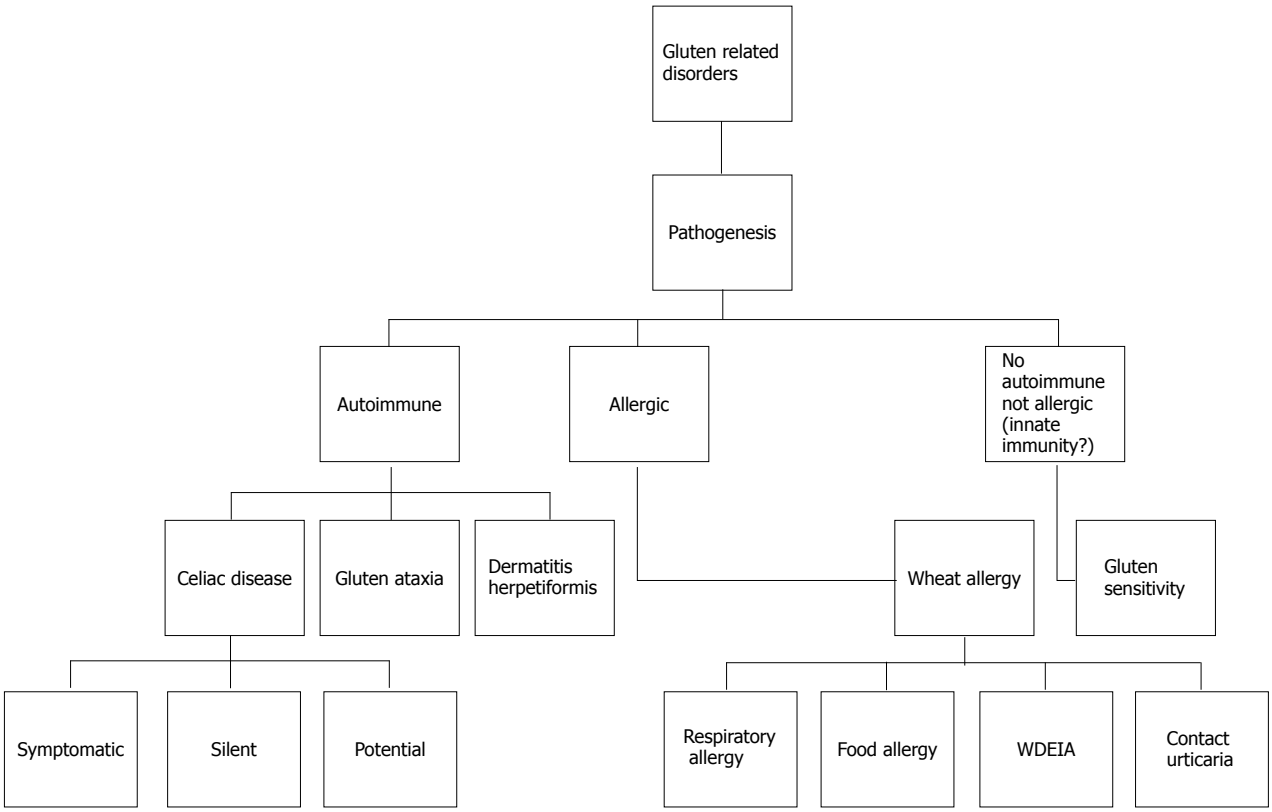
Diagnostic tools for GRDs have progressively improved over time[6,7]. In the 1980s, classification of GRDs was very simple, because celiac disease (CD) and dermatitis herpetiformis (DH) were the only known diseases with a well-documented role of gluten in their pathogenesis. More recently, gluten and other proteins have been recognized as a possible cause of wheat allergy (WA). In addition, more patients with intestinal and extraintestinal symptoms related to ingestion of gluten but without evidence of CD or WA have been identified as potentially affected by non-celiac gluten sensitivity (NCGS), a disorder aknowledged by the scientific community only in recent times[8]. Increasing complexity in the nomenclature and clinical presentation of GRDs has led to the development of a consensus document by a panel of 15 experts on new classification of five heterogeneous GRDs: CD, NCGS, WA, DH, and gluten ataxia (GA)[9] (Figure 1). Each GRD exhibits a unique pathophysiological response to ingestion of gluten, although there can show considerable overlap in the clinical presentation.

The increased prevalence and complexity of GRDs has inevitably sparked growing interest in gluten-free diets (GFDs) in both scientific and non-scientific communities. Although a GFD represents the recommended treatment of GRDs and is believed by many people to be an overall healthier regimen, this is not always the casie. People following a GFD may not meet their nutritional requirements because gluten-free foods may not have the same dietary supplementation as gluten-containing foods[10]. However, a GFD can contribute do meet daily nutritional requirements provided that patients will use a healthful balance of protein, vegetables, fruit, and ancient grains[8]. Even if gluten may not be essential for an healthy diet, an unrequired GFD can be expensive. Furthermore, recognizing gluten-free products can be difficult and time consuming[11,12].

In 2010, the gluten-free food market was worth an estimated $2.6 billion in the United States, showing a steady increase since 2008. This upward trend is expected to continue in the next years[9,13]. The growing gluten-free market may now be between 15% and 20% of the United States population[14]. The increased awareness and knowledge of CD explains only a small fraction of the development of the GFD market, which is probably sustained also by people with different GRDs, such as NCGS and WA. The remaining section of the market includes people who embark on a GFD as occasional users who do not have a medical necessity but believe that popular cereals are unhealthy because of their composition[15]. Consequently, accurate diagnostic criteria for a GFD are needed to distinguish people with a medical condition from those who simply prefer to avoid gluten, leading to different nutrition and follow-up strategies.

CD

CD is an immune-mediated reaction to gluten; it is characterized by an inappropriate T cell- mediated immune response that causes inflammatory injury to the small intestine in genetically predisposed subjects carrying the HLA-DQ2 and/or -DQ8 haplotypes[9]. CD represents a unique model of autoimmune disease because relevant information is known, including the genetic basis (HLA haplotypes) and the triggering environmental factor (gluten)[9]. The disease epidemiology is also well known, with the worldwide prevalence estimated to be 0.6%



Proposed new nomenclature and classification of gluten-related disorders.

to 1% of the general population[16-19]. For each person diagnosed with CD, there are at least another five or six people who have not yet been identified, most of whom are adults without gastrointestinal symptoms (representing the so-called celiac iceberg)[20].

CD is a diagnostic challenge for the clinician because it may develop at any age, even in elderly people, and because of its polymorphic clinical presentation. The clinical spectrum of CD includes symptomatic cases with either intestinal or extraintestinal features as well as silent forms revealed only by serological screening. Intestinal manifestations of CD include diarrhoea, weight loss, abdominal distention, and constipation. Extraintestinal symptoms reflect the systemic nature of the disease and include chronic fatigue, anaemia, reduced bone mineral density, aphthous stomatitis, high aminotransferase levels, joint/muscle pain, and spontaneous abortions, epilepsy, peripheral neuropathy[21].

In 2012, the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) Working Group decided to revise its classification of CD. In particular, the distinction between classic and atypical CD based on symptoms was removed, because atypical signs and symptoms (*e.g.*, anaemia, reduced bone density, neuropathy) can be substantially more common than classic symptoms (*e.g.*, abdominal pain, chronic diarrhoea)[22].

In such a complex clinical picture, case-finding strategies have to be carefully planned. The most relevant scientific organizations in this field, including ESPGHAN, North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition, and American College of Gastroenterology, have identified groups of patients at particularly high risk that should be investigated for CD. Their recommendations are reported in Table 1[22-24]. Diagnostic algorithms for CD consist of initial screening serological tests followed by a confirmatory small intestinal biopsy.

Measurement of serum immunoglobulin (Ig) A anti-tissue transglutaminase antibodies (tTG) has the best diagnostic sensitivity for CD[21,25,26]. Measurement of IgA anti-endomysial antibodies (EMA) is nearly 100% specific for CD, but it is also expensive and operator dependent and therefore is better used as a second-line test[22]. Antibodies to deamidated gliadin peptides (DGP) of the IgG class have been shown to be particularly useful in patients with IgA deficiency and children younger than three years of age[26-28]. Even with the most recent advancements in CD serology, it has been reported that up to 2% of patients with CD do not have any circulating markers of gluten sensitivity, defining a condition of seronegative CD[6].

Since the advent of the Crosby-Kugler capsule, which enabled tissue sampling and histological examination of

intestinal tissue, small intestinal biopsy has been required to confirm the diagnosis in patients with suspected CD and is considered the gold standard for CD[20]. Interestingly, the most recent guidelines from ESPGHAN propose that it may be possible to avoid intestinal biopsy in children who meet the following criteria: (1) symptoms consistent with CD; (2) serum IgA anti-tTG levels > 10 times the upper limit of normal (confirmed with positive anti-EMA in a different blood sample); and (3) positive HLA-DQ2[22]. It remains to be determined whether this new clinical/laboratory standard functions as well as the gold standard of serology plus biopsy, whether different cutoff values for serology kits should be used, and whether including HLA typing is necessary[29]. Nevertheless, with this notable exception, biopsy is still a required and essential element for the diagnosis of CD according to all of the guidelines[22-24].

Histology alone, however, is not specific for the diagnosis of CD, particularly if villous atrophy is absent. For instance, an increase in the number of lymphocytes in the intestinal epithelium can be found in a number of different conditions, including small bowel bacterial overgrowth, drug-associated enteropathy, infectious enteritis (*e.g.*, giardiasis and Whipple disease), Crohn's disease, autoimmune enteropathy, and enteropathy associated with acquired immunodeficiency syndrome[24]. Genetic studies have identified HLA-DQ2 and -DQ8 as the major determinants of susceptibility to CD. Because these haplotypes are common in the general population, determination of HLA is better suited for ruling out the presence of CD in suspicious cases[22].

In light of the aforementioned complexities, the final diagnosis of CD must be based on a comprehensive evaluation of clinical, serological, histological, and, when indicated, genetic elements. This consideration is known as the "4 out of 5 rule".

As such, four of these five criteria should be satisfied for diagnosing CD: (1) presence of symptoms associated with CD; (2) presence of CD-associated autoantibodies (*i.e.*, tTG, IgA EMA); (3) presence of HLA-DQ2 or -DQ8 alleles; (4) duodenal biopsy demonstrating blunting or absence of villi (Marsh Ⅲ) with > 25 lymphocytes/100 enterocytes (with cluster of differentiation 3+ staining); and (5) melioration of symptoms after a GFD[30].

As we improve our understanding of the pathogenesis of CD, the interplay of genetic, epigenetic, and environmental factors may need to be considered as part of the diagnostic process[29]. In this regard, in recent years, more studies have investigated possible novel biomarkers of CD. Intriguing studies have identified $CD4^+$ gluten-DQ2 tetramers in the peripheral blood of patients with CD after a short gluten challenge[31]. These cells were not present in controls or in patients with CD while on a GFD. More recently, Galatola *et al*[32] reported that a small gene expression panel from peripheral blood monocytes could discriminate between patients with active CD and healthy controls. The intestinal microbiome is another novel field of interest in CD, potentially leading to further understanding of its pathogenic mechanism and to the discovery of new markers of disease. An overall lack of Bifidobacteria and high abundance of Firmicutes were found in children with genetic susceptibility for CD who had early exposure to gluten in a study by Sellitto *et al*[33], which examined a small cohort of at-risk infants and controls up to 24 mo of age. The investigators suggest that there may be predictive ability in measuring such biomarkers. Viitasalo *et al*[34] found significant evidence of high levels of antibodies to ASCA (anti-Saccharomyces cerevisiae antibodies), OmpW (Bacteroides caccae TonB-linked outer membrane protein), and I2 (Pseudomonas fluorescens-associated sequence) in patients with early-stage lesions. Because antibody titres decreased after introduction of a GFD, the investigators proposed that Bacteroides and Pseudomonas species may play a part in the pathogenesis of CD. These results should encourage studies of novel biomarkers as we advance toward the possibility of a biopsy-free diagnosis of CD

because they may add further security to the diagnosis of CD.

DH

DH is a skin disease characterized by a blistering rash and pathognomonic cutaneous IgA deposits[35]. Duhring's original description also included patients with different conditions, such as erythema multiforme and pemphigus.

Differently from other GRDs, the prevalence of DH is higher in men than in women (1.5 to 1.9:1).

DH shares an high prevalence of HLA alleles DQ2 (90%) and DQ8 (5%) with CD[36]. Even if a skin rash or other dermatologic manifestations can be common in untreated CD[37], DH presents with unique characteristics. The usual clinical presentation of DH consists of diffuse, symmetrical, grouped polymorphic lesions consisting of erythema, urticarial plaques, papules, herpetiform vesiculae, and blisters followed by erosions, excoriations, and hyperpigmentation[38,39]. DH most frequently involves the extensor surfaces of the elbows (90%), knees (30%), shoulders, sacral region, buttocks, and face. Itching of variable intensity, scratching, and burning sensation immediately preceding the development of lesions are common.

Gastrointestinal symptoms in patients with DH are uncommon (affecting approximately 10% of patients) and usually mild[38,39]. However, 65% to 75% of patients show a celiac-type intestinal atrophy[9]. Even in patients with apparently normal biopsy specimens, an increased number of intraepithelial lymphocytes can be found consistently with a gluten sensitization[9]. Although often asymptomatic in adults, small bowel involvement in patients with DH can be associated with abdominal pain, diarrhoea, iron deficiency, and reduced growth rates in children[38,39].

Celiac-type serological markers (anti-tTG, anti-EMA, anti-DGP antibodies) can be typically found in DH patients. In a recent study, Borroni *et al*[40] identified IgA anti-epidermal transglutaminase autoantibodies as a promising marker for the serological diagnosis of DH[40].

The revelation of IgA by immunofluorescence staining on biopsy specimens of uninvolved skin analysed is another key diagnostic element[41]. Differently from other autoimmune disorders such as pemphigus, which can display homogeneous linear IgA deposits, IgA are detected as granular or fibrillar deposits in the dermal papillae in DH. Sometimes IgA can be found in linear granular deposits along the basement membrane as well[41].

Final diagnosis of Duhring disease can be made according to the histopathologic findings on skin specimen and presence of celiac related antibodies[41]. Once diagnosis have been formulated duodenal biopsies can be avoided, as it is commonly recognized that DH represents the skin counterpart of CD[41].

GA

GA is perhaps the most dramatic representation of neurological involvement in the setting of an immune response to gluten-containing foods. It has been defined as an otherwise unexplained sporadic ataxia with presence of serological antibodies consistent with a condition of sensitization to gluten[42]. Its predominant clinical manifestations include dysarthria, dysphonia, pyramidal signs, nystagmus and other ocular signs of cerebellar dysfunction (in up to 80% of cases), progressive ataxia of gait associated with myoclonus, palatal tremor, or opsoclonus[43]. Only very few subjects with GA experience any gastrointestinal symptoms; however, almost one-third of these patients have histological evidence for small bowel villous atrophy on biopsy specimens[9]. The precise pathogenic mechanism of GA is not clear, but a number of factors probably play different roles. Vitamin deficiency (in particular, vitamin E and vitamin B1) secondary to malabsorption in the small intestine may play a role; however, there is also evidence for a toxic and immune-mediated response to gluten[44]. Different studies suggest that some subjects with GA have both anti-gliadin antibodies and antibodies reacting with Purkinje cells. The latter marker is not present in patients with other causes of ataxia, resulting a pathognomonic feature of GA[44].

It is believed that the Purkinje cells of the cerebellum share epitopes with gliadin proteins and, as further evidence for the role of the immune system, intravenous immune globulin therapy has been reported to improve ataxia[44]. Recently, tTG6 has been identified in specimens of nervous tissue from patients with GA[45]. The molecular structure of tTG6 is similar to the tTG2 molecule involved in the development of CD and to the tTG3 molecule linked to DH[45]. Interestingly, anti-tTG6 deposits of the IgA class have also been found around brain vessels of patients with GA[45] and circulating anti-tTG6 antibodies appear to be a specific and sensitive marker for GA[46]. In light of these considerations, any subject with an history of progressive cerebellar ataxia of unknown origin should be regarded as possibly affected by GA, and tested for anti-gliadin antibodies (AGA), classical anti-tTG and possibly anti-tTG6 IgG and IgA antibodies[9]. Patients displaying positivity for any of these antibodies should be followed up for one year on a GFD. Stabilization or improvement of the ataxia associated with the negativity of antibodies should also be evaluated after the first year on a GFD[9].

WA

WA can be defined as an adverse reaction of the immune system to the the proteins contained in wheat.

In the vast field of WA a further classification can be made, distinguishing: (1) a classical form of food allergy with involvement of gastrointestinal tract,

skin and possibly respiratory tract; (2) a typical form of inhalant allergy (baker's asthma and rhinitis); (3) wheat- dependent, exercise-induced anaphylaxis (WDEIA); and (4) more rarely, a form of contact urticaria. The role of IgE-mediated reactions in the pathogenesis of baker's asthma and rhinitis has been demonstrated as early as the beginning of the 20th century[47].

Symptoms consisting with baker's asthma have been referred by 4.2% of bakery workers after a single year, increasing after 8.6% after the second working year[48]. Symptoms include rhinitis, skin itching/rash, ocular symptoms (including tearing, itching, and conjunctival injection), respiratory symptoms (including coughing, wheezing, shortness of breath, and sputum production), and "grain fever"[49-51].

Alfa-amylase inhibitors are the considered the most prominent allergen ivolved in the generation of symptoms, but different wheat proteins can play a role[52].

Alimentary WA, in its turn, is a less common disease, however in its most severe forms it can lead to serious reactions, including anaphylaxis and death[53].

In contrast to CD, symptoms of WA are typical for an IgE-mediated allergy, including itching and swelling in the mouth, nose, eyes, and throat; skin rash or swelling; wheezing in the respiratory tract; gastrointestinal symptoms such as cramps, bloating, and diarrhoea; and life-threatening anaphylaxis[54]. Differently from CD, WA does not cause permanent gastrointestinal damage[54].

WDEIA is a separate form of WA that is induced by physical exercise after ingestion of wheat. A specific type of grain protein, ω5-gliadin, acts as a trigger factor. Exercise within three hours of wheat consumption can induce an adverse reaction in susceptible people. In some cases, this can also occur when wheat is consumed directly after exercise[9,53]. Patients with WDEIA can refer different symptoms, ranging from urticaria to anaphylaxis and other severe reactions[55]. Although the mechanism of physical exercise-induced anaphylaxis is indistinguishable, an immediate-type hypersensitivity to water/salt-insoluble fraction of gluten has been considered to underlie this disease[53].

Skin prick tests and IgE assays are considered first-level studies for diagnosis of WA[9]. However, interpretation of these tests can be difficult because different confounding factors should be considered. First, a number of commercial kits for skin prick tests lack in sensitivity because they do not include allergens deriving from the insoluble gliadin fraction. Second, cross reactions with grass pollens may be present (especially in adults), resulting in lower specificity[9]. Testing prick by prick with raw material potentially overcomes these problems; nevertheless a definite diagnosis still requires an oral food challenge as a final test in a number of cases[9].

NCGS

NCGS is the "youngest" member of the GRD family and is characterized by intestinal and extraintestinal symptoms that occur after the ingestion of gluten-containing food in subjects in whom CD and WA have been ruled out. Rapid disappearance of symptoms with a GFD and recurrence a few hours/days after gluten reintroduction are also characteristic of this condition[56].

The existence of NCGS was firstly postulated in 1980 by Cooper *et al*[57], who described an evident amelioration of symptoms (bloating, diarrhoea and abdominal pain) in 6 out of 8 women after gluten withdrawal, in absence of the diagnostic criteria for CD.

After 20 years without further mention of this condition, Kaukinen *et al*[58] reported in 2000 that the majority of patients complaining gluten-related symptoms were non actually classificable as as being affected by CD or WA. Since they had a clear benefit from gluten withdrawal, their condition was called NCGS.

In the past 10 years, NCGS has received growing attention as patients have reported more severe nonspecific symptoms with intake of gluten by accident than seen with classic CD[59]. The recent Consensus Conference on GRD[9] is a clear sign of the scientific interest surrounding this clinical entity, even if little is still known about NCGS, especially when compared with current advancements in CD. For instance, reliable studies regarding the actual prevalence of this condition are still lacking. In current studies, prevalence of NCGS ranges from 0.63% in a primary care program[60] to 6% in a tertiary care centre[9].

The pathogenesis of NCGS is another hot topic. Since it was first described, a link between gluten and symptoms was suggested in subjects with NCGS[57]. Indeed, gluten itself has opioid-like activity because gluten proteins can alter the intestinal transit time in healthy volunteers and its action is reverted by naloxone[61]. Furthermore, an experimental model with transgenic mice gliadin-sensitized demonstrated increased secretion of acetylcholine from the myenteric plexus, with consequential enhancement of muscle contractility and increase in epithelial secretion. Gluten withdrawal was able to revert these abnormalities[62]. However, recent studies suggested that gluten may not be the only triggers of NCGS, with different wheat proteins likely playing relevant roles in this condition. For example, some grains and cereals (such as wheat, rye, and barley) are known to be particularly rich in fermentable oligosaccharides, disaccharides, and monosaccharides and polyols (FODMAPs). In turn, FODMAPS are known to provoke gastrointestinal symptoms in patients with irritable bowel syndrome through mechanisms involving gut microbiota, gas production, and fermentation[63]. Similarly to irritable bowel syndrome, FODMAPs can possibly play a role

in generating both intestinal and extraintestinal manifestations in subjects with NCGS. Recent studies have shown that a diet low in FODMAPs results in improved symptoms in patients with self-reported gluten intolerance, supporting the hypothesis of a major role of FODMAPs compared to gluten[64,65]. Furthermore, wheat amylase and trypsin inhibitors, a complex of proteins in innate immunity, could contribute to the origination of symptoms in NCGS[7].

Because it is unclear which component of wheat-based products is responsible for an individual's symptoms, it may be premature to assign all of the blame to gluten. From a clinical point of view, patients with NCGS may display great variability in gastrointestinal (bloating, abdominal pain, diarrhoea, nausea, aerophagia, aphthous stomatitis, constipation) and extraintestinal symptoms (lack of well-being, tiredness, headache, anxiety, foggy mind, numbness, joint or muscle pain, skin rash, anaemia, dermatitis)[66].

Interestingly, mood disorders in NCGS may recognize similar pathophysiological mechanisms to other neurological manifestations observed in gluten-related disorders such as GA, as reiterated toxic insults might an impaired immunological tolerance (*i.e.*, the so-called "toxicant induced loss of tolerance")[67].

Some papers also suggested a relationship between NCGS and neuropsychiatric diseases, with a particular regard to autism and schizophrenia, however the responsibility of gluten in conditions affecting the nervous system remains hot topic requiring additional studies[68].

Other important clinical aspects of NCGS are its frequent occurrence in first-degree relatives of patients with CD and a straightforward prevalence in female subjects (6:1)[66]. Heterogeneity in clinical presentation with identification of various subgroups of patients has been noticed by some investigators[65,69], possibly reflecting different pathogenic roles for the various proteins and carbohydrates contained in wheat and other gluten-rich cereals. Consequently, it has been speculated that NCGS only provides the best current description of a heterogeneous group of conditions with the common feature of improvement in symptoms on withdrawal of gluten[70]. At this time, it appears that NCGS is not associated with malabsorption or nutritional deficiencies or with any increased risk of autoimmune disorders or intestinal malignancy[24]. Therefore, differently from subjects affected by CD, patients with NCGS should not fear contaminations due to inadvertently introduced traces of gluten.

As noted in the preceding text, before diagnosing NCGS other conditions such as WA or CD should be excluded with appropriate tests during a gluten-containing diet.

WA should be excluded by testing for serum IgE antibodies to gluten and wheat fractions and by skin prick tests, while CD must be ruled out by the negativity of celiac-specific antibodies, *i.e.*, IgA tTG, IgA EMA, and IgG DGP. A duodenal biopsy is also highly recommended because of the possibility of seronegative CD, occuring in 1%-2% of all patients with CD[6].

HLA-DQ2 and -DQ8 aplotypes are present in 50% of subjects with NCGS, representing a low prevalence compared with CD (95%), only slightly higher than in the general population (30%)[9]. Genetic studies investigating non-HLA regions are still lacking and, in general, the immunogenetics of NCGS are still non-existent[71].

Once identified negative criteria for the diagnosis of NCGS, the double-blind, placebo-controlled challenge (DBPCC) was proposed as a first positive diagnostic criterion. DBPCC trials have been highly as a confirmatory test for NCGS because of a possible placebo effect generated by gluten withdrawal[9]. However, a DBPCC is time-consuming and requires a close follow-up of patients and thus is currently used only in research[70].

The identification of other positive criteria and diagnostic markers is of great interest in NCGS. Recently, an elegant retrospective study by Kabbani *et al*[72] analysed 238 patients with symptoms responsive to GFD without prior diagnosis or exclusion of CD, demonstrating that patients with CD and patients with NCGS may have different clinical presentations. In particular, patients with NCGS were less likely to have malabsorptive symptoms, nutrient deficiency, and a personal history of autoimmune diseases, which is consistent with previous reports[24]. Consequently, the investigators concluded that patients who improve with a GFD but have negative findings on serology, lack of malabsorptive symptoms, and absence of risk factors for CD are likely to have NCGS and may not need to routinely undergo diagnostic endoscopy[72]. Nonetheless, these interesting findings need to be validated by future prospective studies.

In regard to serological markers, it was recently shown that 56% of patients with NCGS have circulating IgG AGA antibodies[73], which is consistent with the results from other investigators[69]. Interestingly, after starting a GFD, almost all of the patients with NCGS had normalization of AGA IgG levels, whereas these antibodies were still present in 40% of patients with CD after gluten withdrawal[74]. Strict compliance with and a good response to a GFD, with significant improvement in symptoms, were significantly related to the disappearance of AGA IgG in patients with NCGS[74]. Still, AGA IgG cannot be considered a reliable biomarker of NCGS because it can be detected in multiple different disorders, including autoimmune diseases, as well as in healthy subjects. As the cost of DNA sequencing is spectacularly reducing, it could be interesting for the clinicians to characterize the different subgroups of patients with this condition[71]. Consequently, further research on biomarkers of NCGS

is strongly encouraged.

CONCLUSION

Based on the data presented in this report, it is clear that clinical manifestations of GRDs cover a wide variety of medical specialties, ranging from gastroenterology to allergology and from neurology to dermatology. Within the large family of GRDs, two opposite trends seem evident. First, we have a great deal of information about the clinical presentation, pathogenesis, and diagnostic markers of some diseases (with CD as a prototypic example). Second, there are some more recently accepted conditions, such as NCGS, with many clinical and diagnostic aspects still to be investigated. Consequently, different priorities are required for different situations. In regard to CD, identification of new early microbial or non-microbial markers represents a promising field of interest, eventually leading to an early and non-invasive diagnosis in the future. In the case of NCGS, first we have to understand whether it constitutes a singular entity or only provides the best description of a heterogeneous group of conditions attributable to different wheat-related food constituents. Only studies with more homogeneous groups of patients will be able to provide relevant information on this apparently frequent but still elusive condition.

Abstract

Asthma and obesity are epidemiologically linked; however, similar relationships are also observed with other markers of the metabolic syndrome, such as insulin resistance and dyslipidemia, which cannot be accounted for by increased body mass alone. Obesity appears to be a predisposing factor for the asthma onset, both in adults and in children. In addition, obesity could make asthma more difficult to control and to treat. Although obesity may predispose to increased Th2 inflammation or tendency to atopy, other mechanisms need to be considered, such as those mediated by hyperglycaemia, hyperinsulinemia and dyslipidemia in the context of metabolic syndrome. The mechanisms underlying the association between asthma and metabolic syndrome are yet to be determined. In the past, these two conditions were believed to occur in the same individual without any pathogenetic link. However, the improvement in asthma symptoms following weight reduction indicates a causal relationship. The interplay between these two diseases is probably due to a bidirectional interaction. The purpose of this review is to describe the current knowledge about the possible link between metabolic syndrome and asthma, and explore potential application for future studies and strategic approaches.

Key words: Asthma; Metabolic syndrome; Obesity; Hyperinsulinemia; Dyslipidemia

Core tip: Asthma is a complex syndrome that encompasses multiple phenotypes. The relationship with obesity has been addressed in the past; however, the underlying mechanism of such a relationship seems to be more complex, and not explained by the body weight alone. The metabolic syndrome carries a condition of systemic inflammation that could potentially explain the influence on asthma onset and severity. This is a rather unexplored area that could potentially open new scenario in the diagnostic algorithm and in the strategic approach, with a more comprehensive assessment of the disease.

INTRODUCTION

Asthma is among the most common chronic diseases worldwide. The disease is poorly controlled despite available therapies in a large proportion of patients[1], with long-term impairment and disability[2-4]. Among factors impairing the control of symptoms and the lack of response to treatment, obesity is to be taken into account, as stated by recent guidelines[5].

It is well recognized that obesity and asthma are epidemiologically linked[6-9]. This relationship is also observed between asthma and other markers of the metabolic syndrome, such as insulin resistance and hypertension that cannot be accounted for by increased body mass alone[9-12]. The World Health Organization has reported that obesity has dramatically increased during the last few decades. In 2009-2010, more than one-third of United States adults (35.7%) were obese[13]. In this scenario, an estimated 300000 deaths per year are directly attributable to obesity, mainly due to heart diseases, diabetes, cancer, obstructive sleep apnea syndrome (OSAS), arthritis, and psychological disturbances, leading to the concept that obesity represents a risk factor for several pathologies in different clinical conditions[14]. In this regard, overweight and obesity have been demonstrated to be associated in a dose-dependent fashion with the risk of having asthma[15], and obesity appears to be a predisposing factor for the asthma onset, both in adults and in children, as assessed by several cross-sectional studies[16]. In addition, obesity could make asthma more difficult to control and to treat; interestingly, weight-loss interventions in overweight severe asthmatic patients have shown substantial improvements in the clinical status, lung function, symptoms, and overall asthma control[8,17,18]. However, the mechanism linking obesity and asthma is still a controversial issue.

The obese-asthma phenotype is characterized by a paucity of airway inflammation. Although obesity may predispose to increased Th2 inflammation or tendency to atopy, other mechanisms that are independent of inflammatory infliltrates need to be considered, such as hyperglycaemia, hyperinsulinemia and dyslipidemia in the context of metabolic syndrome. Metabolic syndrome is defined as a syndrome that involves three of the following characteristics: dyslipidemia (high levels of apoB lipoproteins and triglycerides, and/or low high density lipoprotein cholesterol), an impaired fasting glucose metabolism, hypertension or central obesity[19-21]. Metabolic syndrome is directly involved in the increased prevalence of coronary heart disease, atherosclerotic diseases, and diabetes mellitus type 2[20-22]. Other metabolic abnormalities have been reported in patients with metabolic syndrome (chronic proinflammatory and prothrombotic states, liver disease and sleep apnea)[20-22]. In the literature, some authors consider that the aforementioned criterion is a combination of risk factors rather than a specific syndrome[23]. On the other hand, epidemiological data reveals that there is a high prevalence of metabolic syndrome in both childhood and young adulthood, and pattern seems to be related to several inflammatory diseases including asthma[22].

EPIDEMIOLOGICAL LINK BETWEEN ASTHMA AND METABOLIC SYNDROME

In obese individuals, the risk for asthma in overweight and obese individuals is increased and does not differ with gender[24,25]. In a recent report, Dandona *et al*[26] showed that in obese asthma patients, with or without type 2 diabetes, there is an increased expression of pro-inflammatory mediators. Following gastric bypass surgery and weight loss, the expression of the aforementioned mediators and plasma metabolites fall significantly suggesting that the pro-inflammatory effect of obesity can be downregulated upon adipose tissue reduction. Assad *et al*[27] recently showed that BMI predicts asthma in women more than metabolic sybndrome[28], however, Agrawal *et al*[29] suggested that calculation of parameters was conducted on entirely different scales, thereby limiting comparison of strength. In another study, Brumpton *et al*[11] evaluated the associations of metabolic syndrome with the cumulative incidence of asthma in adults in 23245 individuals after an 11 years follow up (Nord-Trøndelag Health Study 1999-2008), showing that metabolic syndrome predisposes to. In a large mendelian randomization study, Granell *et al*[30] recently found that higher BMI increases the risk of asthma in non-atopic (1.90, 95%CI: 1.19-3.03) and atopic children (1.37, 95%CI: 0.89-2.11).

PATHOPHYSIOLOGICAL MECHANISMS

Obesity-associated asthma is characterized by the presence of neutrophilic airway inflammation, increased morbidity, and resistance to corticosteroids. The mechanisms underlying the relationship between metabolic syndrome and asthma are yet to be fully understood[31]. In the past, these two conditions were believed to occur in the same individual without any pathogenetic link. However, the improvement ~~of~~ in asthma symptoms following weight reduction implies a causal relationship between obesity and asthma[32,33]. The interplay between these two diseases could be based on a bidirectional interaction. For example, obese asthmatics are at higher risk of metabolic syndrome as opposed to obese individuals who do not suffer from asthma, suggesting that asthma *per se* can increase the risk of developing metabolic syndrome[34]. Similarly, metabolic syndrome has been demonstrated to increase the severity of asthma[35,36]. Recently, changes in the expression of pro-inflammatory mediators such as leptin, IL-6, TNF-α, C-reactive protein and adiponectin have been demonstrated in obese asthmatics[37], implying their potential role in the pathogenesis of

obesity-associated asthma. However, due to the paucity of available literature in this area, it appears difficult to draw definite conclusions until additional experimental and epidemiological data are collected.

A cross-sectional study published by Bruno *et al*[38] recently analyzed the influence of BMI on asthma control in subjects with severe forms of the disease, demonstrating that the optimal state of asthma control is lower in obese than in normal weight and in overweight severe asthmatics and the number of asthma exacerbation episodes are significantly higher in obese than in normal or overweight severe asthmatics. These results may be explained with the inflammatory cascade that the adipose tissue generates. Indeed, the obese state is characterized by the so-called low-grade systemic inflammation[38]. Subcutaneous fat is the major source of fatty acids for the liver, and of free fatty acids in the circulating plasma[39,40]. Subcutaneous fat is related to insulin resistance and to visceral adipose tissue[39,40]. Abdominal subcutaneous fat from obese subjects has been reported to be an inflamed adipose state characterized by tissue macrophage accumulation. This pathologic tissue has been associated with impaired local vasodilatation, peripheral hyperinsulinemia, and insulin resistance[39-41]. Macrophage presence in the tissue is associated with an increase of plasma high-sensitivity C-reactive protein (hsCRP) levels and local amounts of TNF-α[39,40]. The precise mechanism of this event remains to be elucidated; however, adipokines have been proposed as important endocrine mediators since they are related to adipose tissue function and modulation. The following proteins are listed as adipokines, which are envisaged as markers of fat body mass and distribution, as well as tissue function: (1) leptin; (2) adiponectin; (3) ghrelin; (4) vaspin; (5) retinol binding protein 4; (6) apelin; (7) progranulin and MCP-1; (8) omentin; (9) resistin and chemerin; and (10) fetuin[42,43]. Adipose derived hormones may represent molecular links between asthma and inflammation. For example, adiponectin is known to exert anti-inflammatory effects, by inhibiting the eosinophil functions. Indeed, pre-treatment with adiponectin has been demonstrated to diminish the eotaxin-mediated chemotactic responses, by binding the adiponectin receptors AdipoR1 and AdipoR2 that are expressed in human eosinophils[44,45]. In addition, adiponectin has been shown to act as a protector to human bronchial epithelial cell that are involved in the pathogenesis of asthma[46].

High serum levels of resistin have been recently documented in asthmatic children[47]. More important, an *in vitro* study showed that the resistin production strongly increases in obese patients with severe persistent asthma[48], providing support to the notion that resistin can be depicted as a pro-inflammatory cytokine mainly in severely obese asthmatics. Conversely, high leptin levels are associated with a more severe disease and this even in non-obese asthmatics[49,50]. Leptin can upregulate systemic inflammation and may lead to an impairment in lung function[51]. Increased expression and secretion of pro-inflammatory cytokines such as TNF-α, IL-6, and IL-12 were detected when exposed to leptin[52]. Also, the systemic inflammation may contribute to drive insulin resistance, endothelial dysfunction and high blood pressure conditions. The results of a survey confirmed that leptin levels were highly associated with asthma especially in premenopausal women independent of BMI[51]. Guler *et al*[53] also suggested that serum leptin concentrations were a predictive factor for asthma in boys, even after adjusting for obesity. Previously, leptin-mediated increased bronchial hyperactivity in obese mice models had been documented[32].

The changes in the adipose tissue in metabolic syndrome favour the production of mediators that modulate the transcription factors. When they are activated by their ligands, they are able to control genes that are involved in intermediate metabolism[54]. In this regard, peroxisome proliferator-activated receptors (PPAR)-gamma agonists may attenuate the upper airway allergic inflammation by induction of T_{reg} cells and inhibiting the proliferation of effector T cells[55].

Diet-induced dyslipidemia may affect the trafficking of immune cells to the lung in diseases such as asthma[56]. In pulmonary physiology, circulating low density and high density lipoproteins (LDL and HDL) are both taken up by specific receptors, and consequently block local cholesterol biosynthesis[56]. Alveolar cholesterol homeostasis has been demonstrated to affect surfactant synthesis in normal lung physiology[56]. Conversely, HDL promotes surfactant production, and lung fibroblast growth. Adipose tissue reduction by diet or surgery, modulation of cholesterol, or glucose metabolism, has an important effect in asthmatic patients. The apolipoprotein E (ApoE)-low density lipoproteic receptor pathway appears to be involved in the pathogenesis of a murine model of allergic asthma[1]. However, the mechanism by which this protein modulates asthma pathogenesis has never been fully elucidated. ApoE has been hypothesized to ~~as~~ negatively modulate the degree of airway hyperresponsiveness[57]. Perhaps, this mechanism can also apply to humans. Low levels of serum HDL were found to be associated with an increased risk for asthma in adolescence[58], and a recent analysis on 85555 adults demonstrated that high triglycerides and low HDL were associated with wheezing, supporting their role as markers of inflammation[59]. Recently, the association between LDL and asthma was investigated by Scichilone *et al*[60], who found that in mild asthmatics, the least pro-inflammatory LDL (LDL-1 and LDL-2) are lower than in healthy subjects, whereas the most pro-inflammatory (LDL-3 and LDL-4) are higher. In addition, the serum concentrations of LDL-3 (most pro-inflammatory) were

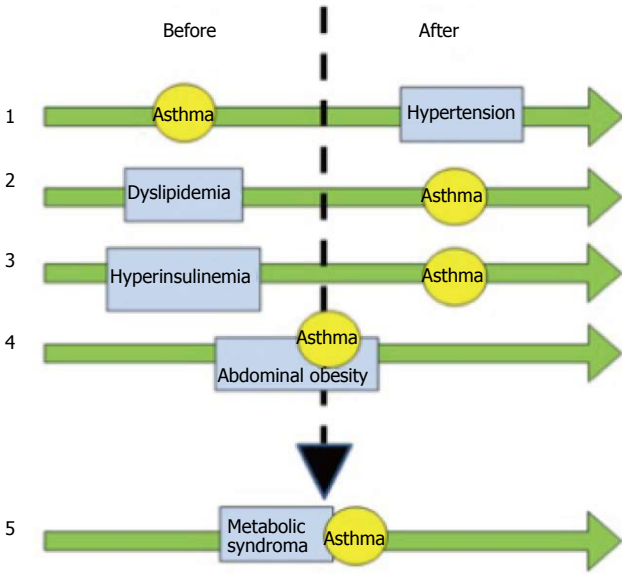

Figure 1 Relationships between asthma and features of metabolic syndrome. The different conditions are divided into "before" and "after" to explain which occurred earlier, implying a causal association. The green arrows describe the temporal evolution and the time when the diseases occurred. Arrow 1 sets asthma as a risk factor for systemic hypertension due to the chronic use of corticosteroids. Arrows 2 and 3 depict the role of dyslipidemia and hyperinsulinemia as risk factors for asthma, due to the abnormalities of the lipoprotein pattern and the influence on the M2 receptors, respectively. Arrow 4 shows the bidirectional association between asthma and obesity. Arrow 5 summarizes the influence of the above-described associations, showing the tight relationship between metabolic syndrome and asthma. Also see text for the explanation.

negatively associated with lung function, suggesting their contribution to the occurrence of the inflammatory changes of the airways[60]. Insulin excess can also directly alter lung cellular physiology and this would represent a fundamental common molecular link between asthma and metabolic syndrome[61]. There is substantial data that mechanistically links insulin and insulin like growth factor-1 to lung development and function. It is conceivable, although not proven, that hyperinsulinemia may lead to development of lung disease, particularly asthma[62]. Experimental studies that directly address this possibility are strongly advocated.

Recent observations seem to focus on the mitochondrial dysfunction as main mediator of the pathogenetic link between metabolic syndrome and asthma. Defective mitochondrial biogenesis in the adipose tissue is well documented in metabolic syndrome[63-66]. However, the involvement of mitochondria alterations among the risk factors of metabolic syndrome and asthma is unknown[67-72].

Oxidative stress on both pulmonary and extra-pulmonary inflammation in obesity may play a major role[73,74]. Oxidative stress is characterized by increased reactive oxygen species (ROS), which induce functional changes of the airways. On this basis, increased oxidative stress may be recognized as a potential mechanism by which obesity results in increased asthma severity. In this regard, the renin angiotensin aldosterone system, a potent inducer of oxidative stress, is often activated in patients with metabolic syndrome, and results in increased levels of angiotensin Ⅱ. Angiotensin Ⅱ seems to be able to determine bronchial hyperresponsiveness[75] and airway remodelling[76]; however, the mechanisms by which this occurs are not yet fully understood.

CURRENT AND FUTURE DEVELOPMENTS

Figure 1 describes the temporal and causal relationships between asthma and features of metabolic syndrome. The role of lipoproteins in the pathogenesis of asthma pathogenesis supported the use of statins in asthmatic patients[77-83]; however, there are still some controversies[84-86]. Even though the aim of statin use in asthmatic patients is related to cholesterol metabolism, most of the reports have highlighted the anti inflammatory properties[77-79,86,87]. An *in vitro* study showed that lovastatin attenuates the differentiation and proliferation of asthmatic bronchial fibroblasts[85], airway smooth muscle cells[86]. Both simvastatin and atorvastatin treatment reduce inflammatory cells in sputum[86]. The mevalonate-dependent and-independent pathways have been identified as potential opportunities for novel treatments with statins in asthma develop new treatments for asthma[78]. Even though statin therapy could be beneficial for a subgroup of asthmatic patients that are either overweight or obese, similar important advantages can be obtained by diet and exercise[20,26]. Biphosphonates could have a beneficial effect in asthmatic patients; alendronate has been shown to have a protective effect by decreasing eosinophil airway inflammation by chemokine secretion, eotaxin, and down-regulating cytokine secretion induced by Th2 and Th17 cells[88]. Retinoic acid[89], retinoids[90] and fenretidine[91] appear to have a beneficial effect on the inflammatory asthmatic response by decreasing the inflammatory milieu. As a consequence, signal transduction pathways inhibition by these compounds could decrease the occurrence of bronchial constriction. Further studies are required to ascertain the possible beneficial effect of new therapeutic elements to control hypertension and endocrine disorders in asthmatic patients with metabolic syndrome. In patients with severe uncontrolled or non responding asthma[92,93], biological therapies seem to be relevant. Interestingly, chemokines and chemokine receptors, CCR3 and CCR4, have been involved in adipose tissue mass increase and insulin resistance[94,95]. Thus, therapy involving chemokines or chemokine receptor inhibition could potentially provide beneficial effects on asthmatic patients with metabolic syndrome[96]. Finally, a therapeutic option in asthmatic patients with diabetes could be represented by thiazolidinediones, oral diabetes medications that selectively activate

PPAR receptor gamma, which have potent anti-inflammatory properties thus reducing the number of exacerbations[97,98].

CONCLUSION

The scope of the current review is to explore the possible link between metabolic syndrome and asthma. Early endocrine disturbances seem to predispose to severe or difficult to treat asthma. Hypertensive and diabetic patients should be screened for respiratory function in the effort to identify cases of airway hyperreactivity or subclinical asthma. Specifically designed studies are needed to address the influence of metabolic syndrome on asthma occurrence and severity, and to unveil the potential underlying common mechanisms. Future studies will hopefully provide convincing evidence on useful therapeutic schemes that today are still unrevealed.

Abstract

Voltage gated calcium channel (VGCC) antibodies are generally associated with Lambert-Eaton myasthenic syndrome. However the presence of this antibody has been associated with paraneoplastic as well as non-paraneoplastic cerebellar degeneration. Most patients with VGCC-antibody-positivity have small cell lung cancer (SCLC). Lambert-Eaton myasthenic syndrome (LEMS) is an autoimmune disease of the presynaptic part of the neuromuscular junction. Its classical clinical triad is proximal muscle weakness, areflexia and autonomic dysfunction. Fifty to sixty percent of LEMS patients have a neoplasia, usually SCLC. The co-occurrence of SCLC and LEMS causes more severe and progressive disease and shorter survival than non-paraneoplastic LEMS. Treatment includes 3,4 diaminopyridine for symptomatic purposes and immunotherapy with prednisolone, azathioprine or intravenous immunoglobulin in patients unresponsive to 3,4 diaminopyridine. Paraneoplastic cerebellar degeneration (PCD) is a syndrome characterized with severe, subacute pancerebellar dysfunction. Serum is positive for VGCC antibody in 41%-44% of patients, usually with the co-occurrence of SCLC. Clinical and electrophysiological features of LEMS are also present in 20%-40% of these patients. Unfortunately, PCD symptoms do not improve with immunotherapy. The role of VGCC antibody in the immunopathogenesis of LEMS is well known whereas its role in PCD is still unclear. All patients presenting with LEMS or PCD must be investigated for SCLC.

Key words: Voltage gated calcium channel antibody; Lambert-Eaton myasthenic syndrome; Paraneoplastic cerebellar degeneration; Onconeural antibodies; Small cell lung cancer

Core tip: Voltage gated calcium channel (VGCC) antibodies are generally associated with Lambert-Eaton myasthenic syndrome, but also with paraneoplastic or non-paraneoplastic cerebellar degeneration. The autoimmune nature of non-tumour Lambert-Eaton myasthenic syndrome is reflected in its association with various HLA subtypes and other autoimmune diseases such as vitiligo, myasthenia gravis and diabetes mellitus. The most common tumour associated with VGCC-antibody-positivity is small cell lung cancer. Knowledge on the relation between cerebellar degeneration and VGCC is limited, and treatment

response is poor in this group of patients.

INTRODUCTION

Voltage gated calcium channels are immunologic targets for several disease. The calcium channels as a target of the pathogenic antibodies in Lambert–Eaton myasthenic syndrome (LEMS) was first suggested by Fukunaga *et al*[1] in 1983. Subsequent studies showed antibodies against P/Q type calcium channel as the most prominent in these patients[2].

Although voltage gated calcium channel (VGCC) antibodies are generally associated with LEMS, usually seen as a paraneoplastic syndrome with small cell lung cancer (SCLC), rarely non-paraneoplastic cerebellar degeneration may also occur in the presence of this antibody[3,4]. VGCC antibody positivity is observed in 85%-90% of LEMS patients whereas the ratio approaches 100% in LEMS patients with SCLC[5]. Approximately 40% of patients with subacute onset cerebellar degeneration, usually with SCLC, have VGCC antibody positivity[3,6]. Moreover these antibodies can also be detected in SCLC patients without neurological involvement[5].

VGCC

The VGCC is crucial in the depolarization of the cell membrane and cellular influx of calcium in response to action potential. It functions as a secondary messenger in electrical signalization and initiates several cellular mechanisms[7]. They are found in several cells, such as smooth and skeletal muscle fibers, endocrine cells, neurons[7]. The channel also locates on the presynaptic membrane of the axon terminal. VGCC opens by action potential and leads to the entry of calcium ions into the axon terminals. Calcium influx results in movement of acetylcholine vesicles towards the presynaptic membrane and acetylcholine is released into the synaptic cleft. In striated muscles, the VGCC on the membrane of transverse tubules directly activates ryanodine-sensitive calcium channels in the sarcoplasmic reticulum and initiates rapid contraction[7,8].

VGCC is divided into five types: L, P/Q, N, R, T depending on tissues and pharmacological properties[7]. The channel contains 4 or 5 subunits (α1, α2/δ, β and γ).The ion transition pore responsible for the biochemical and electrophysiological properties is the α1 subunit. This subunit contains six helical transmembrane segments (S1-S6) and 4 domains (Ⅰ-Ⅳ)[9] (Figure 1). Ten different α1 subunits have been defined and Cav2.1 α1 subunit is found in P/Q type VGCC[7]. Voltage sensors are located in the S4 segment. The S5 and S6 segments are sensitive to calcium[9]. Antibodies against the S5-6 segments of α1 subunit are detected in 50% of LEMS patients[5]. Other antibodies detected in LEMS patients are against domain Ⅳ and β subunit[5,10]. However, the pathogenic role of β subunit antibodies is still controversial due to its intracellular location.

Antibodies to P/Q type channels are responsible for clinical symptoms of LEMS[5]. Thirty to forty percent of the patients with antibodies to P/Q type channels also have antibodies to N-type channels whereas in 25% patients also have antibodies to L-type channels[5]. Antibodies to N and P/Q type channels are detected in 40% of patients with cerebellar ataxia associated with SCLC[9]. Sry-like high-mobility group box (SOX-1), zic-4, anti-Hu are other antibodies detected in the sera of patients with PCD and SCLC and approximately70% of the patients have one of these antibodies[6].

LEMS

LEMS is the autoimmune disease of the presynaptic nerve terminals. It is a rare disease with a prevalence of 2.3 per million and an incidence of 0.5 per million[11]. It is associated with SCLC in 50%-60% of patients. As the clinical and laboratory features differ in patients with and without SCLC, the disease is divided into two groups as LEMS with SCLC (SCLC-LEMS) and non-tumour (NT-LEMS).The age of onset is 50 years or above and there is a male predominance in patients with SCLC-LEMS. On the other hand NT-LEMS can be seen in all age groups with a peak at the age of 35 and 60 and a female predominance[12].

LEMS hardly occurs in childhood; only 5% of LEMS patients are less than 18-year-old[13]. Our youngest LEMS patient was a eight year-old female.

Pathogenesis

LEMS is a disorder due to antibodies against P/Q type VGCC. VGCC antibodies interact with extracellular S5 and S6 segments of domain Ⅱ, Ⅲ and Ⅳ of α1 subunit and reduce the number of ion channels by cross binding[5,14-16]. The antibodies can also bind to other VGCC types without causing any dysfunction. Although VGCC antibodies usually generate an immune reaction, the response to epitopes varies in LEMS patients[17]. Antigenic modulation followed by clustering and reduction of VGCC leads to reduction in quantal release of acetylcholine in synapses and results in muscle weakness[18]. The down-regulation of the receptors of parasympathetic and sympathetic neurons that cause autonomic dysfunction is also associated with these antibodies.

VGCC antibodies can be detected by radioimmunoassay

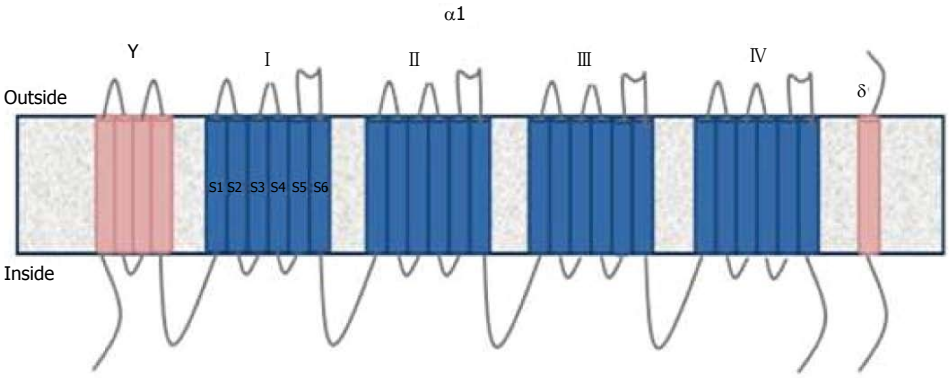

Figure 1 The structure of Voltage gated calcium channels.

in 85%-90% of LEMS patients and 100% of patients with SCLC-LEMS[17,19,20]. P/Q type VGCC are expressed on SCLC cells and this expression results in production of antibodies and cross-reaction with presynaptic VGCC[21]. As the immune reaction is initiated early in tumour development, the diagnosis of LEMS frequently precedes the diagnosis of the SCLC[16]. Besides, VGCC antibodies may be detected in 3%-5% of patients with SCLC without muscle weakness or autonomic dysfunction[16].

Approximately 10%-15% of LEMS patients do not have serum antibodies. However, their serum reproduces LEMS-like symptoms when it transferred to mice. This finding suggests the presence of antibodies at very low concentrations or antibodies against different epitopes of the VGCC that are undetected by routine tests[5]. Antibodies against synaptotagmin, a synaptic vesicle protein, have been found in some seronegative and seropositive LEMS patients[14,22]. Although there is no evidence on their pathogenic role, the blocking of synaptotagmin, which is a Ca^{2+} sensor in the membrane of the pre-synaptic axon terminal may explain the muscle weakness in LEMS[23]. Another such antibody, whose pathogenic role is unclear, is against "sry-like high-mobility group box" (SOX-1) proteins. This antibody is positive in 67% of SCLC-LEMS patients, 22%-32% of patients with SCLC without LEMS and only in 5% of NT-LEMS patients[19].

The role of T lymphocytes in LEMS pathogenesis is unclear. Thymus and other lymphoid organs involved in myasthenia gravis (MG) do not present abnormalities in LEMS and the presynaptic terminals do not reveal T lymphocyte collection[16]. However regulatory T lymphocytes are down-regulated in SCLC-LEMS patients, but not in SCLC patients without LEMS, which suggests the dysfunction of regulatory T lymphocyte in SCLC-LEMS pathogenesis[24].

Unlike SCLC-LEMS patients, the trigger of the immune response is not defined in NT-LEMS.Various HLA associations, also reported with other autoimmune diseases, have been documented: Approximately two-third of patients have HLA-B8 (HLA class Ⅰ) and HLA-DR3, -DQ2 (HLA class Ⅱ) alleles[25,26]. Supporting this phenomenon, monozygous twins have been reported where one has LEMS and VGCC antibodies, and the other, myasthenia gravis and acetylcholine receptor antibodies[27]. On the other hand, HLA association was not found in SCLC-LEMS patients: because tumoral cells do not have strong HLA class Ⅰ antigen expression, these molecules are possibly not involved in the immunopathogenesis[25]. These observations resemble the difference between MG with and without thymoma and reveal the existence of different autoimmune mechanisms in paraneoplastic disorders[16].

Clinical features

The classical triad of LEMS is proximal weakness, reduced tendon reflexes and autonomic dysfunction[16].

Proximal weakness, more prominent in lower extremities, is the first symptom in 80% of patients[16,28]. In the course of the disease, 80% of patients suffer from proximal weakness in both upper and lower extremities[28,29]. Facial, bulbar and distal weakness are also frequent[16]. The weakness is more severe and rapidly progressive in SCLC-LEMS patients[16,28].

Autonomic dysfunction, observed in 80%-96% of patients, is the most common symptom although it is less disturbing than muscle weakness[12,28]. Erectile dysfunction and constipation are more frequent symptoms than urinary retention, dry eye and reduced sweating[5]. The rate and the nature of autonomic symptoms do not differ between SCLC-LEMS and NT-LEMS[16].

On neurological examination deep tendon reflexes are generally reduced or absent. However maximal isometric contraction of the muscle for 10 to 15 s may lead to the appearance of previously depressed or absent deep tendon reflexes and temporarily improve muscle strength, which is called "Post-exercise facilitation". This phenomenon, a characteristic feature of LEMS, is not sensitive[5]. This phenomenon may also mask the reduction of deep tendon reflexes in 40% of patients so the neurological examination must be repeated after a resting period to verify the diagnosis[5].

Associated diseases

The most common co-existence of LEMS is with

SCLC, reported in 50%-60% of LEMS patients[12]. Besides, 0.5%-3% of SCLC patients have LEMS[25]. This co-existence results in a more severe and rapidly progressive neurological disease with shortened survival compared to NT-LEMS which has a near normal survival[16]. Moreover SCLC-LEMS patients tend to be younger than other SCLC patients[19].

Older age, tobacco use, increased ESR support the probability of underlying SCLC. In a Dutch-English cohort study a scoring system called DELTA-P was implemented to predict SCLC in LEMS[12]. According to DELTA-P, dysarthria, dysphagia, chewing or neck weakness(D), erectile dysfunction (E), loss of weight (L), tobacco use (T), age of onset more than 50 (A) and Karnofsky performance less than 60 (P) have a predictive value: patients with a DELTA-P score three or more have higher than 94% risk of having SCLC.

The distinction of SCLC-LEMS from NT-LEMS is important, as treatment options and outcome are different. For this reason, new markers to diagnose SCLC-LEMS are still under investigation. Although SOX-1antibodies are detected in half of the SCLC-LEMS patients, the absence of a commercial kit, and the presence of these antibodies in NT-LEMS limit their use for differential diagnosis[30]. Another study revealed that VGCC antibody against domain IV positivity is more common in NT-LEMS patients than in SCLC-LEMS patients, but this is not used for clinical purposes yet[17].

The co-existence of LEMS with other malignancies such as non-small cell lung cancer, prostate carcinoma, orthymoma has been reported rarely[13] and a random association could not be excluded[5].

In children, the disease is generally non-paraneoplastic; lymphoproliferative malignancy and neuroblastoma are rare associations[13,31]. In accordance with the literature, our pediatric patient did not have any neoplasm.

Other autoimmune diseases such as thyroid disorders, alopecia, diabetes mellitus, MG can occur in NT-LEMS patients probably due to the presence of various HLA subtypes contributing to autoimmunity[32]. In our clinical experience, NT-LEMS patients may have associated vitiligo and myasthenia.

Diagnosis

The time lag between the onset of the symptoms and diagnosis is approximately 4 mo in SCLC-LEMS and 12 mo in NT-LEMS[12,29].

In patients with suspected LEMS, electrophysiological studies with repetitive nerve stimulation are among the most important diagnostic tests. The compound muscle action potential (CMAP) is low after the first stimulation and decreases further after repetitive stimulation at 2-5 Hz[33]. At least 10% reduction in CMAP after low frequency stimulation is considered abnormal and observed in 94%-98% of patients[34,35]. However, this finding may also be present in MG patients. To distinguish these two diseases, nerve stimulation at high frequency (50 Hz) or, as a less painful method for the patient, post-exercise measurement is employed, which increases CMAP by more than 100% in LEMS patients[34,35]. Optimum results will be obtained if treatment is interrupted 12 h before the study and the muscle temperature is above32 ℃.

Although single fiber EMG is a sensitive test, it is used in combination with other tests as it cannot distinguish between MG and LEMS[33]. LEMS patients have increased jitter like MG patients. In case of severe neuromuscular junction dysfunction, the conduction defect in muscle fiber causes a decrease in amplitude and duration of motor unit potential as in myopathies[36].

VGCC antibodies are detected by RIA in 85%-90% of LEMS and in almost 100% of SCLC-LEMS patients[17,19,20]. Although the presence of VGCC antibodies supports the diagnosis of LEMS, the absence of antibodies in a patient with typical clinical features does not exclude the diagnosis.

In 50% of patients SCLC-LEMS, LEMS symptoms precede the diagnosis of SCLC. In addition to scoring systems such as DELTA-P, all patients with the diagnosis of LEMS must undergo computerized tomography of the thorax and positron emission tomography (PET). If the results are negative, the screening must be repeated every 3-6 mo until the second year of the disease[37].

The differential diagnosis of LEMS from seronegative and atypical myasthenia gravis can be challenging. Some clinical findings may be helpful: the progression of weakness is in the craniocaudal direction in MG and the reverse in LEMS; ptosis and facial weakness are less common and severe in LEMS. Electrophysiological studies described above and serological findings assist the clinician in the differential diagnosis.

LEMS with a subacute course can be misdiagnosed as Guillain Barré syndrome (GBS); the presence of sensorial symptoms, neuropathic pain, and elevated CSF protein favor the diagnosis of GBS. Amyotrophic lateral sclerosis may constitute another differential diagnosis, and can be distinguished by the asymmetrical weakness starting in the upper extremities and the presence of upper motor neuron signs.

Treatment

The first choice for symptomatic treatment is 3,4 diaminopyridine[38]. This molecule blocks presynaptic voltage-gated potassium channels and provides a prolonged action potential which increases the quantal release of synaptic acetylcholine[39]. All randomized controlled studies of 3,4 diaminopyridine showed improvement in muscle strength and CMAP amplitudes. The drug is well tolerated although adverse effects like perioral and digital paresthesias and gastrointestinal symptoms are not uncommon. Seizures, which is the most frequent severe side effect, have been reported at high doses exceeding 100 mg/d[40,41]. In our experience, the drug is well tolerated and improves muscle

strength at the dose of 40-60 mg/d.

Other treatments, which can increase the concentration of acetylcholine in synaptic cleft, are pyridostigmine and acetylcholine esterase inhibitors but they are not as effective as they are in MG patients[42].

In case of limited response to 3,4 diaminopyridine, immunosuppressive treatments must be considered. The combination of prednisolone and azathioprine is well studied and documented in LEMS patients[38,42]. Although there is not sufficient data, mycophenolate mofetil, cyclosporine and rituximab are also drugs employed in LEMS treatment[16,43]. Intravenous immunoglobulin (IVIg), another treatment option in paraneoplastic syndromes and MG, can also be used in LEMS. European Federation of Neurological Societies (EFNS) guidelines recommend IVIg in both SCLC-LEMS and NT-LEMS[44]. IVIg is also recommended in pregnant patients, as transplacental transmission of IgG antibodies may cause neonatal LEMS[45]. IVIg is generally preferred as its side effects are rare and it is easily used for the maintenance treatment, which is usually needed in LEMS patients. Plasma exchange whose effect is comparable to IVIg may carry technical difficulties and slightly higher rate of complications[46].

In patients with SCLC, the treatment of the tumour is crucial. The survival of SCLC-LEMS patients is better than in patients with SCLC alone, but there is no relation with VGCC or SOX-1 antibody positivity and survival[17,19]. The better prognosis in these patients may be correlated with the diagnosis time that is earlier in LEMS patients[12,29]. Moreover HLA-B8 positivity is related to prolonged survival in SCLC-LEMS patients[47].

Maintenance of optimal body weight, rehabilitation, frequent examinations for complications such as respiratory infections, and avoidance of drugs impairing neuromuscular transmission are other important aspects of the treatment.

CEREBELLAR DEGENERATION ASSOCIATED WITH VGCC ANTIBODY

Paraneoplastic cerebellar degeneration (PCD) is a syndrome characterized by subacute cerebellar dysfunction[48]. Clinical and pathological features of the syndrome were described by Brain and Wilkinson[49] in 1965 by the evaluation of 13 patients and 6 autopsy cases. Diffuse loss of Purkinje cells is the pathologic hallmark of the disease and usually accompanied by thinning of granular and molecular layers, degeneration of long tracts of spinal cord, dentate and olivary nuclei[4].

Most common neoplasms associated with cerebellar degeneration are lung, breast, ovarian cancers and Hodgkin lymphoma[48]. Onconeural antibodies such as anti-Hu, anti Yo, anti-Ri, anti-CV2, anti-Tr, anti-Ma, anti-Ta, anti zic 4, and anti-mGluR1 as well as VGCC antibody can be detected in PCD[50]. Clinical presentation, neuropathological findings and treatment responses of patients vary according to the type of the onconeural antibody, suggesting distinct immune mechanisms related to different antibodies[4].

PATHOGENESIS

Antibodies against VGCC of the P/Q type or N type are found in 41%-44% of PCD patients, generally associated with SCLC[3,6,9]. The P/Q type VGCC is highly expressed in cerebellar Purkinje cells and in the molecular layer of the cerebellum[9,51]. About 20%-40% of these patients also have clinical or electrophysiological diagnosis of LEMS[3,6]. Neuropathological findings of PCD with LEMS (PCD-LEMS) were reported in 1973 by Satoyoshi *et al*[51] for the first time. In a postmortem study of three PCD-LEMS patients with VGCC antibodies, 70%-80% of reduction in P/Q type VGCC of the molecular layer; loss of Purkinje cells and gliosis in the cerebellar cortex were observed[9,51]. The role of VGCC antibodies in the pathogenesis of PCD is still unclear. In a recent experimental study, antibodies of the IgG type purified from the serum of two VGCC antibody-positive patients with SCLC, one with PCD-LEMS and another patient with isolated LEMS were given to mice intrathecally, the antibodies associated with PCD-LEMS but not from isolated LEMS patients caused cerebellar ataxia in mice[52]. This finding suggests the presence of different epitopes of P/Q type VGCC antibodies which inhibit VGCC's function in cerebellum, or of other additional, yet undiscovered pathogenic antibodies[52].

CLINICAL, LABORATORY AND RADIOLOGICAL FEATURES

Subacute and rapidly progressive gait unsteadiness is the presenting symptom of cerebellar degeneration[50]. Gait and limb ataxia, diplopia, dysarthria are the other prominent symptoms[50]. Sometimes these complaints may preceded by dizziness, nausea and viral infection-like symptoms[50]. Occasionally other signs and symptoms such as dysphagia, nystagmus and sensory deficits can be also seen during the course. Patients who had concomitant LEMS may also show proximal weakness and autonomic symptoms in addition to cerebellar symptoms[4].

The cerebrospinal fluid (CSF) may show mild lymphocytic pleocytosis with elevated protein and oligoclonal bands[48]. VGCC antibodies may also be detected in CSF and there is some evidence of intrathecalsynthesis of the antibodies, and detected in about 25% of the patients[3]. This low percentage may be explained by the absence of CSF analysis in some cases and further studies are needed to increase the rate of antibody presence in CSF.

Initial brain magnetic resonance images or tomography are normal in most patients[4] although in early stages of the disease fluorodeoxyglucose-PET scans may show cerebellar hypermetabolism[50,53], whereas cerebellar

atrophy and cerebellar hypometabolism are seen in the advanced stage of the disease[50].

TREATMENT

Treatment of the underlying malignancy has the priority like other paraneoplastic syndromes[50]. Corticosteroids, plasma exchange, IVIG, tacrolimus and cyclophosphamide are the immunotherapeutic options to be used concurrently with tumour therapy, but most of the cases did not show sufficient improvement despite treatment[50]. Unlike in LEMS, immunotherapy does not result in symptomatic improvement in PCD: this suggests PCD may be associated with irreversible damage of Purkinje cells[3].

NON-PARANEOPLASTIC CEREBELLAR DEGENERATION WITH VGCC ANTIBODY

VGCC antibodies were also found in a few patients with non-paraneoplastic cerebellar degeneration. In a study of the antibody profile of 67 cases with sporadic, late-onset cerebellar ataxia of unknown etiology, VGCC antibodies were found in 12%[54]. Two cases with NT-LEMS who developed cerebellar ataxia during the course of their disease had VGCC antibodies in serum and CSF. Cerebellar symptoms of these patients showed no improvement with different immunotherapies, as in PCD[55]. However a few cases of non-paraneoplastic cerebellar degeneration showed favorable outcome under rituximab and IVIg treatment[56,57].

CONCLUSION

Diseases related to VGCC antibodies are usually associated with SCLC. Therefore, SCLC should be investigated in patients with LEMS and/or cerebellar degeneration. The role of VGCC antibodies in the immunopathogenesis of LEMS is clear, however their role in cerebellar degeneration is not known. Determination of the effect of VGCC antibodies on the pathogenesis of cerebellar degeneration may contribute to the design of more efficient treatment strategies. Therefore, experimental models and pathologic studies that investigate the effect of immune mechanisms at molecular level in the tissue are needed.

Abstract

Asthma is common in childhood. This respiratory disease is characterized by persistent inflammation of the airways even when the child is not in the throes of an attack. Chronic inflammation is caused by an imbalance between pro-inflammatory and anti-inflammatory mechanisms as well as autonomic dysfunction, which plays an important role in the pathogenesis and control of this condition. The impact of these physiopathological aspects leads to inactivity and a sedentary lifestyle, which exerts an influence on functional capacity and control of the disease. The main objective of non-pharmacological therapy is the clinical control of asthma and the minimization of airway obstruction and hyperinflation during an attack. These factors can be controlled with noninvasive ventilation. The aim or the present review was to describe important neural, inflammatory and functional mechanisms that affect children with asthma.

Key words: Asthma; Child; Continuous positive airway pressure; Noninvasive ventilation; Autonomic nervous system; Functional capacity; Inflammatory mechanisms; Evaluation

Core tip: The recurring nature of asthma is related to the clinical control of the disease. Neural and inflammatory mechanisms interfere with this clinical control and affect functional capacity. While the magnitude of an asthma attack cannot be controlled, its clinical impact can be minimized with the use of noninvasive ventilation. Moreover, functional capacity and inflammation can be improved with physical exercise.

INTRODUCTION

Asthma is common in childhood. This respiratory disease is characterized by persistent inflammation of the airways, which is clinically manifested in the form of recurring cough, shortness of breath, wheezing and chest retraction. These episodes are associated with the obstruction of airflow, which is partially reversible and occurs mainly in the morning and at night[1,2].

Controlling the disease is the main objective of asthma management. Such control refers to the most recent clinical manifestations (previous four weeks) with regard to symptoms, limitations to physical activity, the need for a b_2 agonist and the intensity of airflow limitation as well as the reduction of future risks. Asthma is therefore classified as controlled, partially controlled or uncontrolled. Addressing future risks regards reducing the instability of asthma and exacerbations, the loss of lung function and the adverse effects of treatment[2,3].

The incidence of asthma has doubled in the last 20 years due to the actual increase in the number of cases as well as better recognition of the disease on the part of the medical community. The difficulty in comparing epidemiological data from different countries or even different regions within the same country motivated the International Study of Asthma and Allergies in Childhood, which employed a simple, validated, self-administered questionnaire with a small number of items. The authors of the study evaluated 304796 children aged six to seven years from 42 countries and 463801 adolescents aged 13 to 14 years at 155 centers in 56 countries and distinguished three categories of countries based on the prevalence rates of asthma: weak (less than 5%), medium (5% to 6%) and strong (greater than 10%). Brazil was classified in eight place, with a prevalence rate of 20%[4,5].

Despite the difficulties in diagnosing asthma in children, there is evidence that half of all cases are diagnosed by three years of age and 80% are diagnosed by six years of age. Moreover, one third of the initial symptoms begin before the child has completed one year of life. Although 50% of children with asthma in Latin America exhibit daily symptoms and arousals from sleep, only 10% regularly use medication to control asthma and only treat attacks with an inhaler, while only 13% employ preventive measures and the control of exacerbations[6].

The aim or the present review was to describe important neural, inflammatory and functional mechanisms that affect children with asthma.

PHYSIOPATHOLOGY AND INFLAMMATION IN ASTHMA

Asthma is an inflammatory disease involving the participation of mastocytes, eosinophils, T cells and dendritic cells. Among the different phenotypes, atopic asthma is the most common and is characterized by an increase in eosinophils and total immunoglobulin E (IgE), with the considerable participation of mastocytes and their products in events during the acute phase. These cells also participate in the chronic inflammatory process and bronchial hyperresponsiveness, along with macrophages, eosinophils and T lymphocytes[2]. Macrophages can either increase or diminish the inflammatory process, depending on the stimulus. Alveolar macrophages normally suppress lymphocyte function, but this function may be altered in individuals with asthma following exposure to a triggering factor[7] (Figure 1).

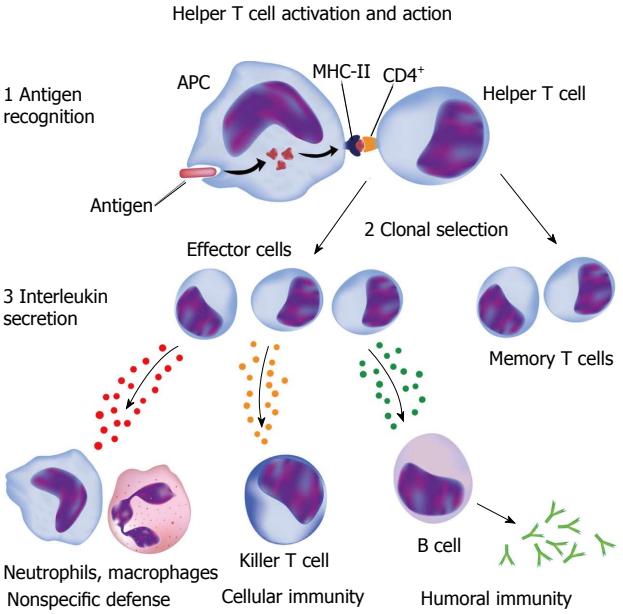

Figure 1 Cellular and humoral response to an antigen. © Can Stock Photo Inc./[Alila].

Eosinophil infiltrate is a physiopathological characteristic of the airways in individuals with asthma and contributes to the differentiation of this disease from other inflammatory conditions. Eosinophils are seen as beneficial in asthma due to their function in inactivating histamine and leukotrienes. However, eosinophils are also involved in injurious processes of the airways tissues, contributing to the development of bronchial hyperresponsiveness.

Chronic inflammation results in the obstruction of distal airways due to the accumulation of secretion and cell debris, the contraction of bronchial smooth muscles, thickening of the epithelial basement membrane and bronchial wall edema[8]. The most striking characteristic of asthma is persistent inflammation of the airways even when the child is not in the throes of an attack. The degree of inflammation is associated with bronchial hyperresponsiveness and symptoms. Chronic inflammation is caused by an imbalance between pro-inflammatory and anti-inflammatory mechanisms[9]. The persistence of this inflammatory condition over the years combined with frequent acute attacks can exert a

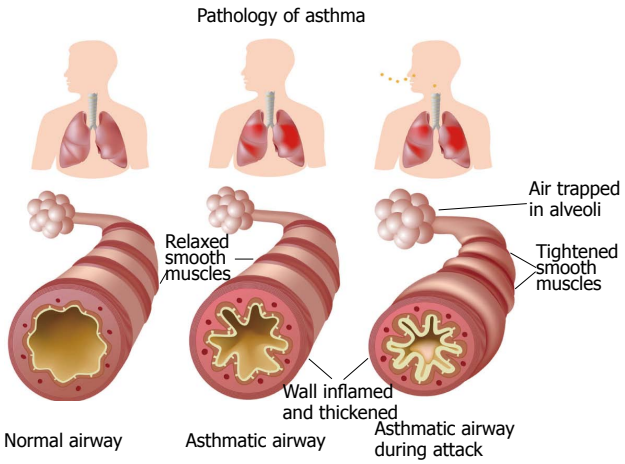

Figure 2 Bronchi in normal conditions, asthma and during asthma attack. © Can Stock Photo Inc./[Alila].

negative influence on lung function (Figure 2).

Inflammation has been the focus of treatment for asthma in the last 20 years. Prior to the 1980s, asthma was seen as recurrent wheezing that responded to b_2 agonists. The inflammatory reaction begins with contact between an allergen (pollutant or virus) and dendritic cells, which activate mastocytes that, in turn, release IgE specific to given allergens. This initial process leads to the release of different mediators. The consequence of this initial phase (four to six hours) of the inflammatory cascade is clinically manifested as bronchospasms[10]. In the late phase of the inflammatory reaction, granulocytes are released by bone marrow and migrate to the target organ (lungs), causing tissue injury and the release of toxins[11,12]. Inflammatory cytokines stimulate the formation of inducible nitric oxide synthase (iNOS). At high concentrations, NO is the major contributor to the inflammatory process in asthma[13] (Figure 3).

Cell apoptosis is maintained activated at all moments of the inflammatory cascade, possibly reducing the reserve of cells that could cease this process. Asthma is characterized by a reduction in apoptotic potential and consequent perpetuation of the inflammatory process. Moreover, the molecules involved in the tissue repair process seem to be relatively ineffective. These events results in chronic inflammation and the structural remodeling of the airways. All these factors seem to be the basis for bronchial hyperreactiveness and other symptoms[10-12].

Differences between childhood and adult asthma

Childhood is the period of greatest incidence of asthma, however the identification of these children still problematic. The clinical syndrome that is recognized as asthma fails to develops in all children and infants with wheezing (in less than half as already stated earlier).

Another difficulty in the identification of asthma in childhood is related to pulmonary function test as

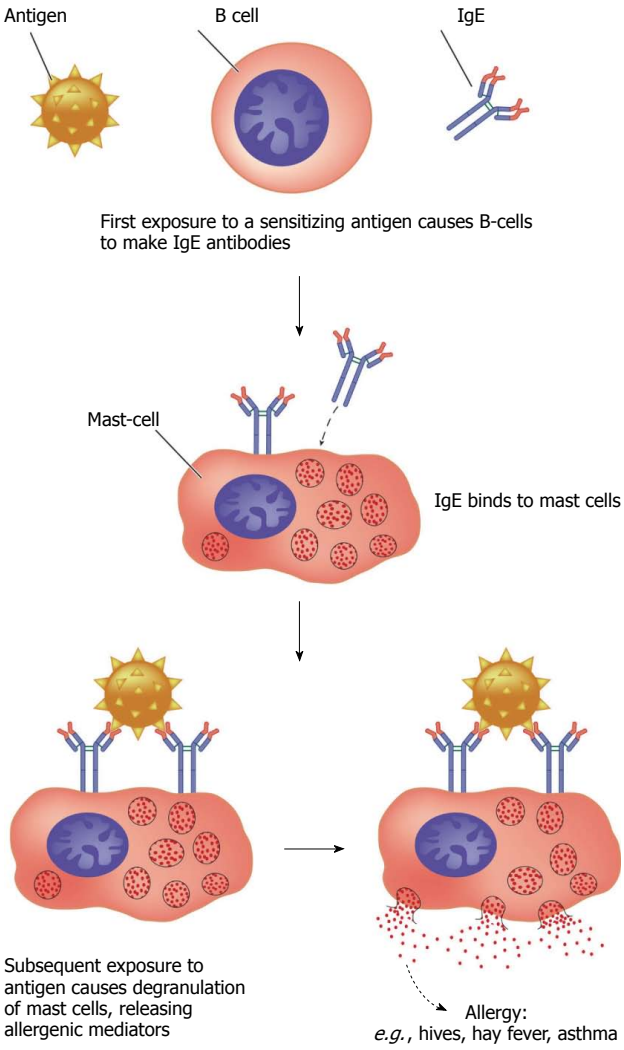

Figure 3 Activation of mast cells and release of IgE. © Can Stock Photo Inc./[Blambs].

well as the documentation of the obstruction and its reversibility objectively and quantitatively in small children. The challenge is to detect by means of non-invasive biomarkers in infants and pre school children who can become asthmatic by facilitating in this way the clinical control and reducing the morbidity of the disease in adulthood.

What is known so far that insults occurred postnatally as aspiration, viral infections or allergic sensitization may alter the airway neural control for long periods[13].

Respiratory infection and asthma in childhood

Various pathogens may cause wheezing in childhood, in particular, respiratory syncytial virus (RSV). Bronchiolitis from RSV increases the risk for recurrent wheezing (more than 3 episodes of wheezing per year) and not persistent (up to 3 episodes of wheezing per year); However, the risk gradually decreases with age and becomes not significant to 13 years of age[14]. These data indicate that RSV infections may contribute substantially to the risk of recurrent wheezing and possibly asthma in childhood and also suggest that

other co-factors (for example: genetic, environmental and development) contribute to the onset or severity of asthma over time.

Respiratory infections and asthma are closely related and children are very susceptible to these infections, but less than half of them develop recurrent wheezing.

Some types of respiratory infection in infancy can stimulate Th1 cells and as regards the pathophysiology of childhood asthma in the balance and the way in which this balance Th1/Th2 is reached in this age group still generate doubts. What is known is that the non atopic child have a reduction of Th2 in the first year of life, already in atopic child Th2 response is associated with the production of IFN-γ in the neonatal period[14].

Atopic asthma is characterized by this imbalance Th1/Th2. Th2 cells when stimulated produces interleukin 4 (IL4) and IL13 that induce the production of IgE by B cells. The IL9 is also produced by Th2 stimulates the proliferation of mast cells which in turn starts the production of histamine, leukotrienes and prostaglandins that lead to an additional activation of eosinophils, basophils and Th2[15].

The endothelial lesion caused by viral infection leads to increased airway permeability facilitating the exposure of allergens to cells in the nerve endings promoting a neurogenic inflammation. Severe respiratory infections increase the recruitment of eosinophils to the airways bringing the risk of persistent asthma in childhood[13].

Fraction of exhaled nitric oxide

Gustafsson *et al*[16] (1991) were the first researchers to isolate the nitric oxide (NO) molecule. According to the authors, NO is formed by the action of NO synthase on the semi-essential amino acid L-arginine. Two basic isoforms are produced: constitutive and inducible[17]. NO synthase performs a number of biological functions, such as neurotransmission, vasodilatation and bronchodilatation as well as playing a role in the immune system. The type Ⅰ constitutive isoform (epithelial) promotes vasodilatation and the type Ⅱ constitutive isoform (neuronal) is responsible for the transmission of stimuli from the central nervous system and autonomic nervous system through the non-adrenergic, non-cholinergic pathway[17,18]. The inducible isoform (iNOS) is stimulated with the perpetuation of the inflammatory process and contributes to this process due to its pro-inflammatory activity. When activated, this isoform promotes an increase in the production of secretion in the airways and a large number of inflammatory cells, favoring necrosis of the ciliated tissue[7,19]. The constitutive isoforms are produced in small amounts that are not detectable in exhaled breath and perform their biological and physiological roles, whereas iNOS is produced in large amounts, has cytotoxic effects and is detectable in exhaled breath (FeNO)[20,21].

FUNCTIONAL CAPACITY

Fear of shortness of breath often makes children with asthma avoid physical exercise, leading to a sedentary lifestyle, psychological and postural problems as well as a poor quality of life. Studies have demonstrated that children with moderate to severe uncontrolled asthma exhibit chronic physical deconditioning and reduced cardiopulmonary capacity[22,23]. Villa *et al*[24] (2011) evaluated children with persistent moderate to severe asthma and found that those with severe asthma exhibited diminished lower limb endurance. Thus, controlled physical activities are needed to prevent the impairment of cardiopulmonary capacity and physical fitness.

Repeated physical activities with varying intensity that last only a few seconds and are intercalated with short rest periods are more appropriate for children. Besides preferring spontaneous activities with a recreational components and considerable variety, children explore the anabolic effects of physical exercise more[25]. Thus, physically-based play activities are indicated for children with asthma. While 40% to 90% of children with asthma exhibited exercise-induced bronchospasms, the regular practice of physical activity is able to improve this symptom, often with no direct impact on lung function[2].

Advances in technology have facilitated the performance of movements and physical activity[26-28]. Interactive video games in the last ten years have contributed to energy expenditure among otherwise sedentary children, with the possible applications regarding lung rehabilitation among children with asthma. However, previous studies have only employed this resource for the training of children without lung diseases[29]. Thus, there is a need for scientific evidence of the benefits of interactive video games for the improvement of physical fitness in this population.

Inflammation and physical exercise

A persistent inflammatory state is a common trait of chronic diseases. Inflammation is indicated by the high concentration of inflammatory markers, such as IL6, tumor necrosis factor alpha (TNFα) and C-reactive protein in the blood plasma[30]. Physical exercise has an anti-inflammatory effect and regular practice seem to offer protection against the development and aggravation of chronic diseases. While children with asthma tend to avoid physical exertion, the practice of physical exercise can be beneficial to this population. However, there are no specific guidelines with regard to the type, intensity, duration and frequency of training[31].

Three mechanisms seem to explain the anti-inflammatory effect of physical exercise. The first is the reduction in visceral fat, as excess fat contributes to the production of pro-inflammatory adipokines,

such as TNF and leptin, as well as the reduction in adiponectin. The second mechanism is the increase in the production and release of anti-inflammatory cytokines, such as IL6, stemming from muscle contractions caused by myosin, which induces different metabolic effects, such as lypolysis and the oxidation of fat, as well as contributing to the homeostasis of glucose during physical exercise. The third mechanism is the reduction in the expression of receptors of monocytes and macrophages, which have a lower inflammatory response to endotoxins in physically active individuals[30-33].

The effect of myokines (IL6 released by the contraction of skeletal muscle) regulates the release of TNFa, resulting in a protective effect[34] (Tilg *et al*[34] 1997). Moreover, IL6 stimulates the release of the anti-inflammatory interleukins 10 and 1ra. IL10 inhibits the production of interleukins 1a and 1b as well as the induction of iNOS[35]. This mechanism may explain the likely effect of physical exercise on changes in the concentration of FeNO.

AUTONOMIC NERVOUS SYSTEM AND CONNECTIONS WITH RESPIRATORY AND CARDIOVASCULAR SYSTEMS

The respiratory and cardiovascular systems are intrinsically linked and the autonomic nervous system (ANS) is one of the pathways that connect these systems[36] (Figure 4).

Moreover, the ANS exerts an important influence on the pathogenesis and control of asthma[37]. Afferent pulmonary nerve pathways regulate cholinergic tone, which is increased when the respiratory rate is increased. This mechanism occurs in response to physiological and physiopathological stimuli. A physiological response occurs when the peripheral respiratory muscles and pulmonary stretch receptors send afferent stimuli to the central nervous system during physical exertion, which results in the reduction in cholinergic tone as well as bronchial dilatation to compensate for the increase in ventilation demand. This mechanism is altered in individuals with asthma[37].

Understanding the relationships between the ANS and respiratory system may help clarify the causes of cardiovascular disorders with a pulmonary origin. From the neuroanatomic standpoint, afferent and efferent neural pathways of the respiratory and cardiovascular systems converge in common regions. Afferent pathways converge in the solitary tract nucleus and efferent pathways converge in the nucleus ambiguous, which is responsible for the generation of the respiratory rate and heart rate[36].

In individuals with asthma, the inflammatory process is increased during periods of exacerbation. The increase in vagal tone during stable periods of the disease may be explained by an attempt to maintain inflammatory control. The ANS exerts an influence on the relaxation and constriction of the smooth muscles of the bronchioles. Relaxation occurs through either the activation of beta receptors of the sympathetic pathway or the activation of the non-adrenergic, non-cholinergic and intestinal peptide pathways. Constriction is mediated by either sympathetic receptors or the vagal cholinergic pathway[37].

Heart rate variability has been used as a measure of vagal autonomic activity and neuroimmunomodulation. A number of studies have addressed the influence of respiration on heart rate variability. Chronic respiratory diseases, such as asthma, demonstrate a link between the inflammatory process and the immune reaction as well as progression with cardiovascular consequences that can contribute to the increase in illness and mortality rates[36].

Asthma and autonomic modulation

The activation of the autonomic mechanism in the respiratory system is due to the reflex response of receptors located in the airways, regulating bronchial contractility[38-41]. Autonomic dysfunction is associated with asthma[42,43], with an increase in bronchial sensitivity to cholinergic constrictors and possibly a reduction in sensitivity to adrenergic b_2 bronchodilators. Besides its essential role in the cardiovascular system, the ANS plays an important role in the regulation of the contraction of bronchial smooth muscles[37].

Asthma severity is directed related to autonomic dysfunction even under conditions in which the patient is not a period of exacerbation. The functions of the ANS in children with asthma also differ in comparison to adults and healthy children[43,44]. This severity is correlated with the magnitude of vagal activation in the stable phase[43]. During periods of exacerbation, children with persistent moderate asthma experience greater action of the sympathetic nervous system, unlike what occurs in stable periods, which conflicts with the hypothesis of hyperactivity of vagal tone in the acute phase[45].

Neural mechanisms are also responsible for the regulation of inflammation. The activation of the vagus nerve is responsible for the inhibition of the activation of macrophages and the synthesis of TNFα as well as the activation of the reticuloendothelial system for the release of acetylcholine[46].

Autonomic modulation and degree of effort in asthma

As mentioned above, asthma progresses with autonomic abnormality during physical effort. The ANS responds to stimuli send by the muscles, lungs and diaphragm for the withdrawal of vagal tone, resulting in an increase in the diameter of the airways. This is a mechanical response to a neural stimulus that allows enhancing the airflow, with a consequent improvement in gas exchange in response to the increase in metabolic demand[37].

Different degrees of physical stress can trigger changes in autonomic modulation in children with

asthma. During physical exertion, the heart rate and cardiac output are increased mainly due to vagal withdrawal stemming from a central command. In the transition from an intense activity involving an increase in heart rate greater than 100 beats per minute, the increase in sympathetic activity is necessary to induce tachycardia as well as increase both heart contractibility and peripheral vascular resistance[47]. During maximum physical effort, this mechanism of vagal withdrawal and sympathetic activation seems to be altered and relatively ineffective in children with asthma. Vagal withdrawal also seems to occur during sub-maximum effort[48] (Figure 5).

Management of shortness of breath and respiratory failure using noninvasive ventilation

During respiratory distress, children with asthma experience bronchial obstruction and hyperinflation, which predisposes such individuals to respiratory failure. Thus, the aims of the management of severe acute asthma include the correction of hypoxemia, alleviation of the airflow obstruction and the reduction of the inflammatory process through medications. The therapeutic goal is to reduce respiratory work and optimize gas exchange. Continuous positive airway pressure (CPAP), which is a form of noninvasive ventilation (NIV), is used to reduce the work of respiratory muscles imposed by hyperinflation of the lungs and produces a change in autonomic modulation stemming from the increase in intra-thoracic pressure[49,50] (Figure 6).

There is scientific evidence of the efficacy of NIV for an asthma attack. Gupta *et al*[51] (2010) report improved respiratory work, fast recovery of lung function as well as reductions in inhaler dose, stay in an intensive care unit and the duration of hospitalization among adults with acute asthma treated with bi-level NIV. CPAP caused changes in both alveolar and intra-thoracic pressures and the activation of pulmonary stretch receptors affects autonomic modulation[37,50]. In a study involving an experimental model, Xue *et al*[52] (2011) found that the increase in intra-thoracic pressure leads to a reduction in bronchial hyperresponsiveness, which persists for up to 24 h following the removal of CPAP. Busk *et al*[53] (2013) found a reduction in bronchial hyperresponsiveness in adults with asthma after seven days of treatment and consider CPAP to be an important non-pharmacological tool for the treatment of this condition.

Parasympathetic nerve stimulation results in both the contraction and relaxation of the bronchial musculature. The non-adrenergic, non-cholinergic

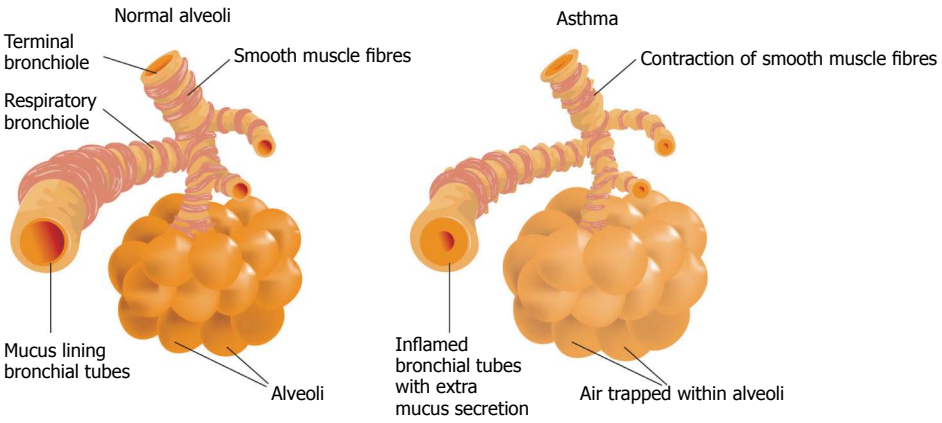

Figure 6 Hyperinflation. © Can Stock Photo Inc. / [Blambs].

pathway (bronchodilatation) is stimulated by pulmonary stretch receptors. Contraction is mediated by acetylcholine and relaxation is mediated by transmitters of the non-adrenergic, non-cholinergic pathway. Cholinergic tone is extremely sensitive to the ventilitory mechanism and is reduced when the respiratory rate is reduced[37]. Thus, CPAP may achieve its positive effects by reducing the respiratory rate and stimulating the non-adrenergic, non-cholinergic pathway through pulmonary stretch receptors. The acute effects of CPAP on autonomic modulation have been demonstrated in other pathological conditions, but there is a lack of scientific evidence regarding the benefits of this method in patients (especially children) with asthma[50].

In a study conducted by our research group[54] involving the evaluation of clinical variables and the ANS in children in the throes of an asthma attack, the activation of vagal tone was found with the administration of CPAP. Parasympathetic activation stimulates both contraction and relaxation of the smooth muscles of the airways. Cholinergic tone is reduced with positive end-expiratory pressure and the reduction in the respiratory rate[37,55].

The findings suggest that the non-cholinergic parasympathetic pathway is activated by the administration of CPAP due to the significant increase in peak flow, which continues after the removal of NIV, suggesting a bronchodilatation response as well as the mechanical stimulation of the opening of the airways. Pulmonary stretch and the activation of the non-cholinergic pathway is believed to assist in the inhibition of the cholinergic bronchoconstriction pathway[37].

CONCLUSION

The recurrent nature of asthma is related to the clinical control of the disease. Neural and inflammatory mechanisms interfere with this control and affect functional capacity. While the magnitude of an asthma attack cannot be controlled, its clinical impact can be minimized with the use of noninvasive ventilation. Moreover, functional capacity and inflammation can be improved with physical exercise.

Abstract

AIM: To present the United Kingdom's first case series of 70 otological cases of endoscopic and non-endoscopic ear surgeries.

METHODS: Prospective case series incorporating a range of endoscopic procedures performed using a 4 mm, 18 cm rigid endoscope, performed by a single surgeon at a single centre. Primary outcome measures included mean average pre and post-operative air-bone gap hearing thresholds and duration of surgery.

RESULTS: Thirty-eight patients underwent endoscopic assisted ear surgery and 32 underwent non-endoscopic assisted ear surgery. In both surgical groups, there was a significant difference between pre and post-operative mean air-bone gaps (P = 0.02). Mean operating time was comparable between both groups. Eight patients developed post-operative complications.

CONCLUSION: Endoscopic ear surgery can be performed safely in a range of otological procedures. This has the potential to become a well-established surgical option for middle ear surgery in the near future. Advantages and limitations are discussed.

Key words: Endoscopic; Mastoid; Surgery; Imaging; Otology; Cholesteatoma

Core tip: The role of endoscopic ear surgery is yet to be properly established but as more otologists adopt this technique, its role will become much more clearly defined and may lead to widespread use based upon positive outcomes for surgery. As with every new surgical technique, a learning curve must first be overcome before reliable conclusions can be drawn about its use. Our series has shown the benefits of using this technique in limited cholesteatoma disease and in providing a good view during revision mastoid surgery with simple pathology.

series and first United Kingdom experience. *World J Clin Cases* 2015; 3(3): 310-317 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i3/310.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i3.310

INTRODUCTION

The advantages of using endoscopes in surgery are well described and relate mainly to their portability and ability to provide clear, high quality images[1]. Endoscopes can also be used in theatre and the outpatient setting. In particular, the benefits for middle ear surgery include the ability to visualise poorly seen structures, such as the hypotympanum and sinus tympani, which are often an obstacle during the open-technique approach[2]. In addition, their use *via* the permeatal approach in bypassing a narrow isthmus can provide direct access and a wide view into the middle ear for surgery[3-5]. Benefits of using an endoscope can therefore decrease operating time due to the reduction in time need to gain access into the middle ear cleft[6] and the subsequent closure at the end of the procedure. The disadvantages of endoscopes used in ear surgery include operator dependence (especially in relation to the one-handed technique), restricted views from narrower endoscopes (*e.g.,* 2.7 mm as compared to 4 mm), the ability to manage complications such as bleeding within a narrower operating field, loss of depth perception, limited magnification, and the need for further training in their use[4,5]. Furthermore, when used solely in a permeatal approach, the surgeon must use a one-handed technique for instrumentation and there may be difficulty passing other instruments alongside, even in wide ear canals. Certainly there is no scope for using the operating drill in its present form.

Endoscopic ear surgery can be applied to a variety of operations including; grommet insertion, myringoplasty[2], attic retractions[6], cholesteatoma surgery[7-15], stapedectomy[1,15], benign neoplasms of the middle ear[16] and neuro-otological procedures[4,17,18]. Based on the literature their use has been most commonly described for middle ear disease (cholesteatoma). It has been suggested that preservation of middle ear mucosa by limited surgery using the endoscope can improve the re-aeration of the mastoid cavity leading to better outcomes in surgery[2]. There are also roles in "second look" middle ear surgery using 30 degree endoscopes to check for disease clearance[14,19].

Many of the surgeries described above are derived from international case series from France, Germany, Italy, India, UAE, China, Egypt, Iran and the United States[1,5,12-14,17-24]. We present the first United Kingdom case series that uses a permeatal exclusively endoscopic approach[20].

MATERIALS AND METHODS

We describe a case series of 70 patients who underwent either endoscope-assisted or non-endoscope-assisted ear surgery by a single senior surgeon in a district general hospital. Data collection was carried out prospectively for endoscopic cases and retrospectively for non-endoscopic cases where all cases were performed within a 2 year period (2012-2014). A 4 mm diameter, 18 cm long rigid endoscope was used in all cases. Primary outcomes include mean average pre and post-operative air-bone gap hearing thresholds or duration of surgery, depending on the type of surgery. Pre and post-operative audiometric data using both air and bone conduction (at 500 Hz, 1 KHz, 2 KHz and 4 KHz frequencies) was recorded. Complications were noted. Statistical analysis was performed using GraphPad Prism (GraphPad Software Inc, La Jolla, CA, United States).

Statistical analysis

The statistical methods of this study were reviewed by Virk J, Cambridge University graduate. The dataset was principally descriptive with simple paired t-testing only.

RESULTS

Seventy patients underwent surgery between the ages of 7-85. Of these, 38 underwent endoscope-assisted ear surgery (Group A) and 32 underwent non-endoscope-assisted ear surgery (Group B). All cases were performed under general anaesthesia. Imaging was reviewed prior to surgery. An endoscope was used exclusively for all patients who underwent endoscope-assisted ear surgery, except in parts of an operation which required the use of a microscope (*e.g.*, mastoid portion of modified radical mastoidectomy or canal wall up mastoidectomy). Procedures in Group B patients were preferentially performed with the microscope such as revision stapedectomies under local anaesthetic or those with extensive disease and the endoscope was not used during the procedure. No cases were converted from endoscopic to open operations. Both groups were matched as closely as possible for type of surgery and demographics.

In Group A, 20 patients had had previous surgery to the operated ear (*i.e.*, ipsilateral ear) compared to 7 patients in Group B. A summary of different operations within Group A and B are shown in Table 1. Tables 2-6 summarise data for each operative group.

Overall, air-bone gap closure was achieved within 10 dB in 9 patients (5 Group A *vs* 4 Group B), within 10-30 dB in 18 patients (8 Group A *vs* 10 Group B), over 30 dB in 9 patients (2 Group A *vs* 7 Group B), over-closure in 5 patients (4 Group A *vs* 1 Group B) and no change in 25 patients (18 Group A *vs* 7 Group B). In both groups, there was a significant difference between pre and post-operative mean air-bone gaps ($P < 0.05$) (paired *t* test, $P = 0.036$ group A and $P = 0.002$ for group B) for patients who underwent stapedectomy, where air-bone gap was a primary

[1]Mean gap calculated over 4 frequencies (500 Hz, 1 KHz, 2 KHz, 4 KHz). PORP: Partial ossicular replacement prosthesis; n/a: Not Applicable.

Eight patients developed post-operative complications that later resolved including otalgia, recurrent otitis media with effusion, transient delayed facial palsy, labyrinthitis, tragal abscess and tympanic membrane perforation and infection of the mastoid cavity (see Tables 2-6). Three patients were planned for further surgery at follow up. Mean post-operative follow up was 8.8 mo; 2 patients were lost to follow up.

DISCUSSION

Ventilation tube insertion

Only one patient in our case series had ventilation tube insertion lasting 25 min. Though numbers are extremely low, and therefore difficult to analyse, this operation took 7.5 min longer than the mean duration of non-endoscope-assisted surgery. In contrast, a recent study examining 260 endoscopic grommet insertions demonstrated operating times between 5 and 10 min in all cases[2]. Another study has shown that there is no significant difference in duration compared to using a microscope, though it does advocate the use of an endoscope when ventilation tube placement is technically difficult[21].

Myringoplasty, Tympanoplasty and Tympanotomy

This series demonstrates that the endoscope can effectively access the middle ear for these procedures. No further incisions were required and an exclusively permeatal approach was used in all endoscopic procedures. Surgical outcomes were good in all cases (Table 2) with shorter mean operating times as compared to Group B (non-endoscope = assisted surgery), 85.8 min *vs* 107.8 min for Group A *vs* B respectively. This is a fairly accurate representation of true operating time, since the same numbers of operations were performed in each group. There is also evidence that excellent hearing thresholds can be achieved endoscopically, as reported by Balasubramanian and Venkatesan, who achieved pure tone average hearing thresholds of 20 dB in 50 myringoplasties performed endoscopically, further confirming the efficacy of this technique in selected cases[2].

Table 6 Petrosectomy

No.	Age	Side	Duration (min)	Previous ipsilateral surgery	Pre-op mean air-bone gap[1]	Post-op mean air-bone gap[1]	Closure	Graft material	Follow up (mo)	Complications
Endoscopic assisted, Group A

Non-endoscopic assisted, Group B										
1	79	R	253	No	Dead ear	90	No change	Not stated	6	referral for cochlear implant

[1]Mean gap calculated over 4 frequencies (500 Hz, 1 KHz, 2 KHz, 4 KHz). CSF: Cerebrospinal fluid; TM: Tympanic membrane.

CSOM and cholesteatoma surgery

Mean operating time was shorter in Group A compared to Group B (171 min *vs* 217.2 min respectively). Since total number of operations here were not equal (n = 15 *vs* n = 10), it is unreliable to claim the difference between these figures is of clinical significance. Variation in anatomy and pre-operative disease state (*e.g.*, actively discharging ear), will also have implications on duration of operation due to technical difficulty.

Cholesteatoma can vary in anatomical spread and severity of disease. In widespread, severe cases, canal wall up mastoidectomy or modified radical mastoidectomy can be performed. Our case series shows a variation in the number of these procedures between both groups. Performing mastoidectomy exclusively with an endoscope is impossible, and therefore drawing comparisons between these groups is difficult, as the endoscope will not have been used during a proportion of surgery in Group A. However, only the endoscope was used for the entire operation where there were cases of limited cholesteatoma, or recurrent disease in revision surgery. Recent literature supports this, demonstrating that an exclusively endoscopic approach can be very useful as a "second look" surgery in in order to identify residual cholesteotoma[11].

The most widely documented use of endoscopic ear surgery has been for cholesteatoma disease. Some studies have examined the use of the endoscope as an adjunct for surgery. Residual cholesteatoma rates in closed cavity surgery have been documented around 9%, which is comparable to use with a microscope alone[14]. One study examined its use peri-operatively after surgery using the microscope. Residual disease was identified in 65/80 cases, and was documented to commonly occur on the stapes footplate, the stapes crura, and the sinus tympani[13]. The use of the endoscope has also been shown to decrease the rate of "open tympanoplasty" during this surgery. Results for localised attic disease have achieved air bone gap closure within 20 dB in around 90% of patients between 3 and 6 years follow up. Figures of 80% disease-free follow up have also been documented on 27 cases with limited attic retractions[6]. Our series demonstrates relatively efficient use of the endoscope during revision surgery, which highlights the importance of a good visibility during technically challenging operations within the middle ear. However longer follow up is required to confirm its efficacy in these revision cases.

Stapedectomy

Our case series of 11 stapedectomies performed using a 4 mm endoscope at 0 and 30 degrees demonstrated the preservation of the chorda tympani all cases, as well as achieving significant improvement in pre and post-operative air-bone closure (P < 0.05) where thresholds were within < 30 dB for all cases. By comparison, the 9 operations performed without the endoscope, also show significant improvement in pre and post-operative air bone gap (P < 0.05), but with a longer mean duration of surgery (136.4 min *vs* 175.2 min for Group A and B respectively). First described by Poe in 2000, endoscopic stapedectomy has gone on to show promise in other countries across the world, achieving significant improvement in air bone gap by comparing pre and post-operative hearing thresholds[1,15]. Our series is in keeping with this.

Petrosectomy

There are some reports of successful use of the endoscope during cholesteatoma surgery within the petrous apex, as was used for one case in our series[22]. Due to the discovery of a CSF leak intra-opertively, the duration of surgery is much higher compared to the non-endoscopic assisted surgery. It is difficult to compare these two surgical approaches for this operation from this single case series.

Clinical applicability

Endoscopic surgery has also been used in a variety of neuro-otological procedures, including acoustic neuroma surgery. Some centres have also begun using it as the first surgical option or as an adjunct to conventional posterior tympanotomy approach in cochlear implantation[23-25]. Its benefit as an adjunct to conventional surgical techniques where wider exposure is required due to a limited direct vision has been well recognised[4,17,18]. Cadaveric studies using the endoscope alone have also documented superior views of the internal acoustic meatus over conventional

techniques, although clinical applicability for this may well take several years to develop[23,25].

The endoscopic technique in ear surgery undoubtedly gives better quality images and access to blind sacs around the middle ear space that would otherwise not have been visualised adequately using a microscope, irrespective of surgical approach. It is minimally invasive thus providing better cosmesis in patients who do not wish to have a scar. Its use in the outpatient setting has gained popularity by consultant otolaryngologists and junior trainees due to its accessibility, portability and superiority over hand drawn diagrams of the tympanic membrane, which often can be unreliable and inaccurate. In addition, our series demonstrates a role in revision mastoid surgery in particular, where, for example, the cavity can be revised by curettage of a high "facial ridge" entirely endoscopically and permeatally.

The most commonly used rigid endoscopes are 18 cm long and 4 mm (as used for all operations in this case series). Some surgeons find this endoscope difficult to manoeuvre due to its length and larger diameter, and advocate using a paediatric nasal endoscope which is 2.7 mm diameter and 11 cm long[1]. However these endoscopes generate poor views and 3 mm endoscopes are available and better suited for ear surgery. Ideally, an endoscope with a small diameter, and shorter length, possibly with a modification to allow the surgeon to keep two hands free but that retains light intensity within a wider field, would be ideal for operating on the middle ear.

In addition, it is worth nothing that there is a learning curve when using any new technique. This may be improved for otolaryngologists where we regularly use the endoscope during endoscopic sinus surgery for example.

Limitations

The numbers for each operation in our prospective case series is low, leaving the study underpowered. However, this case series serves as a pilot study to open the debate of endoscopic ear surgery in the United Kingdom. To enhance our results, more cases would need to be examined in a similar prospective fashion. Only then could reliable conclusions be drawn from comparing endoscopic and open techniques.

Another limitation is the small number in each group, addressed above in regard of the power of the study, alongside the groups being somewhat heterogeneous particularly in the largest group of mastoid and tympanoplasty surgery. However we need to group the surgeries into a grading from simple to complex and these groupings certainly serve to follow this. The groupings, like the above point, serve to illustrate the possibilities of the endoscope rather than to compare the surgeries themselves. Likewise, including in our series, grommet insertion and petrosectomy demonstrates the utility of the endoscope, despite the few numbers. This will be of value and interest to the readership to investigate further despite the small numbers.

The role of endoscopic ear surgery is yet to be properly established but as more otologists adopt this technique, its role will become much more clearly defined and may lead to widespread use based upon positive outcomes for surgery. As with every new surgical technique, a learning curve must first be overcome before reliable conclusions can be drawn about its use. Our series has shown the benefits of using this technique in limited cholesteatoma disease and in providing a good view during revision mastoid surgery with simple pathology.

COMMENTS

Background

Endoscope assisted ear surgery is increasingly common. However its role has not been properly elucidated. The authors investigate potential roles across a range of otological procedures.

Research frontiers

Minimal access surgery from robotic to endoscopic approaches are being increasingly analysed.

Innovations and breakthroughs

This study highlights the role of endoscope surgery in revision mastoid surgery alongside the more well-established role in stapedectomy. The endoscope allows excellent visualisation of the middle ear cleft and any cholesteatoma.

Applications

The endoscope can assist in mastoid surgery, particularly in revision cases. It also has a role in stapedectomy and other middle ear surgery.

Peer-review

Authors described their experience about endoscopic ear surgery. As mentioned by authors, this surgical procedure has already been described in case series numerically significant.

Abstract

May-Thurner syndrome (MTS) also termed iliocaval compression or Cockett-Thomas syndrome is a common, although rarely diagnosed, condition in which the patient has an anatomical variant wherein the right common iliac artery overlies and compresses the left common iliac vein against the fifth lumbar spine resulting in increased risk of iliofemoral deep venous thrombosis. This variant has been shown to be present in over 23% of the population but most go undetected. We present a patient with MTS who developed high output cardiac failure due to an iatrogenic iliac fistula. The patient underwent an extensive workup for a left to right shunt including MRI and arterial duplex in the vascular lab. He was ultimately found to have a 2.1 cm left common iliac artery aneurysm and history of common iliac stent. We took the patient to the operating room for aortogram with placement of an endovascular plug of the left internal iliac artery and aorto-bi-iliac stent graft placement with CO_2 and IV contrast. Subsequently the patient underwent successful stent placement in the area that was compressed followed by 6 mo of anticoagulation with warfarin. The flow from the fistula decreased significantly.

Key words: May-Thurner syndrome; Cardiac failure; Echocardiogram; Cockett-Thomas syndrome; Iliocaval compression

Core tip: To our knowledge, we describe the first case of high output cardiac failure due to iatrogenic iliac fistula and its management in the setting of May-Thurner syndrome (MTS). In our case, an iatrogenic iliac fistula resulted because of prior stent placement in left iliac vein to prevent deep venous thrombosis (DVT) secondary to MTS. We favored aorto-bi-iliac stent graft placement to prevent the fistula from leaking. In our case, the prior vascular stent placement was a clue to search for the fistula. It is important to note that stent placement to prevent DVT in MTS may result in iatrogenic fistula formation.

INTRODUCTION

May Thurner syndrome (MTS) or iliocaval compression or Cockett-Thomas syndrome is a fairly common well recognized and rarely diagnosed condition. McMurrich first described this anatomical variant in 1908 and believed the variant was the result of "congenital adhesions" in the common iliac veins. May and Thurner published this syndrome in 1957 and it was widely recognized as MTS in United States. In Europe, however, Cockett, a British vascular surgeon and Thomas published the condition in 1965 and it was termed Cockett-Thomas Syndrome. May and Thurner postulated that the chronic pulsations of the overlying right iliac artery led to development of a "spur" in the vein wall and that this spur would result in partial venous obstruction.

CASE REPORT

A 61 years old male was admitted to our cardiology service for shortness of breath associated with hemodynamic instability (systolic blood pressure, 95mm Hg and diastolic blood pressure, 59 mmHg). His past medical history is significant for hypertension, congestive heart failure, coronary artery disease (post coronary artery bypass graft - 1999), MTS [treated with left iliac vein stent in absence of PE and deep venous thrombosis (DVT) in 2001], chronic pulmonary embolism, protein C deficiency, restrictive lung disease and mild obstructive lung disease. Additionally, the patient smokes half a pack daily for 30 years.

His immediate physical examination revealed hypotension (105/46 mmHg), jugular venous distension of 6 cm, 2/6 pansystolic murmur at the apex, and bilateral pedal edema was noted. Abdomen was soft and non-tender but was distended with normoactive bowel sounds and and liver edge 1 cm below the costal margin. A chest x ray showed mild cardiomegaly with prominence of the central pulmonary arteries (Figure 1). Initial BNP and fibrinogen levels were both elevated (166.7 hh pg/mL and 553 mg/dL). Other blood tests supported renal insufficiency (creatinine 1.68 mg/dl). Echocardiogram revealed diffuse hypokinesia with a low ejection fraction (35%), cardiac output (11.5 L/min), cardiac index (5.54 L/min per square), end diastolic volume (183 mL), end Systolic volume (101 mL), concentric left ventricular hypertrophy, abnormal diastolic relaxation and mild to moderate mitral regurgitation.

Vascular surgery was consulted for evaluation of a possible pelvic shunt/fistula. After extensive workup for a left to right shunt including MRI and arterial duplex, the patient was found to have a 2.1 cm left common iliac artery aneurysm (21.4 mm) (Figure 2). An Inferior Vena Cava duplex and computed tomography (CT) of the pelvis found evidence of atriovenous fistula at the left iliac vein (discovered 11 years after the initial stent was placed in 2001) (Figure 3).

The patient was taken for an aortogram and heparinized with 5000 units of IV heparin. The right common femoral artery was then accessed and a 5-French sheath was advanced over the wire. An Omniflush catheter was then positioned at the level of L1. The patient had evidence of a high volume fistula from within the left common and hypogastric artery on CO_2 aortogram. Given this finding, an additional magnified view was obtained with the Omniflush catheter positioned at the aortic bifurcation. The Glidewire and Omniflush catheter were then used to select the left hypogastric artery. A 6-French Balkan sheath was brought up and over Magic Torque wire and into the left hypogastric artery. The Amplatz 16 mm plug was then advanced into the distal hypogastric artery. This appeared to be distal to any evidence of the fistula. The plug was then deployed in proper position. Next, a marker pigtail catheter was advanced from the right groin. The left groin cutdown was then performed, using a transverse incision. A 5-French sheath was advanced over the wire. A J-wire was advanced into the descending thoracic aorta. This was exchanged for a Lunderquist wire over the stiff wire. A CO_2 aortogram was again performed. This demonstrated the level of the renal arteries. The main body device, Cook Zenith TFB-28-74 was brought over the Lunderquist wire in the left groin. This was deployed down to the level of the contralateral gate. The pigtail catheter was then pulled down and the top cap was deployed securing the position of the graft. Next, a Kumpe catheter was used to select the contralateral limb from the right femoral sheath. The pigtail catheter was spun confirming proper position. An Amplatz wire was advanced from the right groin. A retrograde injection of contrast was performed from the right groin. Next, the contralateral limb, which was a Cook ZSLE-20-39-ZT, was then deployed with care taken to preserve flow to the right hypogastric artery. Next, the remainder of the main body device was deployed from the left groin. The top cap was then retrieved, and the sheath was removed. Due to the incompetence of a valve, the sheath was then replaced with a Gore DrySeal 18-French Sheath. Next, a retrograde injection of contrast was performed from the left groin. The ipsilateral limb, which was a Cook ZSLE-13-90-ZT was brought onto the field and prepped. This was deployed with care taken to ensure 5 cm of overlap into the left external iliac artery. A 32-French Coda balloon was then used to balloon the proximal and distal sites of fixation, as well as all zones of overlap. Wires were exchanged for a soft wire. This demonstrated evidence of a persistent flow within

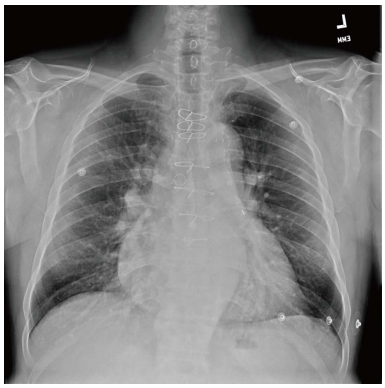

Figure 1 Chest X-ray showing mild cardiomegaly with prominence of central pulmonary arteries.

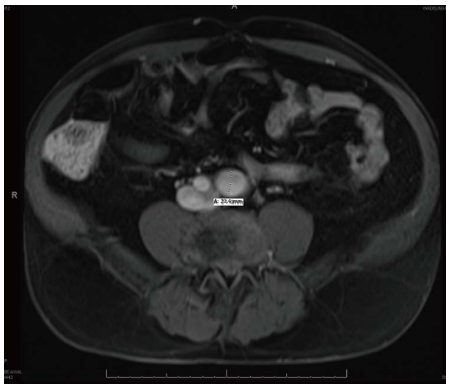

Figure 2 Magnetic resonance imaging of pelvis mark "A" shows 21.4 mm diameter of left common iliac artery.

the fistula that appeared to be less than previous. A completion aortogram was performed. By the end of the procedure cardiac output and cardiac index returned to normal and patient remained stable. Flow through the fistula stopped.

DISCUSSION

MTS is a fairly common, well recognized and rarely diagnosed condition[1]. McMurrich believed the variant was the result of "congenital adhesions" in the common iliac veins[2]. May and Thurner published this syndrome in 1957 and it was widely recognized as MTS in United States whereas Cockett and Thomas published it in 1965 and called the same condition Cockett-Thomas Syndrome in Europe[3]. May and Thurner postulated that the chronic pulsations of the overlying right iliac artery led to development of a "spur" in the vein wall and that this spur would result in partial venous obstruction[4]. Of 430 cadavers, 22% were diagnosed with spurs on left side which is eight times more common than on the right. This came a century after Virchow (1851) first described that thrombosis on the left side was five times more common than on the right side[5]. More recently Kibbe *et al*[6] demonstrated *via* CT the incidence of MTS in asymptomatic patients that correlated with autopsy results reported in the ealy half of twentieth century.

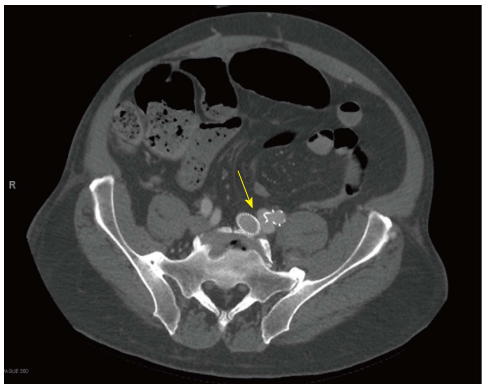

Figure 3 Computed tomography pelvis showing atriovenous fistula of left iliac vessels (yellow arrow) and stent in abdominal aorta.

The goal of treatment of MTS is to reduce symptoms and to reduce the risk of complications. The majority of treatments are geared towards treating DVT. The first known report of treatment of MTS solely by endovascular means was by Berger *et al*[7] in 1995, who successfully placed a venous stent to relieve iliac compression. The initial step in the treatment of DVT in the setting of MTS is thrombectomy with stent placement[8]. Vena Cava filters may be a treatment option for select patients who cannot take anticoagulant medications. Vena Cava filters may not always be used in the treatment of MTS but are used to prevent complications of DVT.

To our knowledge, ours is the first case to report high output cardiac failure due to iatrogenic iliac fistula and its management in MTS. In this case, an iatrogenic iliac fistula resulted because of prior stent placement in left iliac vein to prevent DVT secondary to MTS. We favored aorto-bi-iliac stent graft placement to prevent the fistula from leaking. We managed to successfully reduce cardiac output (11.5 L/min to 8.3 L/min) and cardiac index (5.54 L/min per m sq to 4.0 L/min per squre).

It is important for the practicing physician to note that the identification of high output cardiac failure should lead to a search for the source. In our case, the prior vascular stent placement was a clue to search for the fistula. It is also important to note that stent placement to prevent DVT in MTS can result in iatrogenic fistula.

ACKNOWLEDGMENTS

We thank Prashant Bhensdadia (MD) (Division of Cardiology, Wake Forest Health, 27157), for bringing to notice this interesting case.

COMMENTS

Case characteristics

The patient presented with shortness of breath and bilateral pedal edema.

Clinical diagnosis

The patient was found to high output cardiac failure due to iliac fistula resulting from prior management of May-Thurner syndrome.

Differential diagnosis

Based on patient history, physical exam, and imaging the authors were able to narrow down on the diagnosis by ruling out severe anemia, paget's disease of bone, hyperthyroidism and beriberi.

Imaging diagnosis

The images were obtained by angiography and chest X ray.

Treatment

The patient underwent angiography and stent placement.

Related reports

Abstract

Facial nerve schwannoma occurring within the parotid gland is a rare tumour. We report a case of schwannoma within the parotid gland in a young female patient, who underwent ultrasound and magnetic resonance imaging (MRI) and subsequent surgical excision of the lesion. The lesion showed hyperintensity on T2-weighted and diffusion-weighted MRI. There was no adjacent lymphadenopathy. Although hyperintensity on diffusion-weighted MRI could suggest malignant tumours, the characteristic "string sign" provided the clue for the diagnosis of schwannoma.

Key words: Parotid; Facial nerve; Schwannoma; String sign; Imaging

Core tip: There is a difference in an approach to surgery for benign and malignant parotid masses. For benign lesions, superficial parotidectomy is done; whereas in a case of malignant tumour total parotidectomy is performed with or without excision of the facial nerve. Clinically, it is very difficult to differentiate them because even malignant tumours have slow growth. Hence, here comes the role of imaging which could suggest the nature of the mass and narrow the differentials.

Jaiswal A, Mridha AR, Nath D, Bhalla AS, Thakkar A. Intraparotid facial nerve schwannoma: A case report. *World J Clin Cases* 2015; 3(3): 322-326 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i3/322.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i3.322

INTRODUCTION

Schwannomas of the Facial nerve (FN) are rare benign encapsulated neurogenic lesions. These can arise anywhere along its course[1,2]. Majority of these schwannomas are seen in the intratemporal course of the nerve whereas only 9% are seen in the extratemporal course[3]. In a case series of parotid tumours, schwannomas were found to be very rare accounting for only 2 out of 142 lesions[4]. As presentation is often nonspecific, preoperative

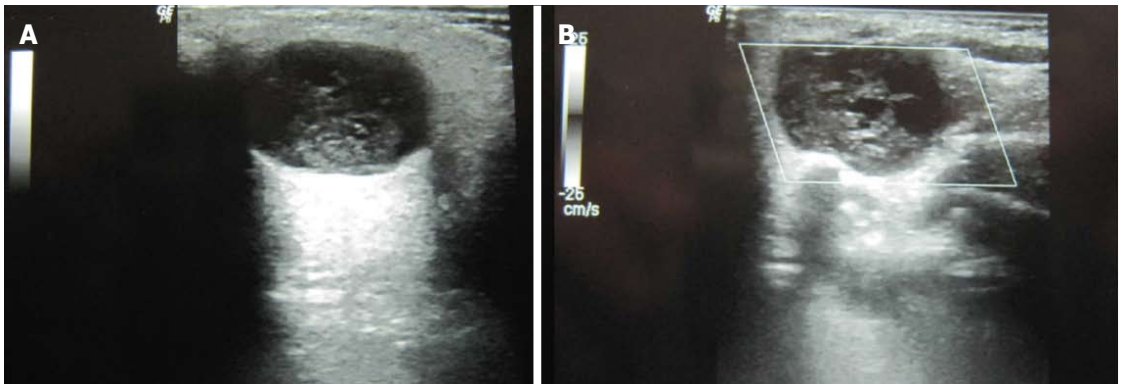

Figure 1 Ultrasound images. A: Left parotid gland shows presence of well defined hypoechoic mass lesion in the superficial lobe with posterior acoustic enhancement; On Color Doppler (B), no internal vascularity could be demonstrated.

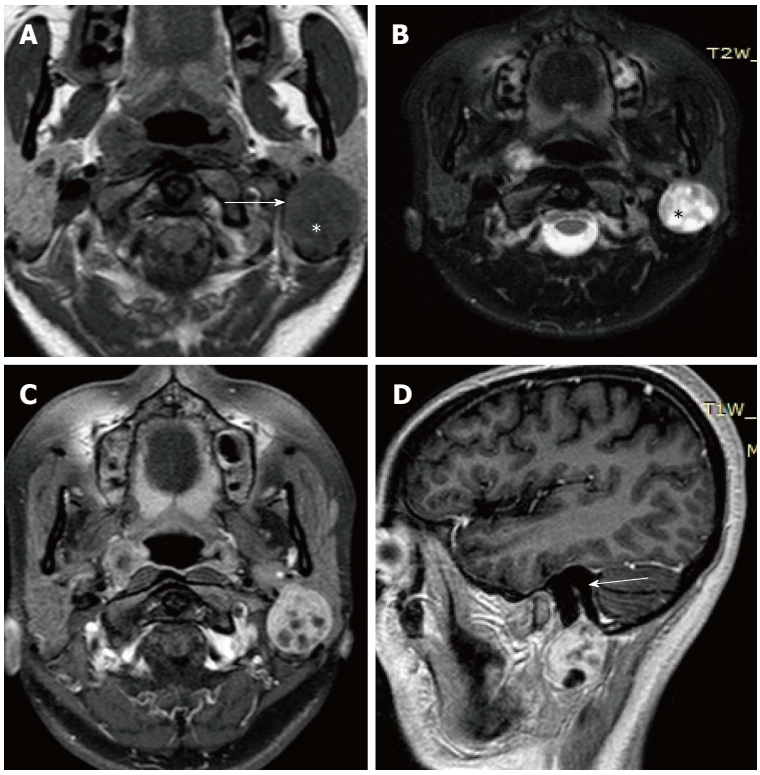

Figure 2 Magnetic resonance imaging images at the level of parotid glands-axial T1W (A), axial T2W (B), Post Gad T1W images in axial (C) and sagittal (D)planes. Arrow in (A) shows presence of well defined intermediate signal intensity mass lesion in the superficial lobe of left parotid with hypointense areas within it (*). These regions (*) are hyperintense on T2W sequence (B) suggestive of myxomatous tissue.On Post contrast images (C and D), the mass enhances homogeneously with few non enhancing areas within. Arrow in D shows the characteristic "string sign" extending along with facial nerve in the stylomastoid foramen.

diagnosis of these tumours is difficult[4].

Clinically these patients do not have any facial nerve dysfunction whereas postoperatively features of facial nerve paresis are common. Hence, it becomes extremely necessary for the surgeon to warn the patient regarding this complication beforehand.

CASE REPORT

A 27-year-old healthy female presented in the surgical clinic with a slow growing painless swelling in the left retromandibular region for the last one year. There was no history of fever or any other constitutional symptoms. Physical examination revealed a soft, non-tender lump measuring approximately 3 cm × 2 cm. Laboratory tests such as complete haemogram, ESR, CRP were found to be within normal limits. Ultrasound examination showed the presence of a well defined, hypoechoic mass in the superficial lobe of left parotid which measured approximately 1.8 cm × 2.3 cm (Figure 1A). The mass showed anechoic areas within it with posterior acoustic enhancement suggestive of cystic component. No calcification or adjacent lymphadenopathy was seen. Color Doppler examination (Figure 1B) did not show any internal vascularity. The differential diagnoses were benign pathologies such as pleomorphic adenoma or less likely an intraparotid lymph node. For further characterisation of the lesion, MR examination of the parotid was performed. MR imaging (Figure 2) revealed a well-circumscribed mass lesion in the left parotid gland. The mass was located just below the stylomastoid foramen with a beak like protrusion into it representing the classic "string sign". T1-weighted

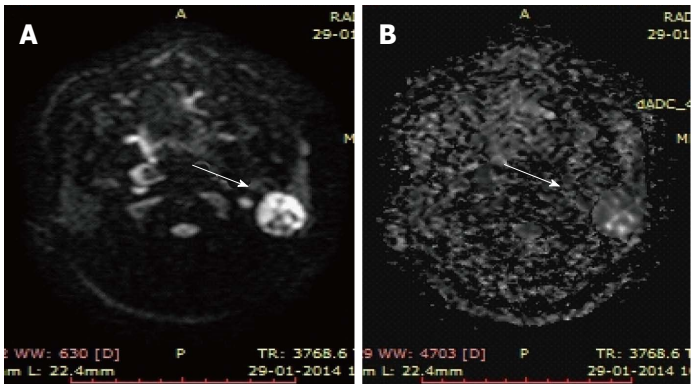

Figure 3 Axial diffusion weighted magnetic resonance imaging. (A) At b = 1000 s/mm^2 hyperintensity is noted throughout the mass (arrow) except the cystic areas. These regions were dark (arrow) on ADC map (B) consistent with restricted diffusion.

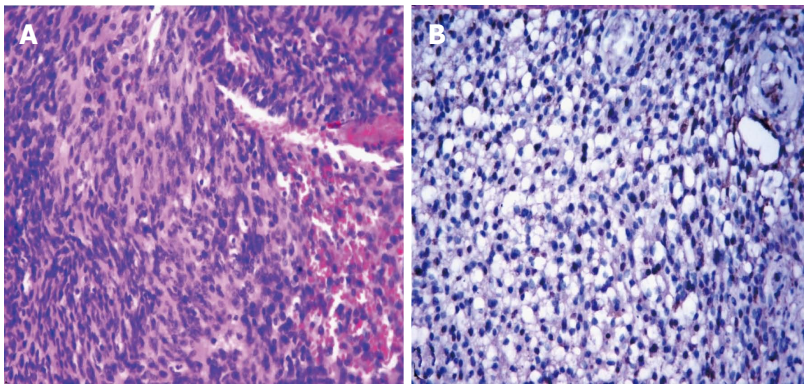

Figure 4 Haematoxylin and eosin stained section shows spindle cells arranged in fascicles (A, × 200). The tumour cells are immunoreactive with S-100 protein (B, × 200).

image (Figure 2A) showed the tumour to be of intermediate signal intensity compared to adjacent muscle, and T2-weighted image (Figure 2B) showed high signal intensity with interspersed areas of lower signal intensity. DWI (Figure 3) showed hyperintensity at b = 1000 s/mm^2 suggestive of restricted diffusion in the solid part of the lesion with facilitated diffusion in the cystic part. On surgical exploration, the mass was found to be in close relationship with the main trunk of facial nerve just below stylomastoid foramen. Postoperatively, the patient developed mild facial paresis. The tumour was histopathologically confirmed to be schwannoma. The spindle cells were immunopositive with S-100 (Figure 4).

DISCUSSION

Schwannomas are benign nerve sheath tumours, composed entirely of differentiated neoplastic Schwann cells. Intraparotid FN schwannoma was first reported by Ibarz in 1927. Since then, fewer than 100 cases of FN schwannomas have been reported. In a study by Fortan *et al*[3], majority of the lesions were found within the intratemporal course, whereas about 9% of the tumours were found in the parotid gland[3]. The frequency of intraparotid schwannomas range from 0.2% to 1.5%[5]. Because of its low prevalence and very few typical clinical and radiological signs associated with it, preoperative diagnosis of intraparotid FN schwannoma is generally difficult.

In a case series of FN schwannomas, the most common clinical manifestation in intratemporal involvement of the nerve was facial nerve dysfunction, whereas in extratemporal course, it was a parotid mass without facial paresis[6].

In patients with a parotid mass, associated facial nerve palsy generally indicates malignancy. But it can also be seen in benign parotid masses such as pleomorphic adenoma and Warthin's tumour. However, none has been reported in intraparotid schwannoma[7].

Similarly in our case, the patient presented with a parotid mass without facial nerve dysfunction, it thus became very difficult to clinically diagnose the schwannoma without the aid of imaging modalities. Ultrasound evaluation in our case showed a well-defined mass with cystic areas within it. Ultrasound when coupled with newer techniques like elastography can help in differentiating benign from malignant parotid masses[8].

MRI images showed that the mass was situated just below the stylomastoid foramen with beaking into the foramen producing the characteristic "string sign". The string sign is due to the vertical orientation of soft tissue on either ends of the mass. The string represents the normal entering or exiting nerve that is in continuity with the nerve sheath tumour.

MRI features described in four cases of facial nerve schwannomas showed heterogeneous lesions that were isointense to brain on both T1- and T2-weighted images[9]. In the present case, the tumour was well defined, isointense and heterogeneously hyperintense to muscle on T1 and T2 weighted images respectively.

Schwannomas may exhibit "target" sign which is characterized by hyperintensity in the periphery

while hypointensity in the centre on T2-weighted images. "Target sign" of neurofibroma is almost pathognomonic[10]. This feature is suggestive of neurogenic neoplasm[11]. In schwannomas, the target sign is due to compactly packed cellular Antoni A regions which is located centrally and loose myxomatous Antoni B regions in the peripheral part[11]. In our case, classical target sign was not observed.

Diffusion weighted imaging features of parotid schwannoma have not been previously described. Restricted diffusion in our case reflects high cellularity of the tumour, supporting the observation that restricted diffusion can be seen in both malignant and benign lesions[12].

Pleomorphic adenomas are the most common tumours of the parotid gland, and a close differential of intraparotid schwannoma due to it being well circumscribed, heterogeneous and hyperintense on T2W sequences[13]. But the presence of "string sign" reasonably excluded the possibility of pleomorphic adenoma in our case.

Adenoid cystic carcinoma, another close differential, is a malignant tumour that has the potential to spread along the nerve sheath[14]. Malignant tumours are hypointense on T2-weighted images and show ill-defined margins on post contrast images[15]. However, T2 hyperintensity and smooth enlargement of the facial nerve canal excludes this diagnosis[14].

In cases of painless swellings of the parotid gland without any neurological involvement, possibility of intraparotid schwannoma should be considered under differentials and the imaging modalities especially MRI revealing characteristic "string sign" further confirms the diagnosis.

COMMENTS

Case characteristics

The patient presented with a slow growing painless swelling in the retromandibular region on left side for the last 1 year.

Clinical diagnosis

The patient's symptoms were nonspecific and presence of painless progressive swelling over a period of 1 year pointed to its benign nature.

Differential diagnosis

Pleomorphic adenoma was ruled out as there was "string sign" showing extension along the facial nerve into the stylomastoid foramen. Adenoid cystic carcinoma was ruled out as the mass showed T2 hyperintensity and well defined margins. Malignant tumours are T2 hypointense with ill defined margins. Even extension into stylomastoid foramen was accompanied by smooth enlargement of the foramen without any irregular erosion.

Laboratory diagnosis

Blood tests were non contributory.

Pathological diagnosis

The excised tumour measured 2.5 cm × 2 cm. Cut surface was fleshy with focal haemorrhage. Microscopic examination showed cellular spindle cells arranged in fascicles. Tumour cells exhibited oval to elongated hyperchromatic nuclei, inconspicuous nucleolus, and fibrillary eosinophilic cytoplasm. Few thick walled blood vessels were seen. No mitosis or necrosis was seen. The tumour cells were immunopositive with S-100; while negative for smooth muscle actin and estrogen receptor. MIB-1 labelling index was < 2%. A diagnosis of schwannoma was given.

Treatment

Under general anaesthesia, excision of the tumour mass was done and sent for histopathological examination.

Related reports

Chung SY *et al* article Facial nerve schwannomas: Computed tomography and magnetic resonance findings published in 1998 in *Yonsei Med J* provide a brief but cumulative overview on the case topic.

Term explanation

Facial nerve schwannoma is a rare neurogenic tumour that arises from the schwann cells of the neurons.

Experiences and lessons

One lesson that the authors learnt from this case was to consider facial nerve schwannoma in the differential diagnosis of parotid mass when a patient presents with painless progressive swelling and imaging shows characteristic "string sign". Restricted diffusion reflects its high cellularity, supporting the observation that restricted diffusion can be seen in both malignant and benign lesions.

Peer-review

Good paper.

Abstract

Achalasia is a prototypic esophageal motility disorder with complications including aspiration-pneumonia, esophagitis, esophageal-tracheal fistula, spontaneous rupture of the esophagus, and squamous cell carcinoma. However, achalasia is rarely associated with esophageal stones and ulcer formation that lead to upper gastrointestinal bleeding. Here, we report the case of a 61-year-old woman who was admitted to our department after vomiting blood for six hours. Physical examination revealed that the patient had severe anemia and mild palpitation in the upper abdomen. CT revealed lower esophageal dilatation and esophageal wall thickening, and an emergency upper endoscopy showed that the esophagus was substantially expanded by a dark round stone, with multiple ulcers on the esophageal wall and a slit in the cardiac mucosa with a large clot attached. The patient's history included ingestion of 1 kg hawthorn three days prior. The acute upper gastrointestinal bleeding was caused by Mallory-Weiss syndrome associated with achalasia and an esophageal stone. For patients with achalasia, preventing excessive ingestion of tannins is crucial to avoid complications such as bleeding and rupture.

Key words: Achalasia; Esophageal stone; Mallory-Weiss syndrome; Upper gastrointestinal bleeding

Core tip: Achalasia is the prototypic esophageal motility disorder that leaves patients at risk for various complications. This is a rare report of long-term achalasia associated with esophageal stone and ulcer formation leading to upper gastrointestinal bleeding caused by Mallory-Weiss syndrome. This paper highlights the importance of avoiding excess tannin ingestion for patients with achalasia to prevent the development of complications such as bleeding and rupture.

Zhang WW, Xie XJ, Geng CX, Zhan SH. Rare case of upper gastrointestinal bleeding in achalasia. *World J Clin Cases* 2015; 3(3): 327-329 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i3/327.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i3.327

INTRODUCTION

Achalasia is the prototypic esophageal motility disorder

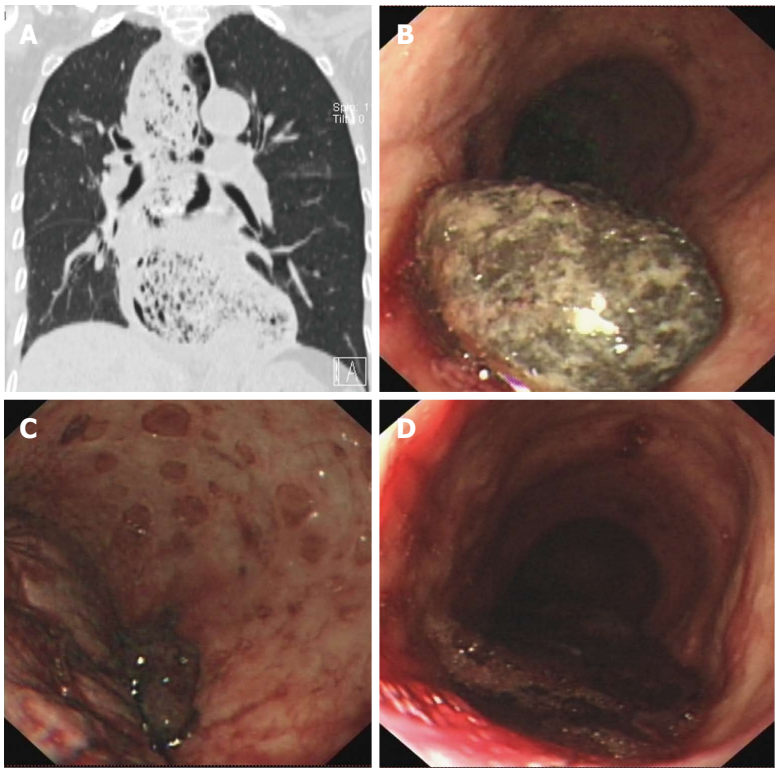

Figure 1 CT and endoscopy imaging. A: CT showed lower esophageal dilatation and esophageal wall thickening; Upper endoscopy revealed; B: A large, dark round stone; C: Multiple ulcers on the esophageal wall; D: A slit in the cardiac mucosa with a large clot attached.

characterized by a hypertensive lower esophageal sphincter with incomplete relaxation upon swallowing, accompanied by aperistalsis of the esophageal body[1]. Patients with achalasia are at risk for developing complications such as aspiration-pneumonia, esophagitis, esophageal ulcers and bleeding, esophageal-tracheal fistula, spontaneous rupture of the esophagus, and squamous cell carcinoma[2]. The prevalence is 10 per 100000 in the United States, involving an equal distribution of men and women of all ages and from all ethnicities[3]. We report a rare case of upper gastrointestinal bleeding in a patient with achalasia that was associated with an esophageal stone, ulcer formation and Mallory-Weiss syndrome.

CASE REPORT

A 61-year-old woman who complained of vomiting blood for six hours was admitted to our department. She experienced dizziness, palpitations, sweating, and fatigue, but did not present with fever, rash or jaundice. Her medical history revealed achalasia that had been present for 30 years, for which she had declined any treatment. When questioned, she reported ingesting 1 kg hawthorn within the past 3 d.

A physical examination indicated that the patient had severe anemia due to pale conjunctiva and nail beds, and mild palpitation in the upper abdomen. Routine blood tests showed: red blood cell count, 1.34×10^{12}/L; hemoglobin, 41 g/L; white blood cell count, 11.25×10^{9}/L; platelet count, 150×10^{9}/L; blood urea nitrogen, 15.99 mmol/L; and creatinine, 98 μmol/L. Lower esophageal dilatation and esophageal wall thickening were revealed upon CT examination (Figure 1A). An emergency upper endoscopy was performed revealing substantial expansion of the esophagus by a dark round stone (Figure 1B), multiple ulcers on the esophageal wall (Figure 1C), and a slit in the cardiac mucosa with a large clot attached (Figure 1D). Endoscopic sprinkling hemostasis and injection of 2.5% sodium bicarbonate were applied to cease the bleeding and dissolve the stone.

DISCUSSION

In achalasia, injury to the lower esophageal sphincter neurons and the loss of the main functional inhibitory neurotransmitter result in a hypertensive sphincter that loses its ability to relax, leading to stenosis of cardia and lower esophagus expansion. Occasionally, patients will present with persistent food retention, and esophageal stone formation can occur in those who have ingested foods rich in tannins, such as hawthorn and persimmon. The pressure of stones can cause multiple ulcers and even upper gastrointestinal bleeding. The discomfort when swallowing and frequent nausea and vomiting can then lead to the development of Mallory-Weiss syndrome.

Currently, there are no curative treatments for achalasia cardia, rather palliative measures are provided, such as oral nitrates or calcium channel blockers, endoscopic pneumatic dilation, injection of sclerosant substances, or surgery[4-6]. However, complications such as bleeding and rupture can be prevented by avoiding excessive ingestion of tannins.

COMMENTS

Case characteristics

A 61-year-old female patient complained of vomiting blood for six hours.

Clinical diagnosis

Acute upper gastrointestinal bleeding from Mallory-Weiss syndrome associated with achalasia.

Laboratory diagnosis

Red blood cell count, 1.34 × 10^{12}/L; hemoglobin, 41 g/L; white blood cell count, 11.25 × 10^{9}/L; platelet count, 150 × 10^{9}/L; blood urea nitrogen, 15.99 mmol/L; creatinine 98 μmol/L.

Imaging diagnosis

CT showed lower esophageal dilatation and esophageal wall thickening. Upper endoscopy revealed a large round stone causing substantial expansion of the esophagus and multiple ulcers on the esophageal wall. A slit in the cardiac mucosa was observed with a large clot attached.

Treatment

Endoscopic sprinkling hemostasis and injection of 2.5% sodium bicarbonate were applied to cease the bleeding and dissolve the stone.

Related reports

Although there are some reports of achalasia combined with esophageal intramural hematoma or esophageal varices, reports of achalasia combined with esophageal stones, ulcer formation and Mallory-Weiss syndrome are rare.

Term explanation

Achalasia is characterized by esophageal aperistalsis and impaired relaxation of the lower esophageal sphincter.

Experiences and lessons

This report not only presents a rare case of upper gastrointestinal bleeding associated with achalasia, but also aims to inform patients with achalasia to avoid excessive ingestion of tannin-rich foods to prevent related complications.

Peer-review

This is a very interesting manuscript reporting a rare case of upper gastrointestinal bleeding as a result of long-term achalasia associated with esophageal stones.

Abstract

Hereditary hemorrhagic telangiectasia (HHT) is a relatively common inherited vascular disorder that was first described in 1864, and is notable for epistaxis, telangiectasia, and arterial venous malformations. While genetic tests are available, the diagnosis remains clinical, and is based on the Curacao criteria. Patients with HHT are at increased risk for both bleeding and clotting events. Because of these competing complications, hematologists are often faced with difficult clinical decisions. While the majority of management decisions revolve around bleeding complications, it is not infrequent for these patients to require anticoagulation for thrombosis. Any anticoagulation recommendations must take into account the bleeding risks associated with HHT. Recent reviews have found that HHT patients can be safely anticoagulated, with the most frequent complication being worsened epistaxis. Large clinical trials have shown that factor Ⅱa and Ⅹa inhibitors have less intracranial bleeding than warfarin, and basic coagulation research has provided a possible mechanism. This article describes the anticoagulation dilemma posed when a 62-year-old female patient with a history of bleeding events associated with HHT was diagnosed with a pulmonary embolism. The subsequent discussion focuses on the approach to anticoagulation in the HHT patient, and addresses the role of the new oral anticoagulants.

Key words: Anticoagulation; Hereditary hemorrhagic telangiectasia; Hemorrhage; Thrombosis; Rivaroxaban; Apixaban; Dabigatran; Warfarin

Core tip: This article reviews an inherited disorder, hereditary hemorrhagic telangiectasia, in the context of a complicated clinical case. It highlights the problem of balancing the risks of bleeding and thrombosis, and raises the question of whether the new oral anticoagulants might provide safer therapy in such patients who need antithrombotic therapy.

CASE PRESENTATION

A 62-year-old female presented to our hematology clinic with previously diagnosed hereditary hemorrhagic telangiectasia (HHT). The patient had lifelong complications associated with this illness, including recurrent epistaxis and pulmonary arteriovenous malformations (AVMs). The patient had received multiple embolization procedures in the past to prevent complications from her pulmonary AVMs. The epistaxis was debilitating, with episodes occurring up to 5 times per day. Further medical history included the presence of a heterozygous prothrombin gene mutation ($PT^{A20120G}$), discovered from a thrombophilia evaluation for recurrent superficial phlebitis 5 years prior. The patient's more recent medical history included the development of a brain abscess 6 mo prior to presentation, which was treated with surgical evacuation. During her post-operative course, she developed a pulmonary embolism (PE) secondary to a deep venous thrombosis (DVT) in her left lower extremity. Initially, the patient was treated with the insertion of an inferior vena cava (IVC) filter, which was placed because of HHT-related bleeding concerns. The IVC filter ultimately developed extensive thrombosis, and the patient was initiated on warfarin therapy 3 mo prior to presentation. Since warfarin was initiated, she has had an increase in the severity of her epistaxis, but not the frequency. On physical exam, the patient had classic telangiectasia on the tongue and oral mucosa (Figure 1). The clinical question posed to our hematology clinic was how to proceed with anticoagulation for DVT/PE in the setting of a genetic thrombophilia and active bleeding in a patient with HHT.

BACKGROUND

HHT, alternatively known as Osler-Weber-Rendu syndrome, is a relatively common autosomal dominant disorder, with an overall frequency of 1 per 5000 to 10000 individuals[1]. HTT was first described in 1864, but this account did not note a pattern of inheritance[2]. Subsequently, multiple case reports specifically included a familial component in their descriptions[3-5]. In 1909, Frederic Hanes officially used the phrase "hereditary hemorrhagic telangiectasia" for the first time[6].

As the name suggests, the disease is notable for autosomal dominant inheritance (hereditary), bleeding events (hemorrhagic), and visibly dilated blood vessels (telangiectasia). Additionally, most patients are affected by larger AVMs, commonly found in the pulmonary, hepatic, and cerebral vasculature[7]. Specific

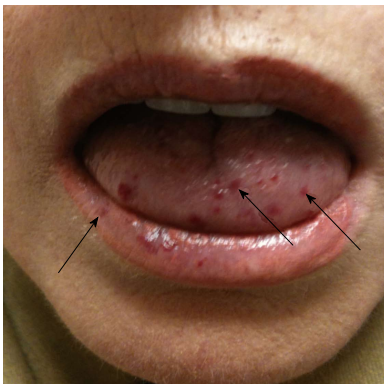

Figure 1 Arrows indicate telangiectatic lesions on tongue and lip of patient.

complications relate to the location of telangiectasia and AVMs, including, but not limited to, epistaxis, gastrointestinal bleeding, visible skin/mucosal manifestations, pulmonary arterial hypertension, pulmonary hemorrhage, and cerebral abscesses. Paradoxically, HHT patients are also burdened by a prothrombotic state due to elevated plasma levels of factor Ⅷ[8]. The balance between hemorrhage and thrombosis is particularly difficult to manage in these patients, and was exemplified in our patient described above.

The underlying pathology in patients with HHT is a primary defect in the vascular wall. The pathophysiology leading to this defect is complex. Patients inherit a mutation in an autosomal dominant fashion; the penetrance of which is highly variable. The three major genes that have been identified are: *ENG* encoding endoglin (HHT type 1), *ACVRL1* encoding activin receptor-like kinase (ALK-1) (HHT type 2), and *SMAD4* encoding Smad4 (HHT in association with juvenile polyposis, JPHT)[9-11]. Over 80% of patients with HHT will have mutations in either the *ENG* or *ACVRL1* gene, with the *ENG* gene accounting for the majority[12]. There is no common mutation in either the *ENG* or *ACVRL1* genes, with over 470 mutations having been described in the *ENG* gene and 375 in the *ACVRL1* gene[13]. Additionally, researchers have been studying two other gene mutations that can cause HHT: *HHT3* and *HHT4*.

Animal models have shed light on how these mutations lead to vascular wall abnormalities. The mutated *HHT* genes described above encode proteins that alter signaling by the transforming growth factor-β superfamily[7]. It is suggested that endoglin, ALK-1, and Smad4 are all part of a common signaling pathway that is altered in HHT. Additionally, studies have shown that vascular endothelial growth factor is increased in HHT patients[14]. In the setting of HHT and an angiogenic stimulus, there is increased proliferation of endothelial cells, excessive vessel branching, and decreased recruitment of mural cells[7]. Ultimately, this process leads to the formation of telangiectases,

Table 1 The Curacao criteria for the diagnosis of hereditary hemorrhagic telangiectasia

Criteria	Description	Percent manifestation
1 Epistaxis	Spontaneous, recurrent	90
2 Telangiectases	Multiple, at characteristic sites:	80
	Lips	
	Oral cavity	
	Finger tips

HHT: Hereditary hemorrhagic telangiectasia; AVMs: Arteriovenous malformations.

which are focal dilatations of postcapillary venules. Once fully developed, these malformed vessels are dilated, convoluted, extend through the dermis, and have excessive layers of smooth muscle without elastic fibers[15,16]. These vessels lack capillaries and connect directly to dilated arterioles. AVMs are similar to telangiectases but have a direct connection between veins and arteries, and are thus much larger. These abnormal HHT blood vessels are prone to bleeding because of their inherently abnormal wall structure, as well as the presence of high perfusion pressures[7].

CLINICAL MANIFESTATIONS

Clinical diagnosis

The diagnosis of HHT remains clinical, although genetic testing has been increasingly utilized. The classic triad of epistaxis, telangiectases, and family history lacks sensitivity and specificity, thus diagnostic criteria were formally created, which are generally referred to as the Curacao criteria (Table 1)[17]. These criteria were recently validated in 263 patients who were screened for HHT and had first degree relatives available for genetic testing[18]. This analysis found that the positive predictive value for a definite clinical diagnosis was 100%, and a negative predictive value for an unlikely clinical diagnosis was 97.7%. Fifty-two study participants had a possible clinical diagnosis, of which 17 (32.7%) had an HHT-causing mutation. Therefore, the utility of genetic testing is most apparent in those with a possible clinical diagnosis. This lends itself to the application of a diagnostic algorithm that can be used to combine the clinical criteria with genetic testing (Figure 2).

Bleeding in HHT

Patients with HHT are at increased risk for both bleeding and thrombosis. Bleeding complications can arise from any location where telangiectases and AVMs are found. The most prevalent form of bleeding in HHT patients is epistaxis, which can be severe and recurrent. Mucosal telangiectases are very common, but their presence is mostly a cosmetic concern. Telangiectases in the gastrointestinal tract are an important source of chronic bleeding, and contribute to the common diagnosis of iron-deficiency anemia found in HHT patients. Perhaps the most important lesions in terms of both morbidity and mortality are pulmonary AVMs. These are present in roughly 50% of HHT patients, although the majority are asymptomatic[7]. The clinical implications of pulmonary AVMs can be divided into two categories: (1) Right-to-left shunting; and (2) Hemorrhage. Right-to-left shunting can result in severe complications, such as brain abscesses and ischemic strokes, as well as less dramatic events such as migraines and dyspnea[19]. Hemorrhagic complications from pulmonary AVMs can include hemoptysis as well as hemothorax. The consequences of pulmonary AVMs can be so severe that current recommendations include screening asymptomatic HHT patients with transthoracic contrast echocardiography (TTCE), or chest computed tomography if TTCE is not available[20]. Cerebral vascular malformations are less common than pulmonary AVMs, but can have devastating effects. Perhaps the most feared complication of HHT is intracranial hemorrhage (ICH), which is most commonly seen with cerebral arteriovenous fistulae (AVF). As vascular lesions in the brain decrease in size, ICH becomes less common. Therefore, AVFs have the greatest risk of ICH, AVMs have intermediate risk, and telangiectasia have the lowest risk. Current guidelines recommend screening for cerebral AVMs with magnetic resonance imaging[20]. One of the more prevalent, but usually asymptomatic, aspects of HHT is hepatic vascular malformations[21]. These can occur as hepatic AVMs (hepatic artery to hepatic vein), hepato-portal VMs (hepatic artery to portal vein), and porto-venous VMs (portal vein to hepatic vein). Lastly, patients rarely may have spinal AVMs that can lead to hemorrhage and subsequent paraplegia.

Thrombosis in HHT

Despite the presence of an overwhelming bleeding propensity, HHT patients also suffer from thrombotic complications. First, they may develop paradoxical thromboembolic stroke from pulmonary AVMs as described above. Second, it seems these patients may also possess an inherent prothrombotic state relating to disturbances in the regulation of coagulation at the endothelial surface. A recent study compared the presence of plasma proteins in HHT-affected adults without a history of thrombosis with non-HHT controls[8]. The researchers found statistically significant elevations in von Willebrand Factor and Factor Ⅷ (FⅧ) in HHT-affected adults. The researchers then evaluated the presence of elevated FⅧ levels in the general HHT population and found that 87 of

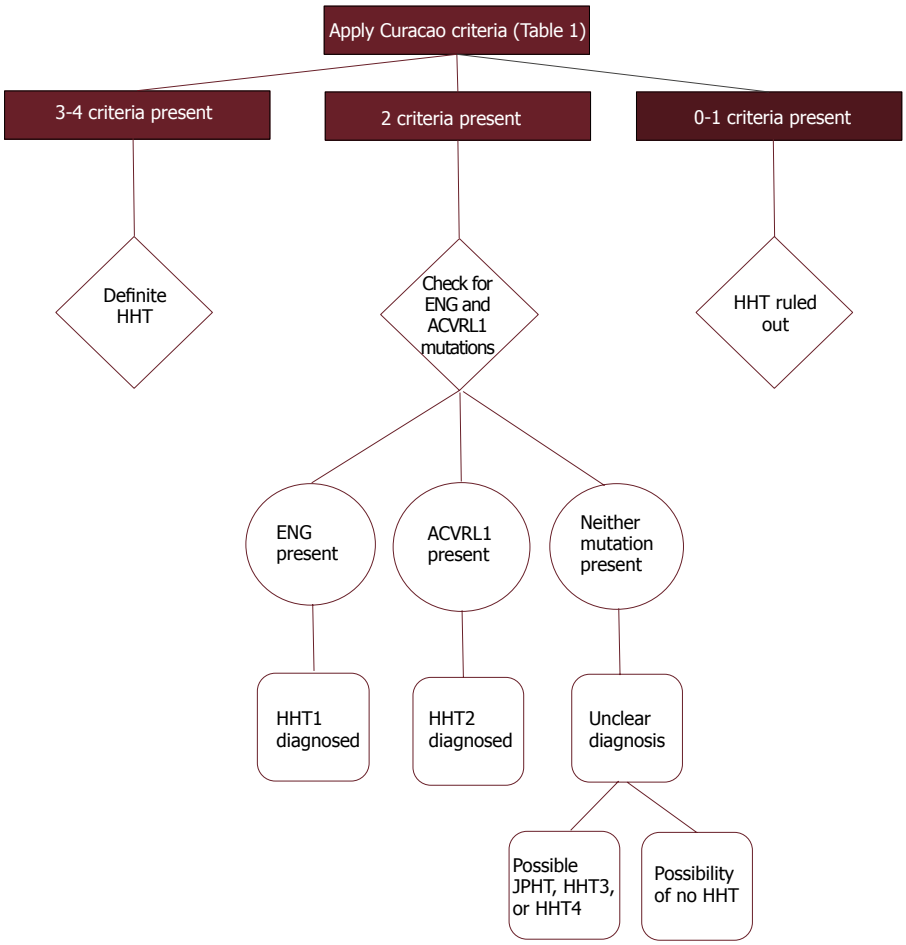

Figure 2 Diagnostic algorithm incorporating the Curacao criteria and genetic testing. HHT: Hereditary hemorrhagic telangiectasia.

125 (70%) individuals had measurements exceeding the upper limit of normal. An inverse correlation was also described between FⅧ level and activated partial thromboplastin time. Furthermore, when compared to HHT individuals with no history of thrombus, HHT individuals who ultimately developed a thrombotic event were more likely to have an elevated FⅧ level when it was initially measured at least 10 mo prior. To summarize the findings of this study, individuals with HHT have higher levels of FⅧ than non-HHT controls, and the degree of FⅧ elevation correlates with future thrombotic risk.

MANAGING THROMBOSIS IN HHT

Traditionally, physicians have been reluctant to treat HHT patients with either antiplatelet or anticoagulant therapy even if otherwise indicated. A recent survey found that 153 of 379 (40.4%) patients with HHT who received antiplatelet or anticoagulant therapy reported no change in epistaxis[22]. Furthermore, 86.9% of patients reported no hemorrhagic events other than epistaxis associated with antiplatelet and anticoagulant use. This survey supports the reasoning that HHT patients who have a strong indication for antiplatelet or anticoagulant use, should not have these agents withheld. Another study examining the use of antithrombotic agents in HHT patients arrived at a similar conclusion[23]. As in the Devlin study, this study found worsening of epistaxis to be the most common complication. There were no new or progressive cases of pulmonary or cerebral hemorrhage, likely because all patients in this study were pre-screened. These data again support the notion that anticoagulation should not be withheld from HHT patients with strong indications for its use. Although bleeding is the major complication associated with all anticoagulant medications, the rate of bleeding varies between agents, and may be of clinical importance in HHT patients.

Choice of anticoagulant agent

For the prior half century, warfarin has been the gold standard of oral anticoagulation. Within the past decade, new oral anticoagulants have been developed and evaluated in clinical trials. Specifically, these agents include the direct thrombin (factor Ⅱa) inhibitor, dabigatran, and the factor Ⅹa inhibitors, rivaroxaban and apixaban (Figure 3). Indications vary by agent, but all have been studied for stroke prevention in non-valvular atrial fibrillation and prevention and treatment of venous thromboembolism (VTE). Interestingly, dabigatran, as well as the factor Xa inhibitors, have

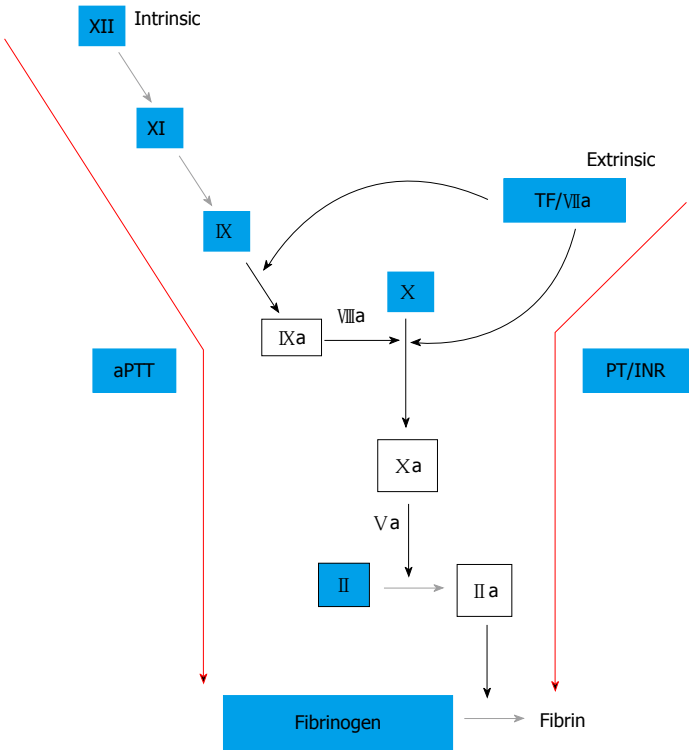

Figure 3 Coagulation cascade. Factors Xa and IIa (thrombin) are the principal targets for the new oral anticoagulants, while factors II, VII, IX, X, and protein C and S are decreased by the vitamin K antagonist, warfarin. Warfarin's effect on the factor VIIa/TF complex is a possible cause of the increased intracranial bleeding seen in warfarin compared to the newer targeted agents.

been associated with reduced intracranial hemorrhage compared to warfarin in patients with non-valvular atrial fibrillation[24-26]. In studies examining the treatment of acute VTE, dabigatran and rivaroxaban had similar bleeding rates compared to warfarin, while apixaban had decreased bleeding relative to warfarin[27-30].

The mechanism by which these new agents lead to similar or improved efficacy in relation to warfarin, while achieving less intracranial hemorrhage, has been evaluated. A recent study compared peak thrombin generation in the presence of both warfarin and dabigatran[31]. This study found that, while the mean lag times were equally prolonged in each group, the peak thrombin level was significantly decreased in the warfarin group. Furthermore, the authors found that in the presence of tissue factor (TF), the peak thrombin level increases. Lastly, it was shown that warfarin has a greater inhibitory effect on peak thrombin level in the presence of TF than dabigatran. When the mechanism of action of warfarin and dabigatran are compared, it is notable that one major difference is the suppressive effect warfarin has on formation of the TF-factor Ⅶa complex which initiates coagulation (Figure 3). Dabigatran, as well as the factor Ⅹa inhibitors, lack this inhibitory effect since these agents blockade the coagulation cascade further downstream. The brain, in particular, has a rich endowment of tissue factor, thus the effect of warfarin is enhanced in the brain relative to dabigatran, which may explain the increased intracranial hemorrhage seen in patient's taking warfarin *vs* the newer target-specific oral anticoagulants. Additionally, there is evidence that some of this effect may be due to reduced drug entry through the blood-brain barrier relative to warfarin[32].

Multiple studies have examined the efficacy of antithrombotic agents in the prevention of recurrent VTE after an initial course of anticoagulation. Both low-dose warfarin and low-dose aspirin have been shown to effectively reduce the risk of recurrent VTE, when compared to placebo, without increasing the risk of bleeding complications[33,34]. As for the new oral anticoagulants, dabigatran and rivaroxaban have been shown to effectively decrease the risk of recurrent VTE, but both increased the risk of clinically relevant bleeding when compared to placebo[35,36]. Notably, dabigatran had a lower risk of major or clinically relevant bleeding when compared to regular-dose warfarin (INR 2-3). Apixaban has been shown to have similar bleeding risk to aspirin when evaluated for stroke prevention in nonvalvular atrial fibrillation[37]. More recently, apixaban was compared at two doses (2.5 mg and 5 mg, twice daily) *vs* placebo in the extended treatment of VTE[38]. In this study, each dose was effective in reducing the risk for recurrent VTE relative to placebo. There was no increased risk of major or clinically relevant bleeding in either dose of apixaban *vs* placebo, or between the two doses.

Due to the inherent bleeding risk in HHT patients, any approach to anticoagulation that may decrease the risk of bleeding would be prudent. Through the use of either a factor Ⅱa or Ⅹa inhibitor, as opposed to warfarin for the acute treatment of VTE, the TF-Ⅶa interaction can be preserved, which may lead to decreased bleeding events, particularly in the brain. Based on the studies reviewed above, it would be reasonable to use either low-dose aspirin, low-dose warfarin, or apixaban to prevent recurrent VTE in a patient at risk for bleeding. Further research is

necessary to fully describe these important differences between anticoagulant agents.

CONCLUSION

The patient presented with a difficult clinical scenario: new venous thromboembolism in the setting of a prothrombin gene mutation and bleeding complications secondary to HHT. The physicians who initially cared for our patient understood this dilemma and opted to place an IVC filter. Unfortunately, this filter thrombosed and the patient was initiated on warfarin. While on warfarin, the patient, like most patients studied, complained of worsening epistaxis, but no major bleeding events.

Our initial approach was to ensure she had been adequately screened for AVMs (pulmonary and cerebral) that could cause severe harm to our patient prior to the initiation of anticoagulation. The next management decision was to address the anticoagulation needs of our patient. Despite her bleeding risk, she had a strong indication for anticoagulation given progressive DVT and PE despite the presence of an IVC filter, as well as a prothrombotic state related to heterozygosity for the prothrombin gene mutation, immobilization, and recent surgery. Our primary options included: continuing warfarin (normal or low-dose); changing to low-dose aspirin; changing to a new oral anticoagulant, such as dabigatran, rivaroxaban, or apixaban; or discontinuing all anticoagulation. At the time of her appointment she had received 3 mo of anticoagulation with warfarin. Despite the role her recent surgery played in provoking the VTE, the presence of a thrombosed IVC filter and heterozygosity for prothrombin gene mutation indicated that she should receive long-term treatment. After 6 mo of anticoagulation, her IVC filter was retrieved as her thrombus burden had declined significantly in her IVC and lower extremities. We hoped retrieval would decrease her risk for recurrent VTE and allow us to eventually discontinue warfarin. Because her epistaxis was more symptomatic on therapeutic anticoagulation, we reduced her INR target range to 1.5-2. After 3 mo of warfarin therapy at a lower target INR, we discontinued anticoagulation completely. Unfortunately, 6 mo after her filter retrieval she developed recurrent right leg pain and a new iliofemoral DVT was identified. Subsequently, a new Celect IVC filter was placed. While recovering from this procedure, the patient developed abdominal pain and was ultimately found to have extensive thrombosis of the portal, superior and inferior mesenteric veins. Therapeutic anticoagulation with warfarin was resumed, and, after six months, her epistaxis became more severe, so her INR range was again reduced to 1.5-2. She has now been on low-dose warfarin for eighteen months and remains free of recurrent VTE or severe epistaxis. If a change to her anticoagulant regimen is warranted in the future, other options include low-dose aspirin and apixaban to prevent recurrent VTE, while minimizing the risk of bleeding.

HHT patients present hematologists with difficult clinical decisions due to the inherent bleeding and thrombotic complications associated with the disease. The majority of management decisions revolve around bleeding complications. When a thrombotic complication arises, anticoagulation recommendations must take into account the bleeding risks associated with HHT. Recent reviews have found that HHT patients can be safely anticoagulated, with the most frequent complication being worsened epistaxis. Patients should be aggressively screened for pulmonary and cerebral AVMs prior to initiating any anticoagulant. Large clinical trials have shown that factor Ⅱa and Ⅹa inhibitors have less intracranial bleeding than warfarin, and basic coagulation research has provided a possible mechanism. In light of this, there is an important role for the use of factor Ⅱa and Ⅹa inhibitors in HHT patients requiring acute anticoagulation. For long-term anticoagulation to prevent VTE recurrence, the agents associated with the lowest risk of bleeding relative to placebo are low-dose warfarin, low-dose aspirin, and apixaban. These agents will have an important role in the long-term prevention of VTE recurrence in patients with HHT.

Abstract

Hypogonadism is prevalent in older men and testosterone replacement therapy (TRT) for older hypogonadal men is a promising therapy. However, a number of important clinical concerns over TRT safety remain unsolved due to a lack of large-scale randomized clinical trials directly comparing the health risks of untreated hypogonadism *vs* long-term use of TRT. Meta-analyses of clinical trials of TRT as of 2010 have identified three major adverse events resulting from TRT: polycythemia, an increase in prostate-related events, and a slight reduction in serum high-density lipoprotein cholesterol. There are other purported health risks but their incidence can be neither confirmed nor denied based on the small number of subjects that have been studied to date. Furthermore, subsequent literature is equivocal with regard to the safety and utility of TRT and this topic has been subject to contentious debate. Since January 2014, the United States Food and Drug Administration has released two official announcements regarding the safety of TRT and clinical monitoring the risks in TRT users. Additionally, the health risks related to the clinical presentation of low or declining testosterone levels not been resolved in the current literature. Because TRT is prescribed in the context of putative risks resulting from reduced testosterone levels, we reviewed the epidemiology and reported risks of low testosterone levels. We also highlight the current information about TRT utilization, the risks most often claimed to be associated with TRT, and current or emerging alternatives to TRT.

Key words: Hypogonadism; Epidemiology; Aging; Low testosterone; Testosterone replacement therapy

Core tip: The topic of testosterone replacement therapy which has seen two official announcements for the United States Food and Drug Administration in 2014, is the subject of several large studies both prospective and retrospective, and there is unsettled debate about the safety and efficacy of this treatment. Readers should become familiar with this topic and be aware that further

publications and announcements are likely in the near future.

LOW TESTOSTERONE EPIDEMIOLOGY AND RISKS

Production of testosterone (T) and serum T concentrations decline as men age. Hypogonadism may be defined either as serum concentration of T (either total T, bioavailable T or free T) or as low T plus symptoms of hypogonadism. The Baltimore Longitudinal Study on Aging reported the incidence of total serum T < 325 ng/dL to be 20% for men in their 60s, 30% for men in their 70s and 50% for men over 80[1]. In an authoritative review by Kaufman and Vermeulen[2] in 2005, similar rates and trends in the reduction of total serum T level were reported. The Massachusetts Aging Male Study reported that 12.3% of men aged 40 to 70 had a total serum T of < 200 ng/dL with 3 or more symptoms of hypogonadism[3]. The Boston Area Community Health Study reported that 5.6% of men aged 30 to 70 were hypogonadal, as defined by total serum T < 300 ng/dL; or, free serum T < 5 ng/dL plus 3 or more symptoms of hypogonadism[4].

Hypogonadism causes a wide range of signs and symptoms including loss of libido, erectile dysfunction, diminished cognitive function, depression, lethargy, osteoporosis, loss of muscle mass and strength[5]. In a literature review on the burden of hypogonadism in adult men, Maggi *et al*[6] demonstrated strong evidence associating hypogonadism with sexual dysfunction and cognitive impairment; and, less compelling evidence associating hypogonadism with depressive symptoms, fractures, and mortality. Several recent studies also reported the health risks associated with untreated hypogonadism, including increased all-cause mortality[7,8], coronary artery disease[9], and stroke[10].

Unfortunately, studying the health risks associated with untreated hypogonadism is often limited by the lack of universally accepted diagnostic criteria, and by study design variations[6].

Hypogonadism does not appear to be identical across racial and ethnic boundaries. In a health screening project among 819 men in Taiwan, the prevalence of hypogonadism (total serum T < 300 ng/dL) ranged from 16.5% for men in their 40s, 23.0% for men in their 50s, 28.9% for men in their 60s, and 37.2% for men older than 70 years of age[11]. The prevalence of hypogonadism among men in Taiwan is higher than the prevalence reported in the Massachusetts Male Aging Study[3], for a similar age group. There are no definitive biological explanations for differences in the epidemiology of hypogonadism. Candidate reasons are related to various lifestyle factors as well as genetic reasons, including the CAG repeat sequence, within the androgen receptor (AR). Rajender *et al*[12] reviewed over 30 studies on the AR trinucleotide repeat and infertility. Overall, for European populations, no significant distinctions were drawn, based on the CAG repeat. However, in Asian populations, four studies indicated a longer repeat was associated with infertility, two indicated no difference was present, and one study reported a shorter length (samples were all oligozoospermic for this subgroup). While there is a suggestion that CAG repeat length may determine androgen responsiveness, this issue is not clearly settled.

Nevertheless, a strong inference remains that race and ethnicity play a role in both the genotype and phenotype as they relate to the epidemiology of hypogonadism.

In summary, the reported prevalence of low T in older men range from 5.6% to 50%, depending upon study design, level of T blood concentration used, and study subjects' age. Combining serum T measurement with signs and symptoms most commonly seen with androgen deficiency are recommended in order to confirm the diagnosis of hypogonadism.

Hypogonadism comes with economic burden as well. An analysis of 8538 men, between the ages of 34 and 65, found direct and indirect cost differences associated with hypogonadism[13]. This study examined an administrative database spanning four years and three months. Men with at least two diagnoses for hypogonadism, or, at least one prescription for testosterone therapy with at least one diagnosis for hypogonadism were considered hypogonadal in the analysis. They were matched against those not satisfying either of the two criteria. Those in the hypogonadal group (n = 4269) had direct health care costs, that exceeded the eugonadal group (n = 4269) by an average of $7100 over the course of the observation window. Due to the expense of treatment for HIV/AIDS, those affected individuals were excluded in another analysis to avoid skewing the difference. The difference in direct costs was then $5579, meaning that the hypogonadal group incurred an additional cost of just over $109 per person per month. Indirect costs went up a little more than $30 per person per month. Examples of mean disease- specific costs for hypogonadal *vs* eugonadal were as follows (these numbers do not exclude those with HIV/AIDS): Cardiovascular and metabolic health: $1453 *vs* $757; Pain: $980 *vs* $365; Mental health: $558 *vs* $176. The hypogonadal group had a higher Charlson's Co-morbidity Index at baseline, with a mean of 0.95, as compared to the eugonadal group at 0.28. In risk-adjusted analyses of costs, the difference in health care costs (both direct and indirect) was $4869, or just over $94 per person per month on average.

This investigation plainly demonstrated higher economic burden and presence of co-morbidities for

hypogonadism. Additionally, it highlighted a potentially serious threat to the interpretation of all observational studies in the testosterone replacement therapy (TRT) field-compliance. Over 31% of individuals in the hypogonadal did not receive TRT during the observation period. Similarly, within the hypogonadal group receiving therapy the proportion of days covered under TRT therapy was only 38% based on medical claims data. These study findings demonstrate that the economic burden for the hypogonadal group is higher than the eugonadal group even when 2/3 of the hypogonadal group did receive the TRT. However, because at least 31% of the hypogonadal group did not receive testosterone replacement, and those that did receive testosterone replacement were covered less than 40% of the time, it's not possible to infer whether or not TRT was mitigating the additional burden. The socioeconomic burden of hypogonadism should be addressed in detail in future observational and clinical trials, to provide robust metrics on the risks, benefits, and costs of TRT.

TRT

An increased awareness of the health risks associated with untreated hypogonadism has caused a substantial increase in TRT utilization in men[14]. The efficacy of TRT has been demonstrated in several randomized clinical trials[15-17] and has shown minor to moderate improvements in lean mass and muscle strength[18,19], increased bone mineral density (BMD)[18,20], modest enhancement in sexual function[21-23], reduced adiposity[18] and lessening of depressive symptoms[24]. In 2011, the estimated sales for TRT were 1.6 billion dollars in the United States[25]. However, significant questions remain regarding the safety of TRT because no large-scale randomized clinical trials have directly compared the health risks of untreated hypogonadism *vs* long-term TRT use[25].

Enthusiasm for TRT utilization has been tempered by concerns regarding the health risks of this therapy. Meta-analyses of clinical TRT trials as of 2010 have identified three major adverse events resulting from TRT: (1) polycythemia; (2) an increase in prostate-related events; and (3) and a slight reduction in serum high-density lipoprotein (HDL) cholesterol[26-28]. Clinical concern over the health risks of TRT was heightened in mid-2013 when a meta-analysis reported increased cardiovascular (CV) risk in men receiving TRT[29]. Similarly, a recent retrospective study reported increased risk of stroke, myocardial infarction, and all-cause mortality in hypogonadal men receiving TRT after angiography[30].

CARDIOVASCULAR AND CEREBROVASCULAR RISKS OF TRT

Two widely established health risks associated with TRT are polycythemia (> 3.5-fold increase in risk)[26,27] and reduced HDL cholesterol[27]. These risk factors represent increased risk for CV and cerebrovascular events. Serious concern regarding the safety of TRT was raised in 2010 when the data and safety monitoring board (DSMB) of a double-blind randomized clinical trial recommended discontinuation of the trial because elderly hypogonadal men (with a high prevalence of chronic disease) experienced an increased incidence of CV events after receiving TRT[31]. This randomized clinical trial was discontinued because 23 participants in the TRT group (approximately 22% of all TRT participants) *vs* 5 participants in the placebo group (approximately 5% of all placebo participants) experienced adverse CV-related events within the first 6 mo. Adverse events ranged from chest pain (n = 1) to myocardial infarction (MI) (n = 3 with one death suspected from MI), with peripheral edema being the most commonly reported side-effect (n = 5).

A large meta-analysis evaluating CV risks associated with TRT (including 27 RCTs and 2994 older men) also reported that TRT increased risk for CV-related events by 1.54 times (odds ratio = 1.54) in comparison to placebo treatment[29]. In a similar but more recent and larger meta-analysis of 75 RCTs on CV risks and TRT, no significant association between CV events (both single and composite events) and TRT was established[32]. However a retrospective study reported that men receiving TRT after angiography (n = 1223) experienced a 29% greater hazard ratio-adjusted rate of MI, stroke, and all-cause mortality (95%CI: 1.04-1.58) at 3 years post angiography *vs* men with untreated hypogonadism (n = 7486)[30]. Finkle *et al*[33] evaluated 55000 patients and reported a more than 2-fold greater risk of MI in men who had received a TRT prescription. These results differ from several smaller analyses reporting heightened CV risk and all-cause mortality in men with untreated hypogonadism[26,28]. This is especially important given that the TRT literature has thus far been equivocal and/or underpowered, despite large, coordinated efforts such as the forthcoming series of trials from Snyder *et al*[34].

As a response to the above study reports, the United States Food and Drug Administration (FDA)[35] the Endocrine Society[36] and the United States Veteran's Administration[37] have called for monitoring and reassessing the health risks associated with TRT, respectively. Since these advisory announcements, a number of literature reports have critiqued the TRT literature, particularly the studies by Vigen and Finkle, for issues associated with the study design, statistical methods, and interpretation of findings[38-40].

Notwithstanding several letters to the editor, and several recent TRT articles showing no increased cardiovascular risk, the United States FDA Joint Advisory Panel voted to change the labeling on testosterone replacement medication until larger studies demonstrate a clinical benefit and account for patient safety[41].

PROSTATE RELATED RISKS OF TRT

Another well-established health risk of TRT is increased incidence of prostate/lower urinary tract-related events (*i.e.*, combined incidence of prostate-biopsy, prostate enlargement, elevated PSA, and prostate cancer)[26]. Several coauthors of this commentary recently conducted a double-blind randomized clinical trial (NCT00475501) and observed that TRT produced a 40% prostate enlargement in older hypogonadal male Veterans over 12 mo[42]. These increased prostate-related risks have raised concern that TRT may increase prostate cancer risk or hasten the development of undiagnosed prostate cancer.

However, no published analysis has reported measurable increases in prostate cancer risk or Gleason score in men undergoing TRT, or in hypogonadal men with a history of prostate cancer undergoing TRT[26,27,43]. Despite this, Calof *et al*[26] estimated that an evaluation of 85862 participants is necessary to detect a hypothetical 20% increase in prostate cancer resulting from TRT. The largest meta-analysis evaluating prostate cancer risk associated with TRT included only 1700 men (*i.e.*, < 2% of the necessary population size)[43].

OTHER PUTATIVE HEALTH RISKS ASSOCIATED WITH TRT

A number of putative health risks have been reported with TRT, including fluid retention[31], gynecomastia[44], liver disorders, and worsening of sleep apnea[45]. These adverse outcomes are worrisome because they represent risks for several serious life-threatening adverse events and for other potentially serious clinical conditions. However, current meta-analyses have not established a definite relationship between TRT and these potential health risks, likely because they lack the statistical power. Additionally, the mechanisms through which T incites the above mentioned health risks are not completely understood, but may result in part from tissue-specific 5α-reduction of T to dihydrotestosterone (DHT)[46] or from the aromatization of T to estradiol. This is especially true in the prostate which highly expresses the type Ⅱ 5α-reductase enzyme. Inhibition of this enzyme via finasteride (a type Ⅱ 5α-reductase inhibitor) or dutasteride (a dual type Ⅰ and Ⅱ 5α-reductase inhibitor) reduces circulating DHT 50%-75% and > 90%, respectively[47], and reduces prostate mass[48] and prostate cancer risk[49]. Our team[42] and others[15] have demonstrated that finasteride also prevents prostate enlargement resulting from high-dose TRT without inhibiting the beneficial musculoskeletal or lipolytic effects of T, indicating the clinical viability of this combination pharmacologic therapy. It is unknown whether other potentially life-threatening health risks and other adverse events discussed above are mediated by the 5α-reduction or aromatization of T.

ALTERNATIVES TO TRT

Given that there is currently no global consensus on the medical approach to testosterone deficiency, it is not surprising that alternative approaches to rectifying low T-levels are great in number, yet also lacking widespread agreement[50]. Several decades of research have been completed evaluating the field of selective estrogen receptor modulators and selective androgen receptor modulators (SARMS). Clomiphene Citrate (CC) is an estrogen receptor modulator that is used in the treatment of male hypogonadism in an off-label capacity. Normally estradiol partially regulates testosterone levels, at the hypothalamus, blunting LH and FSH release from the pituitary. As a selective estrogen receptor modulator, CC interrupts this pathway, and consequently there is a greater stimulation for the production of testosterone in Leydig cells[51].

A cohort of 1150 hypogonadal men were evaluated, and matched to produce a final sample of 93 in three groups: CC, Testosterone Injections (TI), or Testosterone Gel (TG)[52]. Each group consisted of 31 individuals. The research team evaluated changes in serum testosterone and patient satisfaction. All treatment modes were effective at raising T-levels. Changes in T-levels (ng/dL) from pre- treatment to post-treatment were as follows: CC = 247-504, TI = 224-1104, TG = 230-412. Patient satisfaction was equal among groups, though the responses in T-levels were not equivalent. The noted difference was in libido, where injection produced the greatest index of libido on the qADAM questionnaire (4 v. 3 for each comparison of injection v. CC, injection v. TG). CC appears to be a suitable alternative to testosterone supplementation. However, larger randomized clinical trials are needed to determine its proper use, potential safety, and whether this agent effectively mitigates the known side-effects of hypogonadism. Similarly, as reported by Taylor *et al*[51], 104 men received either CC or T-Gel (CC = 65, T-Gel = 39). The CC group had higher post-treatment T-levels, 573 ng/dL v. 553 ng/dL. The monthly cost of T-Gel medication is over three times that of CC (Testim 1%, 5 gm daily = $270/mo, Androgel 1%, 5 gm daily = $265/mo, CC 50 mg every two days = $83/mo). Thus, in terms of cost-effectiveness, CC would appear to be advantageous. However, more research is needed to determine its proper use.

SARMS

The combined research and clinical goals of SARMS are the reductions in catabolic actions initiated by hypogonadism and/or aging in order to preserve skeletal muscle and bone allowing for the individual to maintain functional activities of daily living, reduce fall and fracture risk, and consequent disability. SARMS are of particular interest because of recent guidance documentation[41] on the restriction of exogenous testosterone administration warranted by observational studies indicating an

increased risk of cardiovascular events[30,53]. In light of the recently cited effects on the cardiovascular disease system, SARMS are the most likely candidates to improve skeletal muscle mass in hypogonadal individuals. SARMS are engineered to bind to the androgen receptor without inducing other known side effects (*e.g.*, prostate related events and polycythemia) of TRT. Several SARMS, including JNJ-28330835[54], BMS-564929[55], MK-0773[56], and others have shown a positive levator ani/bulbocavernosus muscle complex/prostate ratio in pre-clinical rodent models, demonstrating an improved anabolic/androgenic ratio is associated with these drugs[57]. The anabolic to androgenic ratio with limited side effects is the therapeutic target of SARMS research.

CONCLUSION

In summary, circulating testosterone concentrations decline throughout the aging process in males[2]. The prevalence of low circulating testosterone (*i.e.*, hypogonadism) is approximately 20% in men between 60-70 years of age and increases to roughly 50% of men over 80 years of age[2]. The use of TRT has increased substantially among men in recent years[14] because of an increased awareness of the risks associated with male hypogonadism (*e.g.*, muscle and bone loss, and increased frailty)[58,59]. However, TRT safety remains of primary concern, as do the potential health risks of untreated hypogonadism. To date, the largest prospective clinical trials that have been conducted on TRT involved only several hundred individuals; as such, they were dramatically underpowered to assess many of the more rare, yet severe health risks that are putatively associated with TRT. Unfortunately, even the largest meta-analyses on adverse events associated with TRT lack sufficient power to detect these and other potentially life-threatening health risks. Additionally, these clinical trials and meta-analyses have only assessed health risks during relatively short-term TRT or for only a very brief follow-up period after the cessation of TRT, which is concerning because once TRT is initiated it is typically continued throughout the lifespan. TRT studies should address additional external factors that may contribute to the reported risks and benefits currently associated with TRT including: diet, exercise, neutraceutical supplementation, sleep, and obesity.

Abstract

Atherosclerosis is a chronic inflammatory disease arising from lipids, specifically low-density lipoproteins, and leukocytes. Following the activation of endothelium with the expression of adhesion molecules and monocytes, inflammatory cytokines from macrophages, and plasmacytoid dendritic cells, high levels of interferon (IFN)-α and β are generated upon the activation of toll-like receptor-9, and T-cells, especially the ones with Th1 profile, produce pro-inflammatory mediators such as IFN-γ and upregulate macrophages to adhere to the endothelium and migrate into the intima. This review presents an exhaustive account for the role of immune cells in the atherosclerosis.

Key words: Atherosclerosis; Inflammatory cytokines; Pro-inflammatory mediators; Immune cells; Adhesion molecules

Core tip: Activated endothelium to adhere to the endothelium and move into the intima with the expression of adhesion molecules appears to be an early event in atherosclerosis, which allows mononuclear leukocytes such as monocytes and T-cells. This inflammatory mechanism must be explained before determining a new therapy.

INTRODUCTION

Atherosclerosis is one of the leading causes of morbidity and mortality arising from coronary artery disease, stroke, and peripheral vascular disease. The pathophysiology of atherosclerosis is best characterized with hyperlipidemia and inflammation[1,2].

For a long time after recognition, atherosclerosis was associated with passive lipid accumulation in the vessel wall. Nowadays we know that atherosclerosis is a chronic inflammatory disorder caused by lipids, particularly low-density lipoproteins (LDLs), and leukocytes[3]. Atherosclerosis is likely to be initiated by the activation of endothelium with the expression of adhesion molecules, and this in turn enables the adhesion of mononuclear leukocytes, such as monocytes and T-cells, to the endothelium and also their transmigration into the intima. At this point, the lesions may be present with rare cells such as dendritic cells (DCs), few neutrophils and

B-cells, and also with smooth muscle cells (SMC), which transform phenotype into synthetic SMC and move into the intima from the media[4].

Polymorphonuclears (PMNs) are recruited and adhered to the endothelium upon the subsequent expression of adhesion molecules, such as E-selectin, P-selectin and intercellular adhesion molecule 1 (ICAM-1)[5]. The endothelial cell expression of selectins and vascular cell adhesion molecule 1 (VCAM-1) is further increased by pro-inflammatory cytokines and mmLDL, and this facilitates the infiltration of the monocytes into the intima[6]. As a result of intimal lipid accumulation, disturbed blood flow, low shear stress, and other stimuli, the transition of monocytes, which are major precursors of macrophages, through the endothelium is allowed by endothelial cells[3]. Endothelial cells and SMCs are triggered by oxidized LDL (OxLDL), and this leads to the secretion of monocytic maturation factors such as monocyte-colony stimulating factor (M-CSF). Monocytes are transformed to macrophages and phagocytose modified lipoproteins, mainly due to the scavenger receptors AI and CD36[7], and then become foam cells[8]. Macrophages may be activated by PMNs following the secretion of tumor necrosis factor (TNF)-α, interleukin (IL)-8, and interferon (IFN)-γ. In addition, the release of myeloperoxidase from granules can stimulate the formation of reactive oxygen species (ROS), as well as the secretion of other pro-inflammatory cytokines, including TNF-α, IL-1, IL-6, IL-8 and granulocyte macrophage colony stimulating factor (GM-CSF) from macrophages. In response, ROS transform the extravasated LDL into OxLDL, consequently forming the foam cell development[9].

Monocyte recruitment and the size of atherosclerotic lesion are bound to decrease if a failure is experienced in adhesion molecules, such as P-selectin, ICAM-1 and VCAM-1, or their interactions with their respective ligands are constrained[10,11].

MONOCYTES AND MACROPHAGES

After the migration from the circulation into the intima of the arterial wall, monocytes are converted to macrophages and DCs. These cells then transform into foam cells by taking up modified lipoproteins[12]. There are three major monocyte subsets in humans[13,14]: the classical $CD14^{++}CD16^{-}$ subset is similar to the mouse Ly6C high inflammatory subset and also presents a high expression of CCR2, and the non-classical $CD14^{+}CD16^{++}$ monocytes are considered to match the $Ly6C^{-}$ cells in mice, which express high levels of CX3CR1 and CCR5 but low levels of CCR2[15]. The third subset, however, is known as the intermediate $CD14^{++}CD16^{+}CCR2^{+}$ subset[16]. Of these, the classical subset includes nearly 90% of the monocytes circulating in humans[17]. The patients with coronary artery disease present with increased amount of pro-inflammatory $CD14^{+}CD16^{+}$ monocytes and serum TNF-α levels[18], and this monocyte subset is in negative correlation with fibrous cap thickness[19].

After chemokinesis, monocytes adhere to and spin on endothelial cells by interacting with E- and P-selectins[20,21]. Lipoprotein-binding proteoglycans are secreted by monocytes in the intima, leading to enhanced accumulation of modified LDL, which carries on inflammation[22,23].

Tissue damage and repair are closely linked to monocytes, and a discrepancy to occur in these processes may have critical results for plaque formation and stability. Importantly, monocytes consist of dissimilar subsets along with different cell surface markers and functional features, and this diversity of components may be associated with the angiogenic processes in atherosclerosis[24].

The formation of atherosclerotic lesions is heavily dependent on the transformation of monocytes into macrophages; for instance, M-CSF-knockout mice show resistance to the development of atherosclerosis[25].

Every phase of the course of disease includes abundant amounts of monocyte-derived macrophages[12], and these cells an important role in lipid accumulation and advancement of atherosclerosis[24]. Also, their crucial role in atherogenesis has been proven by the reduction of lesion formation in monocyte-deficient apolipoprotein E (ApoE) knockout mice and LDL receptor knockout mice[26,27].

The polarization of macrophages towards a specific phenotype has been reported to be positively affected by lipids, growth factors, and cytokines; the M1 macrophages that are classified by means of classical methods may result in plaque vulnerability, whereas the M2 macrophages which are activated by alternative methods may increase plaque stability[28]. The phenotypes of M1/M2 macrophages can be exchanged depending on the conditions of their microenvironment[29].

Many macrophages and dendritic-like cells are known to have membrane-bound lipid droplets in the cytoplasm even at very early phases of atherogenesis. As they comprise lipid deposits, these cells are called "foam cells" and their course of development is initiated when apolipoprotein B-containing lipoproteins (apoB-LPs) are absorbed and processed by phagocytes[21]. While producing matrix metalloproteinases with regards to plaque rupture, macrophages can be primed by oxLDL to develop a foam cell macrophage which bears the characteristics of M1 and M2 activation[28]. Inflammatory cytokines and chemokines that promote inflammation and contribute to the regulation of monocyte/T cell infiltration are generated by macrophages/foam cells[30-33]. With the macrophages in the atherosclerotic plaque, it is possible to generate a wide range of proinflammatory cytokines such as IL-1, IL-6, IL-12, IL-15, IL-18, TNF family members, and MIF, as well as anti-inflammatory cytokines like IL-10 and transforming growth factor beta family members[34,35]. Additionally, IFNγ may trigger the macrophages to produce ROS and neopterin. It has been reported that neopterin levels increased in acute coronary syndrome and neopterin may be useful for the assessment of inflammation related to atherosclerosis[36].

Being the most abundant cell type in atherosclerotic plaques, macrophages have a strong effect on plaque

development and progression due to its overwhelming influence on intra-plaque cholesterol homeostasis, inflammation, necrotic core initiation, and extracellular matrix degradation[37].

Toll-like receptors (TLRs) represent the most comprehensively studied and described type of pattern recognition receptors. TLRs are characterized as type 1 transmembrane proteins involving an ectodomain with leucine-rich patterns that are needed to recognize pathogen associated molecular patterns, a transmembrane region, which determines the locations of the cells, and an intracellular toll interleukin 1 receptor region required for downstream signaling. Up to now, a minimum of 13 TLRs have been described, and each of them present with a degree of specificity for a number of endogenous and exogenous ligands[38]. Expression of TLRs is performed by a number of various cells, such as leukocytes, DCs, and T and B lymphocytes[39]. Atheroma development can be directly influenced by TLRs since the lipid uptake is promoted when the stimulation of macrophages is conducted with TLR2, TLR4 and TLR9 ligands[40,41]. According to recent studies on ApoE$^{-/-}$ mice, even small amounts of TLR4 and TLR2 have positive effects on the deposition of early-stage intimal foam cells in some regions in the aorta which are sensitive to lesion development[42]. The macropinocytosis of lipids in differentiated macrophages can be stimulated by TLR4[43]. Increased expression of scavenger receptors induced by TLR3, TLR4 and TLR9 can be used as a mediator for increased lipid absorption[39,44]. These receptors and their ligands may also interrupt the cholesterol efflux mechanisms, which may have a contributory role in the development of foam cells[28].

THE DENDRITIC CELLS

Dendritic cells, which are antigen-presenting cells (APCs), exhibit a variety of antigens to T cells in addition to initiating and sustaining immune responses as well as inhibiting the activation of T cells. The capacity of DCs in the activation or inhibition of T cells relies on its cytokine production profile and expression of cell surface co-stimulatory molecules. DCs are transformed by activated innate immune receptors, such as the TLR, into APCs that activate T effector cells, whereas, immunological tolerance is produced by antigen presentation which develops when TLR activation is not present. Therefore, DCs play a critical role as a connector between innate and adaptive immune responses[45].

DC has a heterogeneous population with four major categories: conventional DCs (cDCs), plasmacytoid DCs (pDCs), monocyte-derived DCs, and Langerhans cells[46]. Monocytes or DC precursors, which are present in the bone marrow, constitute the two sources of DCs.

Monocytes are completely transformed into monocyte-derived DCs in inflammation and as a reaction to growth factors like GM-CSF or TLR4 ligands. The capacity of presenting antigens along with the ability to cross-present antigens belongs to the DCs that originate from monocytes[37]. DCs are capable of generating a wide range of anti-inflammatory and proinflammatory cytokines. As an example, some proinflammatory cytokines, such as TNF, IL-6, and IL-12, which have been proven to contribute to the atherosclerosis can be generated by TLR binding[47-49]. However, TLR binding may also generate IL-10, which is known as an atheroprotective cytokine[50].

The DCs in mice are best known for their expression of CD11c and they present with healthy mouse aortas, predominantly in the adventitia[51]. In mice, the amount of mRNA expression of CD11c is higher in the sites of the aortic arch susceptible to atherosclerosis, compared to the sites that are resistant to atherosclerosis. Contrary to healthy vessels, most of the DCs in atherosclerotic aortas are localized in the intima[52].

The deposition of CD11c^{+} DCs at the vascular regions prone to atherosclerosis is associated with the increase in the expression of VCAM-1[53]. Mature DCs are more abundant in advanced lesions. High level of expression of human leukocyte antigen (HLA)-DR and interactions with T cells are mostly observed in the sites of the plaque that are predisposed to rupture[54]. The deposition process of the dendritic cells in the intima may be interrupted if the fractalkine receptor CX3CR1 in the aorta is impaired, and this may be an indication that these cells may be transformed from Ly-6Clo monocytes which are known to induce high levels of CX3CR1[55]. OxLDL, in line with the elevation in the production of T cells, functions as an antigen upregulator for the DC expression of HLA-DR and its co-stimulatory molecules[56]. DCs carry out the expression of scavenger receptors (LOX-1, CD36 and CD205) which facilitate their uptake of oxLDL activating the NFκB pathway, and evolution to DCs with a pro-inflammatory cytokine profile[57]. Once DCs are activated by oxLDL in the plaque, they move to secondary lymphoid organs and initiate the clonal proliferation of the T cells that are specific to oxLDL[28].

Following TLR9 activation, it is a common event for pDCs to produce high amounts of IFNα and β, and TLR9 has been reported to contribute to atherosclerosis by promoting macrophage recruitment[58]. The recruitment of monocytes, memory T cells, and DCs to the region of inflammation is reportedly influenced by the CCL2 secreted by DCs[59].

DCs, as prominent mediators of immune responses, may also act as the regulators of innate or adaptive immunity against the potential antigens that are engaged in atherosclerosis[60]. In brief, the roles of dendritic cells in atherosclerosis can be summarized as the induction of chemokines and cytokines, presentation of antigens, and lipid absorption that might trigger inflammation or promote tolerance[37].

T CELLS

The role of adaptive immunity in atherosclerosis was

verified by the presence of antibodies and oxLDL-specific T cells along with the accumulation of oligoclonal T cells in lesions[6,61]. T cells are targeted to the vessel wall in line with macrophages, but to a lesser extent. Activation of T cells in the arterial wall is a reaction to antigens, and after this activation, the T cells initiate the production of pro-inflammatory mediators, by which the inflammatory response is intensified and thus the disease development is worsened[62]. Moreover, most of the pathogenic T cells in atherosclerosis have the characteristics of Th1 since they generate pro-inflammatory cytokines such as IFN-γ and perform the activation of macrophages[63,64]. The reactions mediated by Th1 have harmful effects on the development of atherosclerosis. Vascular smooth muscle cells are recruited by IFN-γ to inhibit the synthesis of collagen, and this leads to harmful effects for the protective thick fibrous cap of the plaque. Also, the activation of monocytes/macrophages and dendritic cells by IFN-γ results in the continuation of the pathogenic Th1 response[30].

Previous studies report that the removal of IFNγ or its receptors leads to a reduction in atherosclerosis, whereas the injection of recombinant IFNγ results in a growth in the size of the lesions[65-67]. The detection of Th2 cells in the atherosclerotic lesions is a rare occurrence. The cytokines produced by Th2 cells include IL-4, IL-5, IL-9, and IL-13. Th2 cells also have contributory effects on the production of antibodies by B cells. As the production of IFN-γ is decreased by these cells, the responses caused by Th2 were thought to be the antagonists of proatherogenic Th1 effects, hence rendering atheroprotection. Nevertheless, how atherosclerotic progress is affected by Th2 pathway has yet to be proven and the role Th2 pathway relies not only on the phase and location of the lesion but also on the method of experimentation to be used[62]. According to some studies on animals, both Th1 and Th2 responses are involved in the progression of atherosclerosis, and lesion formation is started primarily by Th1 activation through a switch towards a proatherogenic response by Th2 in the chronic stage of plaque formation[68]. The expansion and cytokine induction of highly activated effector T cells can also be inhibited by another T cell called TCRγδ$^+$ CD4$^-$ CD8$^-$, and this cell may need to be further analyzed since it is likely to have antiatherogenic characteristics[69,70]. The regulatory T cells (Tregs) have critical roles in the inhibition and suppression of inflammation and also in the regulation of adaptive immune responses. Moreover, these cells can induce tolerance by inhibiting the effector CD4$^+$ and CD8$^+$ T cells[71,72].

IL-10 has been reported to inhibit atherosclerosis, and thus the athero-protective effects of regulatory T cells may be improved when they generate IL-10[73,74]. Studies also report that IL-10 has a protective function in the development and stability of atherosclerotic lesions[72,73].

Th17 lymphocytes represent another T helper subset associated with inflammation, and this subset does not share the same lineage with Th1 and Th2[75]. IL-17 has been demonstrated to have protective and pathogenic effects in a number of autoimmune diseases[76,77].

The main cytokines expressed by Th17 cells include IL-17A and IL-17F along with IL-21 and IL-22. The role of Th17 is still debatable despite the detection of Th17 cells in the atherosclerotic lesions in mice and humans, because both atherogenic and atheroprotective effects have been attributed to these cells[78-80]. IL-17 is also considered to enhance plaque stability since elevated IL-17 induction in human lesions results in a decrease in the number of macrophages, an increase in SMC deposit, and a phenotype with a more fibrotic profile[81].

Proatherogenic profile of IL-17 has been shown previously by many studies[82-85]. In these studies, the evidence for the proatherogenic effect of IL-17 is attributed to the fact that both IL-17 and IFN-γ are expressed by the CD4$^+$ T cells that are separated from atherosclerotic coronary vessels[86].

CD8+ T cells are detected in both murine and human plaques[87,88]. The number of CD8$^+$ T cells is low in the early stages of lesions; however, these cells seem to be the dominant T cell type in the advanced stages of human lesions[88]. CD8$^+$ T cells may have a proatherogenic function since the lesion size was increased and also the recruitment of these cells to the lesion site was promoted when the responses of these cells were stimulated with a CD137 agonist[89].

B CELLS

The responses produced by the Th2 cell have important roles in the activation of B cells, the differentiation of plasma cells, and the production of antibodies that are unique to antigens. B cells are evident in atherosclerotic lesions, but their population is smaller than that of T cells[90]. However, the role of B cells in atherosclerosis remains controversial as two recent studies have reported that the atherosclerotic progression in mice is inhibited when B cells are blocked by the use of an antibody against CD20[91,92]. The evidence that some types of IgM and IgG have atheroprotective effects may suggest that B cells have the ability to protect against atherosclerosis. Moreover, plaques have been detected with both IgM and IgG at all phases of lesion progression[93]. Anti-oxLDL IgM antibodies have been proven to provide protection against atherosclerosis, probably because they achieve oxLDL binding and thus suppress oxLDL absorption by using macrophages and avoid the development of foam cells[94,95]. On the other hand, to what extent the oxLDL-specific IgG is effective remains a controversial issue because both beneficial and inverse effects have been reported in epidemiological studies[96]. OxLDL-specific antibody IgG titers are associated with atherosclerosis[94,97,98], whereas oxLDL-specific IgM titers are related to atheroprotection[99,100]. Nonetheless, the B cell subsets and their roles in atherosclerosis need to be further

analyzed[37].

CONCLUSION

Atherosclerosis is a multiphase process which is characterized with the activation of endothelial cells with the expression of adhesion molecules and monocytes/macrophages, and the transmigration of DCs, T cells and some B-cells into the intima, and also the transfer of modulated types of LDL to matrix components. Monocytes/macrophages are highly abundant and differentiate into foam cells which are rich in modulated LDL.

According to clinical and experimental data, the atherogenic process involves the cells of both the innate and the adaptive immune system, and these cells generate diverse cytokines that may have both pro and anti-inflammatory functions[101-103]. To immunomodulate the atherosclerosis is the primary aim of some clinical studies. Among these, the experimental studies with anti-LDL antibodies and vaccination studies with LDLs are under way[1,104]. Oral administration of oxidized LDLs is reported to be effective on the inhibition of atherosclerosis and production of Tregs in peripheral lymphoid tissues[105]. The functions of immune and inflammatory modulators in the formation and development of atherosclerosis have been better analyzed in recent years and thus provided a deeper insight into these mechanisms. Accordingly, more and more advanced techniques in the diagnosis and prognosis of atherosclerosis, along with new treatment procedures for inflammatory and immune factors, have been developed[106]. However, there is still much to learn about immune cells and their mechanisms affecting atherosclerosis. We believe that further studies investigating immune cells and their mechanisms will help to shed light on atherosclerosis.

Abstract

AIM: To investigate whether endoscopic papillary large balloon dilation (EPLBD) can be safety and effectively performed in patients aged ⩾ 80 years.

METHODS: Lithotomy by EPLBD was conducted in 106 patients with bile duct stones ⩾ 13 mm in size or with three or more bile duct stones ⩾ 10 mm. The patients were divided into group A (< 80 years) and group B (⩾ 80 years). Procedure success rate, number of endoscopic retrograde cholangiopancreatographies (ERCP), and incidence of complications were examined in both groups.

RESULTS: Group B tended to include significantly more patients with peripapillary diverticulum, hypertension, hyperlipemia, cerebrovascular disease/dementia, respiratory disease/cardiac disease, and patients administered an anticoagulant or antiplatelet agent (P < 0.05). The success rate of the initial lithotomy was 88.7 (94/106)%. The final lithotomy rate was 100 (106/106)%. Complications due to treatment procedure occurred in 4.72 (5/106)% of the patients. There was no significant difference in procedure success rate, number of ERCP, or incidence of complications between group A and group B.

CONCLUSION: EPLBD can be safely performed in elderly patients, the same as in younger patients.

Key words: Elderly patients; Endoscopic papillary large balloon dilation; Endoscopic sphincterotomy; Large bile duct stones; Choledocholithiasis

Core tip: Endoscopic treatment by papillary large balloon

dilation for large stones can be safely performed in elderly patients, the same as in younger patients.

Endoscopic papillary large balloon dilation for bile duct stones in elderly patients. *World J Clin Cases* 2015; 3(4): 353-359 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i4/353.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i4.353

INTRODUCTION

The number of elderly patients with common bile duct stones has been increasing associated with the global prolongation of life expectancy[1]. Endoscopic retrograde cholangiopancreatography (ERCP) has been recognized as a treatment with less risk and lower mortality than surgery[2]. Endoscopic treatment for choledocholithiasis should be attempted as the first choice of treatment because of its high success rate in addition to its low invasiveness and low incidence of complications[3]. Although a report indicated that ERCP related procedures may be hazardous for patients with common bile duct stones as well as in elderly patients aged ≥ 80 years[4], it is often reported that this procedure can be useful and safely performed even in elderly patients[5-20]. The usefulness of endoscopic treatment using endoscopic papillary large balloon dilation (EPLBD) which is a new papillary treatment using a balloon of large diameter for large bile duct stones or multiple bile duct stones has been recently reported. Most of the reports described the procedure as safe and useful[20-34]. However, there have been some cases of death[35]. Since elderly patients often have an underlying disease, they may follow a fatal course, thus they require special attention[4]. There are few reports on the usefulness of this procedure in elderly patients[20], and it has not been examined sufficiently. This report examined usefulness of EPLBD in patients aged ≥ 80 years.

MATERIALS AND METHODS

The study involved 106 patients (A) with bile duct stones ≥ 13 mm in their short diameter, or (B) multiple (≥ 3) bile duct stones with the smallest more than 10 mm in the shortest diameter, but without confluence stones. These patients were selected from among those with bile duct stones visiting our hospital or our affiliated hospitals from November 2009 to June 2014. Inclusion criteria were patients who could undergo endoscopic sphincterotomy (EST), and who gave their informed consent to the procedure. Exclusion criteria were coagulopathy (international normalized ratio > 1.5), marked thrombocytopenia (platelet count < 50000/mL), patients who could not discontinue the administration of an anticoagulant or antiplatelet agent, patients for whom endoscopic biliary drainage was difficult (Billroth-Ⅱ or Roux-en-Y), patients with the papilla within the diverticulum, patients with stenosis of the intrapancreatic bile duct, stone diameter > 30 mm (shortest diameter), and patients who do not give their informed consent.

We selected 79 patients with new bile duct stones and 27 with recurrent stones. All cases of recurrent stones were those after EST. We performed EST in 65 patients and it had been already performed in 41 patients. Fourteen patients whose stones were not recurrent and EST had been already performed were difficult cases referred to our hospital for a lithotomy. The average diameter of the stones was 14.29 (10-28) mm, the number of stones was 5.73 (1-30) and the diameter of the bile duct was 16.97 (10-28) mm. As for the gall bladder, 77 patients were calculous, one was acalculous and 28 had undergone cholecystectomy. Parapapillary diverticulum was noted in 50 patients. The patients were divided into group A (< 80 years) and group B (≥ 80 years). The clinical background of patients in these 2 groups is shown in Table 1. Patients in group B tended to have significantly more frequently peripapillary diverticulum, hypertension, hyperlipemia, cerebrovascular disease/dementia, respiratory/cardiac disease, or were taking an anticoagulant or antiplatelet agent. There was no significant difference in other factors between group A and group B. One session of treatment lasted up to 60 min after inserting the endoscope. The condition of the patients was observed, and if the patient showed much discomfort, the procedure was completed after inserting the drainage, even while in the process of treatment. Before ERCP, all patients were given a standard premedication consisting of intravenous administration of midazolam (3 to 10 mg), and the dose depended on age and tolerance. Scopolamine butylbromide or glucagon was used for duodenal relaxation. During ERCP, arterial oxygen saturation was continuously monitored using a pulse oximeter. Patients were kept fasting after the procedure for at least 24 h with drip infusion of 2000 mL and remained hospitalized for at least 72 h. For cannulation, catheters PR-104Q, R110Q-1 and PR233Q were used. A 0.025-inch or 0.035-inch guidewire (Jagwire: Microvasive, Boston Scientific Corp., Natick, MA; Revo Wave: PIOLAX, or VisiGlide: Olympus Corp.) was used. The endoscopes used were JF240, JF260V, TJF260V (Olympus Corp.), backward side-viewing endoscope, for patients with no history of gastric resection and patients of Billroth-I. After cholangiography, a guidewire was placed in the bile duct to conduct EST. Clever-Cut3V (Olympus Corp.) was used as the knife for EST. EST was conducted using a single electrosurgical current generator (PSD-20, Olympus Corp.) at a power of 25 watts. For those in which an incision had been already

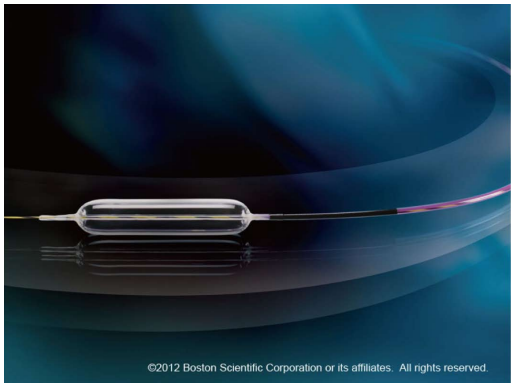

Figure 1 Endoscopic papillary large balloon dilation. CRE 12-20 mm (Wire-guided type 5.5 cm, Boston Scientific Corp., Natick, MA).

made, a guidewire was placed in the bile duct after cholangiography to perform EPLBD. In performing EPLBD, CRE 12-20 mm (Fixed wire type 8 cm or Wire-guided type 5.5 cm: Boston Scientific Corp.) was used depending on the diameter of the bile duct (Figure 1). For balloon dilation, a contrast agent mixed with saline solution at a volume ratio of 1:1 was used to slowly inflate it. Inflation was performed until the notch on the balloon disappeared (Figure 2). However, regardless of the disappearance of the notch, balloon dilation was completed when the papilla was dilated enough for stone removal. The balloon was dilated in a position where it was possible to confirm the tip of the balloon in the papillary side on the endoscopic image, and the position was maintained. After the notch on the balloon disappeared, the balloon was promptly deflated. When we considered it necessary to perform lithotripsy of the stone, we did it without hesitation.

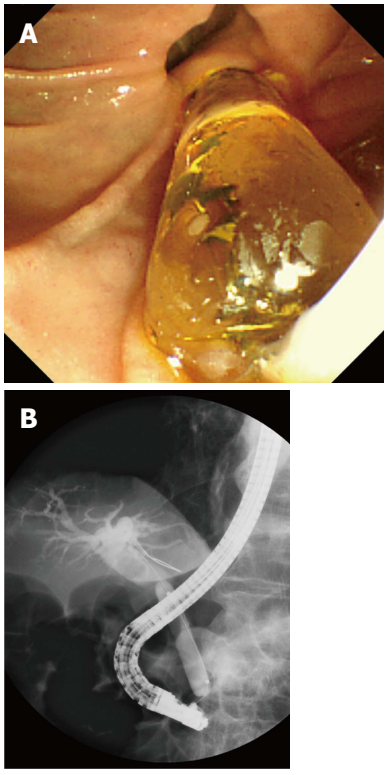

Figure 2 The papilla. A: The papilla was gradually dilated using a large balloon. Dilation was continued until the notch on the balloon disappeared (endoscopic image); B: The papilla was gradually dilated until the notch on the balloon disappeared (fluoroscopic image).

The basket catheter used for lithotripsy was LBGT-7245S (ZEON Medical) or BML-V237QR-30 (Olympus Corp.). Peroral cholangioscopy (POCSL) was performed by mother-baby system using CHF-B260 (Olympus Corp.) as the cholangioscope and Autholith (Northgate) as the electrohydraulic lithotripsy probe. The basket catheter used for collecting stones was FG-22Q or FG-V416Q (Olympus Corp.), LBGT-7245S (ZEON Medical) or BML-V237QR-30 (Olympus Corp.) The balloon catheter used was EXP718200 (ZEON Medical) or FS-QEB-XL-B (COOK). No drainage tube was inserted when lithotomy was successful, while it was inserted when we thought a stone still remained.

Iatrogenic morbidity was assessed according to the criteria of Cotton *et al*[36]. The observation period was 30 d after the procedure and any coincidental event noted during the period was considered as an early coincidental event. All the treatment procedures were performed after obtaining the informed consent from the patients in writing. This study was conducted after the study protocol was approved by the ethics committee of Chiba University.

Statistical analysis

Pearson χ^2 test with Yates correction and Fisher's exact test, when appropriate, were used for statistical analysis of categorical variables. Data were analyzed using SPSS software version 11 (SPSS, Chicago, IL). Differences with a P value of < 0.05 were considered statistically significant.

RESULTS

The success rate of lithotomy in the initial treatment was 88.7 (94/106)%. The final lithotomy rate was 100 (106/106)%. The time necessary to perform lithotomy was 39.4 (10-128) min and the mean treatment frequency was 1.21 (1-4) times. Lithotripsy was needed in 11.3 (12/106)% of the patients. Among the patients requiring lithotripsy, 6 had a highly tortuous bile duct and 6 had significantly large bile duct stones. For lithotripsy, endoscopic mechanical lithotripsy was performed in 10 patients and POCSL in 2. Complications due to the treatment procedure were observed in 4.7 (5/106)% of the patients, including bleeding in 1.9 (2/106)%, perforation in 0.9 (1/106)%, pneumonia in 0.9 (1/106)%, and acute cholangitis in 0.9 (1/106)%. Patients were classified into group A or group B for the analysis of data (Tables 2 and 3). The lithotomy success rate was 88.1 (52/59)% in group A, and 89.4 (42/47)% in group B and that for final lithotomy was 100%, both in group A (59/59)% and in group B (47/47). The lithotripsy rate was 10.2 (6/59)% in group A, and 12.8 (6/47)% in group B. Operation time was 37.59 ± 26.94 (12-125) min in group A, and 42.02 ± 27.12 (10-128) min in group B. The number of ERCP was 1.24 ± 0.683 (1-4) in group A, and 1.17 ± 0.529 (1-4) in group B. The incidence of complications was 6.8 (4/59)% in group A and 2.1 (1/47)% in group B, and there was no significant difference between group A and group B, regarding other parameters.

DISCUSSION

This study showed that elderly patients aged ≥ 80 years often have underlying diseases, however, results of treatment for large bile duct stones or multiple bile duct stones using EPLBD lithotomy were equivalent to those aged < 80 years in terms of success rate, lithotripsy rate, procedure time, number of ERCP, and complications caused by the procedure. EPLBD is the endoscopic treatment for bile duct stones reported by Ersoz *et al*[21] in 2003. Recently, the reports on the results of treatment for choledocholithiasis using EPLBD have been increasing[20-35]. Ordinary endoscopic papillary balloon dilation (EPBD) employs a balloon 4-10 mm in diameter for papillary dilation, whereas EPLBD is performed using a balloon 12-20 mm in diameter. Before this procedure was reported, lithotomy of large bile duct stones or multiple bile duct stones was difficult without lithotripsy of the stone. This procedure has the advantage that compared with EPBD or EST a larger papillary aperture can be obtained. It is reported in randomized controlled trials and meta-analyses that the larger papillary aperture enables easy insertion of the device as well as lithotomy of stones the same size as that of the dilated balloon without lithotripsy of the stones in many patients[34,37,38], which may be advantageous because the duration of the procedure would be shortened[26]. In this study many patients were cured after one session of treatment. There are many reports describing that in the nature of things, elderly patients have many underlying diseases, whereas the comparison of patients aged 80 years or greater with those aged less than 80 years showed the similar tendency[11,19]. Shorter treatment time is naturally an advantage even in young patients, and this study confirmed that a shorter treatment time was desirable for elderly patients because many of them have underlying diseases such as respiratory disease. Shorter treatment time is beneficial for elderly patients. There was no difference in the success rate of the procedure itself, however, many patients aged ⩾ 80 years have peripapillary diverticulum according to a past report[19], and this study also showed elderly patients tended to develop it, thus when performing the procedure, it may be necessary to pay attention to perforation. The presence of peripapillary diverticulum may cause deviation of the course of the bile duct leading to difficulty in cannulation[39]. However, this study revealed that there was no difference in the success rate of the procedure between the two groups. The reason may be due to recent advancement of the endoscope and its related treatment instruments. In this study, EPLBD was performed after EST. There are past reports describing

that it is possible to safely perform EPLBD without performing EST[35]. According to this study many elderly patients not only have peripapillary diverticulum but also are taking an anticoagulant or antiplatelet agent, thus if it were possible to safely perform EPLBD without performing EST, the procedure time would be shortened even further and the risk of perforation or bleeding would also be reduced.

Although a shorter procedure time and success of the procedure are very important for elderly patients, a low rate of complications derived from the procedure is also required. Past reports showed that complications caused by this procedure occurred at a low rate[20-35]. In the present study, complications occurred at a low rate and there was no difference between the two groups, suggesting it is possible to safely perform EPLBD even in elderly patients. The most problematic complications among ERCP related procedures is pancreatitis. Although it is reported that pancreatitis is less likely to occur in elderly patients because of their reduced pancreatic function[40], this study revealed there were no such results at all, suggesting that safety of the procedure is not only ensured for elderly patients but also that of the procedure itself is ensured. Reports describing usefulness and safety of EPLBD in elderly patients are currently limited to retrospective studies, thus a prospective study is necessary to confirm our findings.

EPLBD can be safely performed in elderly patients the same as in younger patients.

COMMENTS

Background

The usefulness of endoscopic treatment using endoscopic papillary large balloon dilation (EPLBD), which is a new papillary treatment using a large diameter balloon for large bile duct stones or multiple bile duct stones has been recently reported. Most of the reports have described this procedure is safe and useful. However, there are some cases of death. Since elderly patients are often complicated with underlying diseases, they may follow a fatal course after EPLBD, thus they require special attention. There are only a few reports on the usefulness of this procedure in elderly patients, and sufficient examination has not been conducted. This report examined the usefulness of EPLBD in patients aged ⩾ 80 years.

Research frontiers

The results of EPLBD in patients with bile duct stones ⩾ 13 mm in their short diameter or patients with three or more bile duct stones ⩾ 10 mm in their short diameter were examined.

Innovations and breakthroughs

EPLBD for bile duct stones was reported by Ersoz *et al* in 2003. Recently, its indication has widened. The reports describing the usefulness and safety of EPLBD in elderly patients are currently limited to retrospective studies. A prospective study is necessary to confirm our findings.

Applications

In patients with large common bile duct stones, endoscopic sphincterotomy (EST) + EPLBD is a good alternative to conventional EST. Before this procedure was reported, lithotomy of large stones or multiple stones was difficult without lithotripsy of the stones. Endoscopic treatment by papillary large balloon dilation can be safely performed in elderly patients the same as in younger patients.

Terminology

Treatment by EPLBD, which is lithotomy without lithotripsy for large stones by dilating the papilla using a large balloon, after performing EST has been reported. Endoscopic treatment by papillary large balloon dilation can be safely performed in elderly patients the same as in younger patients.

Peer-review

This is a retrospective study evaluating whether EPLBD can be safely and effectively performed in elderly patients. This study may be of interest to the readers.

Abstract

AIM: To evaluate the effects of two different doses of sugammadex after maintenance anesthesia with sevofluorane and remifentanil and deep rocuronium-induced neuromuscular blockade (NMB).

METHODS: Patients between 20 and 65 years of age, with American Society of Anesthesiologists physical status classification Ⅰ-Ⅱ, undergoing gynecological surgery were included in a prospective, comparative and randomized study. NMB was induced with an injection of 0.6 mg/kg of rocuronium followed by continuous infusion of 0.3-0.6 mg/kg per hour to maintain a deep block. Anesthesia was maintained with sevofluorane and remifentanil. Finally, when surgery was finished, a bolus of 2 mg/kg (group A) or 4 mg/kg (group B) of sugammadex was applied when the NMB first response in the train-of-four was reached. The primary clinical endpoint was time to recovery to a train-of-four ratio of 0.9. Other variables recorded were the time until recovery of train-of-four ratio of 0.7, 0.8, hemodynamic variables (arterial blood pressure and heart rate at baseline, starting sugammadex, and minutes 2, 5 and 10) and adverse events were presented after one hour in the post-anesthesia care unit.

RESULTS: Thirty-two patients were included in the study: 16 patients in group A and 16 patients in group B. Only 14 patients each group were recorded because arterial pressure values were lost in two patients from each group in minute 10. The two groups were comparable. Median recovery time from starting of sugammadex administration to a train-of-four ratio of 0.9 in group A and B was 129 and 110 s, respectively.

The estimated difference in recovery time between groups was 24 s (95%CI: 0 to 45 s, Hodges-Lehmann estimator), entirely within the predefined equivalence interval. Times to recovery to train-of-four ratios of 0.8 (group A: 101 s; group B: 82.5 s) and 0.7 (group A: 90 s; group B: 65 s) from start of sugammadex administration were not equivalent between groups. There was not a significant variation in the arterial pressure and heart rate values between the two groups and none of the patients showed any clinical evidence of residual or recurrent NMB.

CONCLUSION: A dose of 2 mg/kg of sugammadex after continuous rocuronium infusion is enough to reverse the NMB when first response in the Train-Of-Four is reached.

Key words: Rocuronium; Sugammadex; Neuromuscular block antagonism; Monitoring neuromuscular function; Neuromuscular block rocuronium

Core tip: The release of sugammadex in recent times has been a global shift in the strategy of the reversal of neuromuscular blockade (NMB) induced by aminosteroid neuromuscular blocking. The use of this drug has been increasing slowly, and consequently, we receive more and more questions in regards to its efficacy and safety. In this study we compared the dose of 2 mg/kg to 4 mg/kg sugammadex to reverse the NMB when first response in the train-of-four is reached after continuous infusion of rocuronium. Both doses have been shown to be effective for recovery from NMB.

Efficacy of different doses of sugammadex after continuous infusion of rocuronium. *World J Clin Cases* 2015; 3(4): 360-367 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i4/360.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i4.360

INTRODUCTION

Neuromuscular blockade (NMB) is an important technique in modern anesthesia because it improves surgical conditions by suppressing voluntary movements or muscular reflexes. The use of neuromuscular blockers is highly beneficial in determined types of surgery, such as laparoscopy, as it improves the surgical access and the visual field[1]. However, the extended use of NMB is associated with increased postoperative morbimortality due to the risk of residual neuromuscular paralysis or recurarization and the development of subsequent complications[2,3]. Such complications can be reduced by objective monitoring of muscle relaxation and NMB reversal after the surgical procedure.

The release of sugammadex [Bridion®, merck sharp and dohme, Oss, The Netherlands] triggers a change in the way of reversing aminosteroid neuromuscular blocking drugs. Sugammadex is a gamma-cyclodextrin with a lipophilic cavity that traps aminosteroid neuromuscular blocker molecules to form an inactive complex, thus preventing their union with nicotinic receptors and reversing their effects[4,5]. Clinical data suggests that sugammadex has a favorable efficacy and safety profile[4,6,7], allowing a safer and faster recovery-even from deep NMB[8]-than the commonly used combination of acetylcholinesterase inhibitors and anticholinergic agents.

Halogenated anesthetics, such as sevoflurane, increase the effect and duration of rocuronium[9], and this effect is clinically most significant when using a continuous infusion of rocuronium[10]. However, such do not appear to alter the efficacy or safety of sugammadex[11-13]. We hypothesize that a dose of sugammadex could result in a suitable recovery time although it depends on the individual redistribution and elimination of rocuronium as well[14]. The provider has not defined what the ideal dose of sugammadex for reversal the NMB when first response in the train-of-four (TOF) is reached. So, we have designed a study based upon on this hypothesis: after a surgical procedure, a dose of 2 mg/kg sugammadex is comparable to a dose of 4 mg/kg for reversal the NMB induced by a continuous infusion of rocuronium administered when first response in the TOF (T1) is reached.

MATERIALS AND METHODS

Patients and methods

A prospective, randomized and comparative study was designed to include patients undergoing a gynecological surgery, and took place over one year. The study was approved by the Regional Research Ethics Board of Principality of Asturias (Ref 118/2013; approved in August, 2013) and, after being given a verbal explanation, all patients gave their written informed consent. Applicable regulations and good clinical practice guidelines concerning NMB were followed in all cases[15].

The study included patients between 20 and 65 years of age, with American Society of Anesthesiologists (ASA) physical status classification Ⅰ-Ⅱ, who were scheduled for elective gynecological laparoscopy procedures under general anesthesia with sevoflurane requiring NMB with a minimum duration of 1 h, and carried out by the same surgical team.

The sample size was calculated on the basis of data for previous recovery time from NMB to first response in the TOF after sevoflurane anesthesia followed by 4 mg/kg sugammadex[14]. A 50% increase in recovery time was considered to be clinically relevant. To obtain statistically significant results with a probability of

type Ⅰ error (α = 0.05), probability of type Ⅱ error (β = 0.10), and a statistical power of 90%, a total of 22 patients were required. Therefore, 32 patients were recruited to compensate for any possible losses.

Patients were randomized to receive a dose of 2 mg/kg (group A) or 4 mg/kg (group B) after surgical procedure by the responsible anesthesiologist as previously had been determined. A manual randomization method was performed.

Exclusion criteria were as follows: previous known neuromuscular disease, obesity [defined as a body mass index (BMI) $\geqslant$ 30 kg/m^2], allergy to any drug used in the general anesthesia, history of malignant hyperthermia, liver or kidney insufficiency, predicted difficult airways or a previous history of difficult intubation, use of drugs that affect the neuromuscular system (for example: magnesium, anticonvulsants, aminoglycosides), pregnancy or lactation, or any other medical condition which could affect level of consciousness.

Anesthesia and neuromuscular monitoring

All patients received intramuscular 2 mg midazolam as premedication. Standard monitoring was performed once the patients were in the operating room (pulseoximetry, capnography, electrocardiography and noninvasive arterial pressure). Patients were preoxygenated with FIO_2 of 1.0 for 3 min before induction of anesthesia with intravenous propofol (1.5-2.5 mg/kg) and fentanyl (1-2 mcg/kg).

Neuromuscular function was monitored through kinemyography (KMG) in form of the Mechanosensor-Neuromuscular Module Transmission (M-NMT®) (GE Healthcare, Helsinki, Finland) integrated in the Datex-Ohmeda anesthesia machine. The right arm was placed at an angle of 90° to the longitudinal axis of the body and the electrodes were placed on cleaned skin 3-6 cm apart over the ulnar nerve at the wrist. M-NMT was placed on the adductor pollicis muscle. Physical means were used to maintain the peripheral temperature above 35 ℃.

Once the induction of anesthesia was finished and before the administration of rocuronium, the M-NMT monitor was calibrated using 200 μs pulses at a rate of 2 Hz, starting at 5 mA with increments of 5 mA. The maximal current was increased by 15%, yielding the supramaximal stimulation. The 0.6 mg/kg of rocuronium bolus was then injected provided that a first 2 Hz TOF stimulation for 1.5 s yielded four equal responses within 15% of the calibration. When there was no measurable response to TOF stimulation, the patients were intubated and mechanical ventilation was initiated. This initial dose was followed by a continuous infusion of 0.3-0.6 mg/kg per hour of rocuronium which was adjusted to maintain a deep block with a TOF response of zero and PTCs less than 10 for the duration of the procedure. TOF stimulations were repeated every 15 s throughout the study. A PTC mode was initially applied 5 min after obtaining complete NMB and repeated every 6 min. Anesthesia was maintained with sevoflurane 1%-3% end-tidal. In both groups analgesia was provided by remifentanil with a dose of 0.05-0.5 mcg/kg per minute.

Upon completion of the surgery, the administration of sevoflurane, remifentanilo and rocuronium ended. At the reappearance of the T1, every patient received a dose of sugammadex according to the group in which they had been randomized (2 mg/kg in group A, or 4 mg/kg in group B), and they were awoken once complete NMB reversal (TOF ratio $\geqslant$ 0.9) was reached. Neuromuscular monitoring was continued until patients were extubated. Once recovered, they were transferred to the post-anesthesia care unit.

After one hour in the post-anesthesia care unit, a member of the team who was blind to the sugammadex dose that the patient had received, evaluated in each patient the presence of any residual paralysis through neuromuscular monitoring and performed a clinical assessment by signs of muscular weakness and clinical tests (lifting the head for more than 5 s, holding a tongue depressor between the teeth and generalized muscular weakness). The post-anesthesia oxygen saturation, breathing rate and any possible hemodynamic instability as well as the appearance of any adverse effect was also recorded. The same post-surgical analgesia protocol was applied to all patients.

Statistical analysis

Patient baseline quantitative variables in the two groups were compared by two-sided Student *t*-test if they followed a normal distribution. Categorical variables were analyzed by Pearson χ^2 test (or Fisher Exact test if expected count less than 5). Odds ratio (OR) and its CI was calculated if necessary.

The primary efficacy variable was the time (in seconds) between commencing sugammadex administration and reaching recovery of the TOF ratio to 0.9. The time until recovery of TOF ratios to 0.7 and 0.8 were studied too. We used the statistical approaching method described by Rex *et al*[14]. The CI approach was used to demonstrate equivalence in recovery of the TOF ratios between the two treatment groups. Non statistical signification was established if the two-sided 95%CI for the estimated difference of median between group A and group B was within the interval ranging from 0% to 50% of the median of group B. The 95%CI was obtained by using the nonparametric methods of Hodges-Lehmann. Similarly, TOF ratio to 0.7 and 0.8 were studied.

The hemodynamic variables were the evolution of arterial blood pressure (AP) and the heart rate (HR) after sugammadex injection. AP and HR were recorded every 5 min throughout the intervention: previously, during the start of sugammadex, and 2, 5 and 10 min after initiating administration of the drug. Any possible secondary effect associated to its administration was also recorded.

Table 1 Demographic characteristics

Sugammadex (dose)	Group A (n = 16)		Group B (n = 16)		P-value
Age (yr)	43.6	(SD 12.01)	47.1	(SD 14.18)	0.46
Weight (kg)	65.5	(SD 11.22)	60.9	(SD 10.62)	0.25
Height (cm)	163.2	(SD 4.76)	160.1	(SD 5.91)	0.12
BMI (kg/m^2)	24.1	(SD 3.56)	23.2	(SD 3.65)	0.47
Intervention (time-minute)	95.2	(SD 26.91)	94.7	(SD 30.02)	0.96
ASA (1-2)	1.4	(SD 0.51)	1.2	(SD 0.48)	0.28
ASA 1[a]	n = 9	(56.25%)	n = 12	(75.00%)	0.23

Analyzed by student t-test. Both groups are similar. [a]ASA 1 is expressed as percentage of patients with an ASA index of 1 in its group and a Fisher exact test was executed. BMI: Body mass index; ASA: American Society of Anesthesiologists.

Data for AP and HR were analyzed by repeated measure analysis of variance (ANOVA-RM). The within-subjects terms were the AP and HR values for each patient, and the repeated term was the time point (baseline, starting, and minute 2, 5 and 10). Pillai's Trace[16] is calculated for AP and HR and their interactions with sugammadex doses. They were corrected with epsilon multipliers if the assumption of circularity had been violated following Mauchly's test[17]. Lower bound was elected to be the most conservative. Post-hoc analyses were executed. The P-values < 0.05 were considered significant. All tests were 2-sided. Data was analyzed using SPSS 17.0 for Windows (SPSS Inc., Chicago, United States).

RESULTS

A total of 32 patients were included in the study, 16 patients in group A and 16 patients in group B. All descriptive variables are summarized in Table 1. However, AP was not taken in the 10th minute in two patients in each group. Because AP in the 10th minute is a related sample within temporal evolution (the others are AP baseline, pre-sugammadex, minute 2th and minute 5th), only 14 patients from each group were computed (another two were excluded). So, all results were analyzed by per-protocol; however, AP values were lost in two patients in each group for the 10th minute.

The gynecological interventions were fourteen vaginal assisted laparoscopic hysterectomies (43.7%), eleven laparoscopic ovarian cystectomies (34.4%) and seven laparoscopic adnexectomies (21.9%). The two groups were comparable in terms of age, BMI and ASA (Table 1). Surgical time was more than 60 min in all cases.

All patients recovered to a TOF ratio of 0.9 within 3 min (maximum value 175 s). Median recovery time from starting of sugammadex administration to a TOF ratio of 0.9 was 129 s in group A and 110 s in group B. The estimated difference in recovery time between the two groups was 24 s (95%CI: 0 to 45 s, Hodges-Lehmann estimator). This CI was entirely within the predefined equivalence interval (for a median of 110 s in group B = 0 to 52.5 s), so equivalence was assumed. Times to recovery to TOF ratios of 0.8 and 0.7 from start of sugammadex administration were not equivalent between groups. Median time to recovery to a TOF ratio of 0.8 was 101 s in group A and 82.5 s in group B, with an estimated difference of 18 (95%CI: -5 to 39 s, Hodges-Lehmann estimator). 95%CI was out of predefined equivalence interval of 0 to 43.7 s. Median time to recovery to a TOF ratio of 0.7 was 90 s in group A and 65 s in group B, with an estimated difference of 10 (95%CI: -10 to 35, Hodges-Lehmann estimator). So, 95%CI was out of predefined equivalence interval of 0 to 32.5 s. Equivalences were not assumed for TOF ratio 0.8 and TOF ratio 0.7 (Table 2).

There was no significant variation in the AP and HR between the two groups. Although both of them maintained AP and HR within normal ranges the entire time, there was a logical increment of AP and HR as time passed until the effect of anesthetic drugs disappeared. So, post-hoc analyses were statistically significant across the 2nd, 5th and 10th minute within each group (Figure 1).

Based on neuromuscular monitoring and clinical signs, none of the patients showed any clinical evidence of residual or recurrent NMB. Although group B had more adverse events than group A, there was no statistical difference between them (group A: 12.5% *vs* group B: 18.7%, OR = 1.62; 95%CI: 0.23-11.26, P = 0.99). There were no severe adverse effects, even with an increased dosage of sugammadex. As a consequence, in the immediate post-operatory period in group A, there was one case of nausea and another case of pain, while in group B, there was one case of nausea, one case of pain and one patient suffered tremors in lower limbs (Table 3). Habitual symptomatic treatments were adopted and they were effective without any more clinical relevance.

DISCUSSION

Our study suggests that a dose of 2 mg/kg sugammadex is enough for the recovery of NMB induced by a continuous infusion of rocuronium in patients who kept anaesthetized with sevoflurane. This lower dose did not

Table 2 Train-of-four ratio studies

	Group A (n = 14)		Group B (n = 14)					
	Mean	Median	Mean	Median	Assumed calculated interval (increased of 0% to 50% of median in group B)	Estimated difference median by Hodges-Lehmann estimator	95%CI	
TOF ratio 0.9	118.8	129	96.6	105	0 to 52.5	24	0 to 45	Differences not assumed
TOF ratio 0.8	96.7	101	80.1	82.5	0 to 43.7	18	-5 to 39	Assumed
TOF ratio 0.7	78.4	90	66.3	65	0 to 32.5	10	-10 to 35	Assumed

Based on the value of the median of TOF ratio in the Group B, an interval was calculated to establish the acceptable variation of the median values in the Group A (an increase from 0% to 50% respect Group B). The Hodges-Lehmann estimator was calculated for the differences between TOF ratio 0.7, 0.8 and 0.9 medians with their 95%CI. All values are expressed in seconds. If the Hodges-Lehmann 95%CI was contained in the 95%CI based on medians of the Group B, no statistical and clinical differences would be assumed. TOF: Train-of-four.

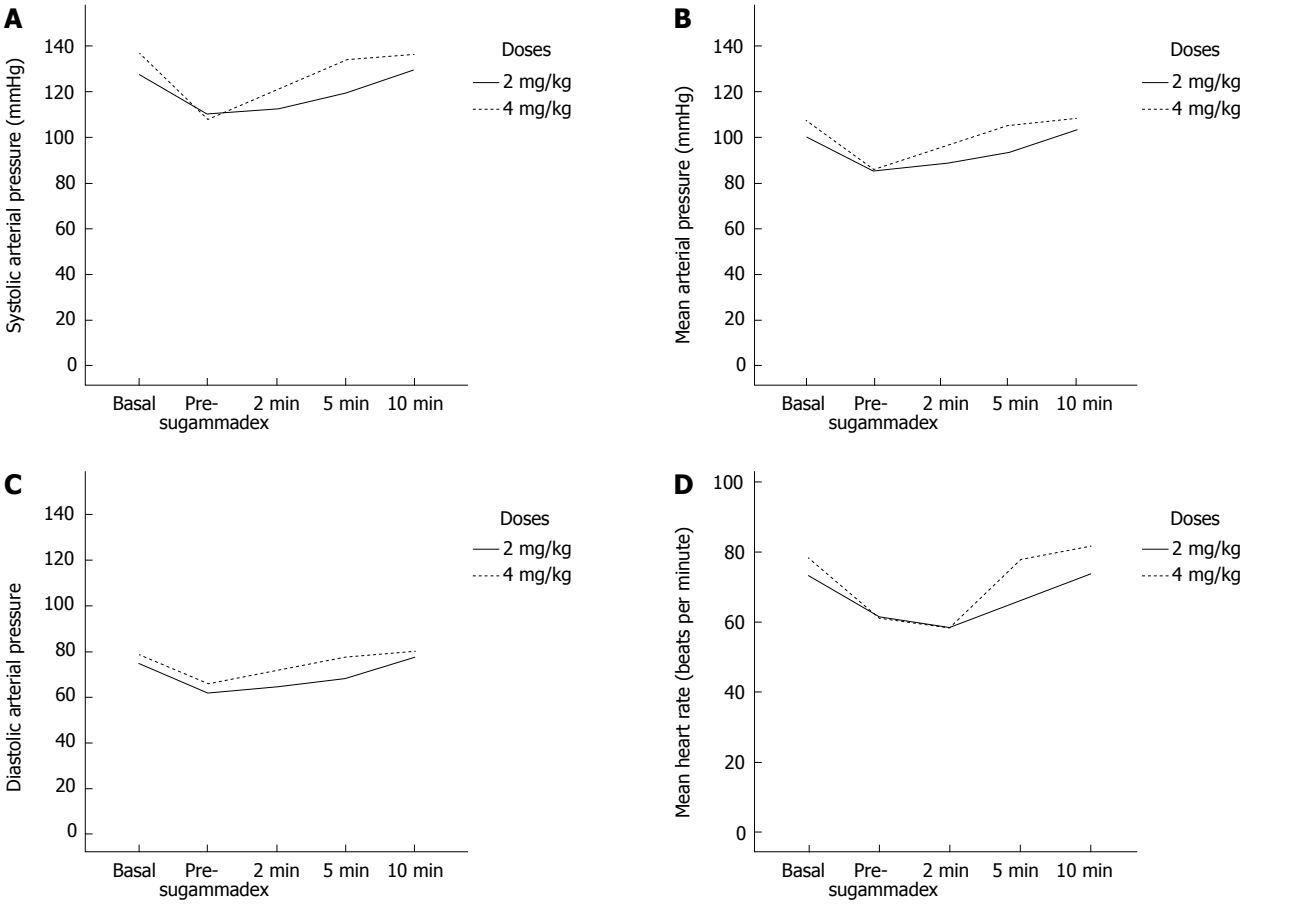

Figure 1 Arterial pressures and heart rate after sugammadex administration. A: Systolic arterial pressure; B: Mean arterial pressure; C: Diastolic arterial pressure; D: Mean heart rate. The increased amount of arterial pressures and heart rate after sugammadex administration was statistically significant as the time passed (post hoc analysis in ANOVA-RM). But the values were in the normal range the entire time. So, it only shows the activity of both administered doses and there was no statistical significance between them.

have any clinically relevant recovery time augmentation or increased risk of residual recurarization. We have not been able to observe other adverse events in our patients.

The main limitation in our study was the lack of rocuronium and sugammadex plasma concentration determinations at different moments of the study. Although previous studies have shown a similar rocuronium pharmacokinetic profile when compared continuous infusion *vs* intravenous bolus dose[18], significant variations in plasma concentrations of rocuronium were also observed in those continuously infused with this drug (highly variable, up to 30% for some patients)[14]. For this reason, neuromuscular transmission monitoring suggested a better option in patients who received continuous infusions of rocuronium as a more realistic approach to the global effect of the drug. This is not routinely used in current

Table 3 Adverse events

Adverse events	Group A	Group B
Arterial hypertension	0%	0%
Arterial hypotension	0%	0%
Bradycardia	0%	0%
Cough	0%	0%
Headache	0%	0%
Nausea	6.20%	6.20%
Pain	6.20%	6.20%
Residual neuromuscular blocking	0%	0%
Vomiting	0%	0%
Others	0%	6.20%

daily monitoring in clinical practice[19,20] and a study published in the United Kingdom in 2007 reported that 62% of anesthetists surveyed had never used monitors to evaluate the effect of NMB[20].

Another point of interest was the use of a dose of 4 mg/kg of sugammadex. It has been demonstrated as preferable in the reversion of deep NMB[8]. The provider recommends a dose of 4 mg/kg if recovery has reached at least 1-2 PTCs, and a dose of 2 mg/kg sugammadex when spontaneous recovery has occurred up to least the reappearance of second response in the TOF[21]. Other authors consider in clinical practice that the appropriate dose of sugammadex for reversing a moderate block (TOF-count 1-3) is 2 mg/kg of sugammadex[22].

A TOF ratio $\geqslant$ 0.9 was used as the main desirable objective variable because a postoperative residual curarization TOF ratio < 0.9 is associated with increased morbidity and extended stay in the post-anesthesia care room[23]. It has been published that with 4 mg/kg of sugammadex, the time to recover a TOF ratio of 0.9 from 1-2 PTCs (induced by a bolus of rocuronium under anesthesia with sevoflurane) was 1.7 min compared to 3.2 min with a dose of 2 mg/kg of sugammadex[12]. However, studies comparing the efficacy of sugammadex in surgical patients when NMB was induced through the infusion of rocuronium are very scarce. Rex *et al*[14] demonstrated that just one dose (4 mg/kg) of sugammadex administered at a NMB to T1, after continuous infusion of rocuronium, was sufficient and safe with both sevoflurane and propofol. This use of continuous infusion of rocuronium has been shown to lengthen the NMB recovery time compared with one single bolus[24], thereby providing a more stable drug concentrations with a constant degree of paralysis. In our series, we find that difference between the means of the TOF 0.9 of both groups is lower than previously described: approximately an increase of only 23% *vs* the estimated published of 88%[12]. This difference can be attributed to different time of reversal of NMB and different procedures.

A limitation of our study is the age of the patients and the kind of surgical intervention (young and gynecological patients). In contrast, these patients were elected because they were attended by the same surgical team; hence similar laparoscopic conditions were expected in all cases. We decided to limit the age to 65 years because, even though reversal from profound block with sugammadex can be performed safely and effectively, there have been reports regarding older patients who recover more slowly than younger ones[25,26]. This slower recovery could be due to age-related decreased cardiac output and muscular blood flow[26].

Another possible bias in our study could be that surgical procedures lasted 60 min. They may be classified as insufficient. Nonetheless, it has been seen that a dose of 2 or 4 mg/kg of sugammadex is sufficient for reversion of NMB, even when deep NMB (1-2 PTCs) is maintained for 2 h or more, with reversal being performed when the second TOF response occurs[8,27].

We also observed the safety of using sugammadex. Adverse events related to the administration of sugammadex have been reported in the literature with an incidence of 14%, the most common being nausea, vomiting, bradycardia, hypertension and hypotension, oliguria, vertigo, headache, cough, dry mouth and intraoperative movements[28]. However, these adverse effects were not related with the use of sugammadex[11,12] or the dose administered. In our series, we found a similar occurrence in the two groups and there was no statistical difference between them. We consider that they were expectable, without direct relationship with the studied drug and not clinically relevant.

It could be supposed that the use of sugammadex would lead to a reduction of adverse events in the immediate postoperative period. They require additional resources and a longer recovery time. So, sugammadex could improve efficiency and reduce the costs related to surgical activities[29,30]. Nevertheless, the reduction of the sugammadex dose to save costs could be a mistake which may lead to other complications, such as the recurrence of NMB after an apparently successful recovery[31]. In this study we do not analyze the economic implications of the lower dose. We think that the group size is too small to establish conclusions, because they were selected and calculated to observe the effect on TOF 0.9 of sugammadex in two different doses. A dose of 2 mg/kg is evidently the half of cost of 4 mg/kg but it is only in respect to a simple drug expenditure and we cannot apply it to the complete surgical procedure and its multiple non-contemplated influent variables.

Only future investigation will make enable us to consider readjusting the currently recommended doses in specific circumstances, without an increase in the risks[32]. So, more studies are necessary in different surgical sceneries to understand all possibilities of sugammadex.

In conclusion, in our study, a dose of 2 mg/kg sugammadex was found to be efficient and safe for reversing the NMB when first response in the TOF is

reached, after a continuous infusion of rocuronium without increasing the risk of residual recurarization. Future studies are required to determine any possible readjustments of doses and the consequent risks that lower doses of sugammadex may cause in the reversal of NMB. In the future, with the absence of plasma level of drugs, neuromuscular monitoring will be essential in the daily anesthetic practice, especially when rocuronium is given as a continuous infusion for the immediacy of its results.

COMMENTS

Background

The introduction of sugammadex to antagonize non-depolarising neuromuscular blockade (NMB) has led to significant changes in anaesthesia practice. Residual effects of neuromuscular block can have significant clinical consequences and can cause critical respiratory events. The superiority of sugammadex (*vs* neostigmine) for reversing neuromuscular block has now been well established.

Research frontiers

Sugammadex should be dosed according to the prescriber information issued by the manufacturer. The provider recommends a dose of 4 mg/kg if recovery has reached at least 1-2 PTCs, and a dose of 2 mg/kg sugammadex when spontaneous recovery has occurred up to at least the reappearance of second response in the train-of-four (TOF), but they don´t define the ideal dose of sugammadex for reversal the NMB when first response in the TOF is reached.

Innovations and breakthroughs

This study suggests that a dose of 2 mg/kg sugammadex (*vs* 4 mg/kg) is enough for the recovery of NMB induced by a continuous infusion of rocuronium in patients who kept anaesthetized with sevoflurane when first response in the TOF is reached. This lower dose did not have any clinically relevant recovery time augmentation or increased risk of residual recurarization. The authors have not been able to observe more adverse events in the patients.

Applications

A dose of 2 mg/kg sugammadex was found to be efficient and safe for reversing the NMB when first response in the TOF is reached without increasing the risk of residual recurarization. Future studies are required to determine any possible readjustments of doses and the consequent risks that lower doses of sugammadex may cause in the reversal of NMB. In the future, quantitative neuromuscular monitoring is mandatory and increased postoperative vigilance is required in order to identify the problems of incomplete reversal.

Terminology

After injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient for smooth tracheal intubation, TOF recording demonstrates three phases of NMB: intense, moderate or surgical blockade, and recovery. Intense NMB is also called the period of no response because no response to TOF or single-twitch stimulation occurs. Although this phase it is not possible to determinate exactly how long intense NMB will last, correlation does exist between PTC stimulation and the time to reappearance of the first response to TOF stimulation. Moderate blockade begins when the first response to TOF stimulation appears. This phase is characterized by a gradual return of the four responses to TOF stimulation. The return of the fourth response in the TOF heralds the recovery phase. Satisfactory recovery from NMB has not occurred until the TOF ratio is > 0.9.

Peer-review

This is a study comparing the efficacy and safety of two different doses of sugammadex. The paper is well written and designed.

Abstract

Hair thread tourniquet syndrome is rare and usually affects little children. If the tourniquet is not incised, the affected body part becomes ischemic or even necrotic. An 18 mo old girl was seen in the emergency ward with a painful, red and swollen third toe of the left foot. The toe appeared to be strangulated with a hair, and the diagnosis hair thread tourniquet syndrome was made. After incision of the hair tourniquet the symptoms soon subsided. The diagnosis is easily made if the clinical features are recognized. However, if the tourniquet is not cut through, the affected body part may become ischemic and even necrotic.

Key words: Hair; Thread; Tourniquet; Syndrome; Toe

Core tip: Hair thread tourniquet syndrome is rare and usually affects little children. We present a case of an 18 mo old girl with a strangulated toe. After incision of the hair tourniquet the symptoms soon subsided. The diagnosis is easily made if the clinical features are recognized. However, if the tourniquet is not cut through, the affected body part may become ischemic and even necrotic.

INTRODUCTION

Hair thread tourniquet syndrome (HTTS), or hair tourniquet syndrome, is a syndrome in which children experience strangulation of small extremities (fingers, toes or external genitalia) with a hair or thin wire[1,2]. If the strangulation is not recognized, the affected body part becomes ischemic, and can even necrotize in a few hours to weeks[2,3]. In this report, a patient with HTTS of the third toe is presented, for which she was surgically treated.

CASE REPORT

An 18 mo old girl was presented in the emergency ward, after her mother had noticed a constriction

Figure 1 Strangulation of the third toe: Typical clinical picture of hair thread tourniquet syndrome.

around her third toe of the left foot, that morning. She thought this may have had been caused the previous day, when the child's father had removed some hairs from under the toes, after a visit to the swimming pool. The girl was otherwise healthy and did not take any medication. The mother had had a normal partus (C-section), and the girl had afterwards been in the hospital only once, with fever caused by a viral infection.

On physical examination we saw a healthy looking 18 mo old girl, with a strangulation around the third toe of the left foot. No hair or thread could be seen around the toe. Redness and swelling was seen around the strangulation. A normal capillary refill (< 2 s) was seen. Upon palpation, the toe was painful (Figure 1).

An attempt was made to remove (remains of) the strangulating hairs with a stitch cutter, without success. With the idea that possibly all the hairs had already been removed by the father, the patient was sent home, and the mother was advised to return the next day if the strangulation remained.

Indeed, they returned the next day. Physical examination was similar to the previous day, with unchanged strangulation, and still good capillary refill.

It was decided to incise the hair tourniquet in the operating room under general anesthesia. After incision to the bone-medial, between the proximal and distal interphalangeal joint-some hairs were removed.

One day after surgery, the swelling had largely subsided, and the constriction had almost disappeared. After two weeks the girl was seen again, and all symptoms were gone.

DISCUSSION

HTTS is a strangulation of a small limb, usually a finger or toe, or sometimes external genitalia. When the diagnosis is made correctly, treatment is simple and effective. Differential diagnoses may include cellulitis, erysipelas, or other irritation of the skin (for example after being bitten by an insect), or trauma[3].
