VK DEFICIENCY BLEEDING IN NEWBORNS

Before the identification of VK as an essential cofactor for the production of functional coagulation factors, Townsend[61] (1894) reported 50 cases of a generalized bleeding tendency in neonates in a condition that was named the hemorrhagic disease of the newborn (HDN). He described that HDN differed from hemophilia in its earlier presentation, the lack of a family history and in its self-limiting course. Townsend[61] suggested a link between the mother's capacity to breast-feed and the hemostatic capacity of the newborn infant. After the identification of the role of VK in blood coagulation, the disease was shown to be related to VK nutritional deficiency and was renamed as VK deficiency bleeding (VKDB) by the ISTH Pediatric/Perinatal Subcommittee in 1999[62,63]. Although VK deficiency can occur in adults, it is common in newborns because of their limited VK storage, immature gastrointestinal absorption and due to the low placenta transfer of VK. The diagnosis of VKDB can be made in infants younger than 6 mo of age who present spontaneous bleeding, bruising, or intracranial hemorrhage with a prolonged clotting time but with a normal or elevated platelet count. Since the VKDB patients who present with intracranial bleeding are exclusively breastfed, Greer *et al*[64] investigated phylloquinone intakes in exclusively breast-fed infants in a North America and found that the average daily intake was one-tenth of that in healthy adults while formulated milk contained 50-fold higher concentration of phylloquinone than human milk. Although VKDB is rare in most developed countries, the consequences for the small number of patients who develop intracranial hemorrhage are often catastrophic. Nearly all cases of HDN/VKDB reported in the literature occur in infants who did not receive prophylactic VK supplementation in the newborn period. Consequently, many countries have introduced the routine prophylactic administration of VK at the time of birth to prevent hemorrhagic events[65,66].

THE INVOLVEMENT OF VK IN GENERAL HEALTH

Beyond the originally identified function of VK in blood coagulation system, it has been widely reported that VK has possible benefits on bone health and cardiovascular diseases[6,67]. Menatetrenone, a VK2 analog, has been used safely for the treatment of osteoporosis. Several clinical trials have shown it to be effective for treating osteoporosis in postmenopausal women, although the effects of VK2 alone might not be sufficient[68-70]. The potential benefit of VK in reducing cardiovascular disease risk is also reported and it might due to its function as a cofactor in the post-translational modification of the calcification-inhibiting matrix Gla protein[71,72]. An investigation revealed that UBIAD1-generated VK2 played an essential role in maintaining endothelial cell survival and overall vascular homeostasis[73].

A European large cohort study showed that dietary VK intake was associated with the reduced risk of cancer incidence in the prostate and the lung and that the effects were more pronounced in men than in women[74]. Furthermore, a more recent study demonstrated the association between the dietary intake of VK and the reduced risk of cardiovascular disease, cancer, and all-cause mortality in a Mediterranean population[75].

THE CLINICAL ASPECTS OF VK IN LIVER CANCER

In 1984, abnormal des-carboxy prothrombin was specifically detected in the plasma of patients with HCC[76]. It has since been used as specific diagnostic marker of HCC independent of α-fetoprotein[77,78]. Since the administration of VKs to patients with increased DCP levels showed a transient reduction of DCP levels, HCC was considered to exist under a condition of VK deficiency[79,80]. Earlier studies showed that the administration of VKs on cancer cells including HCC *in vitro*, resulted in anti-proliferative effects[30-33]. Thus, the anti-tumor effects of VK on HCC have been expected to be found *in vivo*.

In 2004 Habu *et al*[81] demonstrated that menatetrenone, a VK2 analog, suppressed the development of HCC in women with viral hepatitis-related cirrhosis. Since then, several randomized controlled studies reported the suppressive effects of menatetrenone on the recurrence of HCC after curative ablation therapy and surgical resection of the liver[82-86]. Although several initial reports with small study populations showed the favorable effects of VK2 in inhibiting the recurrence of HCC after treatment and improving tumor recurrence-free survival, a large randomized control trial (RCT) in which VK2 was administered after curative treatment, failed to show the advantage of VK2 administration[87].

Zhong *et al*[88] reviewed six RCTs and one cohort study, with a total of 930 patients and performed a meta-analysis. Although treatment with VK2 did not reduce the 1-year recurrence rate, there was a significant association between VK2 and reduced 2- and 3-year tumor recurrence. VK2 treatment was also associated with a significant improvement of 1-, 2-, and 3-year overall survival. However, the results might be considered to still be preliminary because the large scale RCT was evaluated at only 1 year. Therefore, a longer follow-up will be required to confirm the effects of VK2 on HCC.

FUTURE DIRECTIONS

Although various studies have reported the anti-HCC effects of VK2, the analogs in current use do not appear to exhibit dramatic anti-tumor effects when administered alone. One way to overcome this situation

is with the co-administration of VK and other reagents with anti-cancer properties. Yoshiji *et al*[85] reported the beneficial effects of VK2 combined with ACE inhibitor. Recently acyclic retinoid peretinoin showed beneficial effects on the recurrence and survival of hepatitis C virus-infected HCC patients after curative therapy[89]. VK2 plus ACR synergistically inhibited the growth of Huh7 cells[49]. Currently sorafenib is the only drug approved for the systemic treatment of HCC[90]. It has been shown to extend the survival period of end-stage HCC patients for several months. However, the effect of sorafenib on HCC is not yet satisfactory. Many novel-developed anti-cancer reagents that specifically target the signal transduction pathway of HCC cells have been tested clinically, but most of trials failed to demonstrate their non-inferiority to sorafenib[91,92]. A combination treatment with sorafenib and VK2 was examined *in vitro* and *in vivo* animal models and the studies showed that VK2 enhanced the tumor-suppressive effects of sorafenib[93-95].

Another way to enhance the effects of VK would be to develop a new VK derivative, which may be achieved by modifying the side chains of VK. Several approaches to develop novel VK analogs have been conducted. Since some of the effects of VK are considered to be mediated by SXR transcription factor as a ligand of VK2[34,56], Suhara *et al*[96,97] screened a series of chemically synthesized VK analogs by measuring the SXR-mediated transcriptional activity and found that the modification of the side chain of VK affects the SXR-mediated transcriptional activity. Setoguchi *et al*[98] synthesized a prodrug of an active form of menaquione-4 that is effectively delivered to HCC cells and which showed the enhanced anti-tumor effects on HCC cell growth.

Recently the repositioning (repurposing) of pre-existing drugs that have been safely used for long-term treatment in a clinical setting has been performed with many drugs such as aspirin and metformin[99,100]. Some of these drugs have begun to be used for chemoprevention and/or for the therapeutic purpose of enhancing anti-cancer effects. VKs seem to be one of the successful examples of repositioned drugs. After the discovery of VK as a cofactor of functional coagulation factor production, it has been shown to be beneficial for the maintenance of bone physiology and the prevention of cardiovascular diseases. Beyond these effects, the novel function of VK as an anti-tumor agent has been applied to the prevention and treatment of HCC, however, the beneficial effects of VK on HCC were found to be limited. The recent progress of novel technologies, such as a genome wide association studies and computational analysis, has been the first step to the repositioning of drugs[101,102]. These approaches will lead to novel applications of VKs and the development of novel VK-based reagents, and may be applied to the treatment of HCC in the future.

Abstract

Recently, many surgeons have been using intraoperative neurophysiological monitoring (IOM) in spinal surgery to reduce the incidence of postoperative neurological complications, including level of the spinal cord, cauda equina and nerve root. Several established technologies are available and combined motor and somatosensory evoked potentials are considered mandatory for practical and successful IOM. Spinal cord evoked potentials are elicited compound potentials recorded over the spinal cord. Electrical stimulation is provoked on the dorsal spinal cord from an epidural electrode. Somatosensory evoked potentials assess the functional integrity of sensory pathways from the peripheral nerve through the dorsal column and to the sensory cortex. For identification of the physiological midline, the dorsal column mapping technique can be used. It is helpful for reducing the postoperative morbidity associated with dorsal column dysfunction when distortion of the normal spinal cord anatomy caused by an intramedullary cord lesion results in confusion in localizing the midline for the myelotomy. Motor evoked potentials (MEPs) consist of spinal, neurogenic and muscle MEPs. MEPs allow selective and specific assessment of the functional integrity of descending motor pathways, from the motor cortex to peripheral muscles. Spinal surgeons should understand the concept of the monitoring techniques and interpret monitoring records adequately to use IOM for the decision making during the surgery for safe surgery and a favorable surgical outcome.

Key words: Motor-evoked potentials; Somatosensory-evoked potentials; Intraoperative neurophysiological monitoring; Direct wave; Spinal surgery

Core tip: Recently, many surgeons have used intraoperative neurophysiological monitoring (IOM) in spinal surgery to reduce the incidence of postoperative neurological complications, including level of the spinal cord, cauda equina and nerve root. Several established technologies are available and multimodality combinations are considered necessary for practical and effective

IOM. Spinal surgeons should understand the concept of the monitoring techniques and interpret monitoring records adequately to use IOM for the decision making during the surgery for safe surgery and a favorable surgical outcome. In this review, the authors will review the different IOM techniques to provide a fundamental concept for better comprehension.

INTRODUCTION

Recently, many surgeons have used intraoperative monitoring (IOM) in spinal surgery to reduce the incidence of postoperative neurological complications, including level of the spinal cord, cauda equina and nerve root. Its importance has been emphasized to prevent an unsuspected and unpleasant neurological deficit after spinal surgery. Surgeons should understand the rationale and clinical basis for IOM to interpret the monitoring alerts and to utilize them for a better surgical outcome. Several established technologies are available and combined motor and somatosensory evoked potentials are considered mandatory for practical and successful IOM. In this review, the authors will review the different IOM techniques to provide a fundamental concept for better comprehension.

MONITORING TECHNIQUES

Spinal cord evoked potentials

This technique was invented in Japan in the 1970s. Electrical stimulation was provoked on the dorsal spinal cord from an epidural electrode[1]. The evoked compound potentials from the stimulated spinal cord are recorded over the spinal cord. The spinal cord evoked potentials (SCEP) correspond to summation of neural activities originating from the ascending and descending tracts and neurons near the recording electrode. The recorded potentials are very vigorous and most likely represent the combined activity of the tracts of the spinal cord, such as dorsal columns, the corticospinal tracts and others[2]. In a practical setting, SCEP cannot provide sufficient information about motor-related function because sensory-related potentials, which are large in amplitude, mask motor-related potentials. The advantages and disadvantages of each modality, including SCEPs, are summarized in Table 1.

Somatosensory evoked potentials

Somatosensory evoked potentials (SEPs) assess the functional integrity of sensory pathways from the peripheral nerve, through the dorsal column and to the sensory cortex. SEPs were first used in the 1970s to monitor the spinal cord function during surgery for scoliosis correction. After stimulation of peripheral nerves, SEPs are recorded both from the spinal cord with an epidural electrode and/or from the cortex. SEPs can be applied for monitoring the peripheral sensory pathways consistently[3]. From a technical point of view, the posterior tibial nerves are stimulated (duration of stimulus, 0.2 ms; frequency, -3 Hz; intensity, -25 mA). SEPs are the result of averaging. The acquisition time is on the order of 1 min[4]. Data are measured to determine latency and amplitude. Latency is a measure of time and is related to distance. Amplitude is a measure of power and characteristically more variable than latency. This potential indicates activities from the dorsal column such as the sensory tract. By shifting the stimulus site, one can identify the laterality of dorsal column lesions. Monitoring the laterality can provide important information during posterior myelotomy for removing intramedullary spinal cord tumors. An increase in latencies greater than 10% and a decrease in amplitudes greater than 50% constitute warning signals. SEPs are altered by the surgical procedure due to a mechanical factor or secondarily by ischemia. SEP alterations can also be related to patient's age, height and length of the limbs, systemic hypotension, hematocrit decrease, hypothermia and anesthesia (volatile agents such as isoflurane, halothane, nitrous oxide attenuate SEPs and should not be used if monitoring is employed). Body temperature is a common factor affecting spinal somatosensory evoked potential (SSEP) latency readings.

SSEP

Monitoring of dorsal column integrity with SSEP is the most commonly used technique in spinal surgery. Large diameter, myelinated and fast conducting cutaneous and muscle afferents carry the peripheral SSEP. SSEP can monitor the dorsal column-medial lemniscus pathway, which mediates tactile discrimination, vibration sensation, form recognition and joint/muscle sensation (conscious proprioception). In SSEP monitoring, stimulation electrodes excite controlled repetitive action potentials that propagate from peripheral nerves to the contralateral sensory cortex through the dorsal roots and the dorsomedial tracts of the spinal cord.

These signals can be recorded at various anatomically accessible locations, such as the peripheral nerve, spinal cord, brainstem and its endpoint and the somatosensory cortex. Platinum subdermal needle electrodes are used for both stimulation and recording. Generally, a 50% decrease in amplitude with an associated 10% increase in latency in comparison to the patient's baseline values constitute a warning signal. A previous study reported that false negative SEP monitoring occurred during surgery in only 0.063% of patients[5]. A large multicenter study has reported that postoperative paraplegia was reduced more than 50%-60% with SEP monitoring[6]. Although SSEP signals are good basic indicators of spinal cord function, they cannot provide much information regarding nerve root function.

Table 1 Summary of advantages and disadvantages of each monitoring technique

	Advantages	Disadvantages
SCEP	Easy to record using very simple hardware	The electrode used to deliver stimulation to the spinal cord should be located in the epidural space and the recording electrode in the intrathecal space
	Provides real-time information because its potentials are large enough without averaging	The malposition of the electrode can occur
		Previous scarring can sometimes impair electrode placement
SEP	Broadly available	Does not directly monitor corticospinal tract. Only assess the functional integrity of spinal cord dorsal columns. In the case of anterior spinal artery syndrome, postoperative paraplegia despite intraoperative SEP preservation has been reported
	Easy to implement	When approaching the intramedullary tumor during the initial dorsal myelotomy, SEPs can completely disappear
	Has no contraindications	SEP recording requires signal averaging, which results in a time delay until data interpretation can generate a response to the surgeon. Therefore, an injury can be irreversible before it is even detected
	Can be combined with other monitoring techniques	
	Allows continuous monitoring throughout case	
	Excellent specificity (approaching 100%)	
Neurogenic	Fast and easy to implement	Their specificity remains relative because they correspond to the joined activation of motor and sensory pathways
MEP	Resistant to most anesthetics	Require curarization
	Sensitive in detecting a lesion	The terminal medullary cone is not monitored
	In case of alert, the lesional level can be determined by displacing the stimulation electrode along the intervertebral spaces	
D waves	Very rapid acquisition	The recording electrode is in the surgical field and its use by the surgeon can produce artifacts
	D waves are specific of motor pathways	Laterality cannot be distinguished
	They can establish a lesional level by displacing the spinal electrode along the intervertebral spaces	D waves cannot be used in small children, generally under 4 yr of age (incomplete maturation of motor path-ways)
	D waves have prognostic value	Cannot be recorded below the level of T12 because there are not enough corticospinal tract fibers
	Correlates most accurately with long-term motor function following intramedullary spinal cord tumor resection	Previous scarring can sometimes impair electrode placement
Muscle MEP	Do not require an averaging. Thus immediate feedback can be available	Require at least partially functional motor pathways
	Preserved sensitivity and sensitivity even after posterior myelotomy	Incompatible with prolonged curarization
		Exceptional adverse effects have been described: tongue or lip laceration, mandibular fracture, cardiac arrhythmia, epileptic seizures, scalp burn and intraoperative awareness
		Often difficult to carry out on patients under the age of 6 yr because of incomplete maturation of motor pathways
Pedicle screw testing	Rapid and easy technique	Sensitive to a large number of anesthetics
	Can be combined with new surgical instruments used during screw placement	Can be distorted by curarization
	High sensitivity for medial pedicle breach	Less sensitive for thoracic pedicle screws than for lumbar pedicle screw
	Useful in minimally invasive surgery where anatomical landmarks may be challenging to visualize	Optimal alarm criteria not firmly established
		Does not directly assess for neurological injury, only provides information regarding pedicle integrity

SCEP: Spinal cord evoked potentials; MEP: Motor evoked potential; SEP: Somatosensory evoked potentials.

Dorsal column mapping

It is important to decide where to perform the myelotomy during intramedullary spinal cord surgery. Anatomic landmarks are often utilized as an indicator for midline intraoperatively. The typical anatomical landmarks for midline of the spinal cord include the dorsal median sulcus between the dorsal columns and the median dorsal sulcal vein which enters the midline raphe. Dorsal column mapping technique can be applied to identify the "physiological midline". It is helpful for reducing the postoperative morbidity associated with dorsal column dysfunction when an intramedullary cord lesion distorts the normal spinal cord anatomy that results in confusion in distinguishing the midline for the myelotomy[7-9]. The multielectrode grid is placed transversely over the dorsal surface of the cord. It has multiple wires and each wire has been stripped of its insulating coating. These recording wires pass parallel to the long axis of the

spinal cord and a reference needle electrode is inserted in a nearby muscle. This multielectrode grid can record the traveling SEP waves from the dorsal surface of the exposed spinal cord very selectively with the amplitude gradient corresponding to the topographic arrangement of the dorsal column. Because of the somatotopic distribution of ascending fibers in the dorsal column, the highest amplitude close to the midline will be recorded after SEP stimulation on the right posterior tibial nerve. By the same reaction from the contralateral side, we can identify "physiological midline" between these two amplitude peaks.

MOTOR EVOKED POTENTIALS

Direct waves (or spinal motor evoked potentials)

D (direct) waves are compound corticospinal action potentials initiated by direct axonal activation with conduction velocity approximately 50 m/s[10], making it possible to monitor the motor pathways from the cortex to the level of the spinal electrode. D waves are obtained by a single transcranial electrical stimulation (intensity, 80-100 mA; duration of stimulus, 0.5-1 ms; frequency, 0.5-2 Hz) recorded from the epidural or subdural space of the spinal cord[11]. It is generated directly by the electrical pulse. Therefore, they are called "single stimulus technique" or "spinal motor evoked potentials (MEPs)". D waves usually do not need averaging, although a few averages improve its quality of recording. This provides clinically real-time feedback. If the D wave amplitude decreases more than 50% of the baseline value or cannot be detectable, there is high probability of severe neurological deficit such as permanent paraplegia.

Neurogenic MEP

Neurogenic MEP is an elicited potential that is electrically stimulated at the spinal cord with epidural electrodes and then recorded from the peripheral nerves. Neurogenic MEPs are recorded by stimulating the spinal cord through electrodes inserted by the surgical team: A flexible spinal electrode inserted into the epidural space proximal to the operating field. The stimulation parameters are the following: intensity, 20-50 mA; duration of stimulation, 1 ms; frequency, 4.1 Hz. Recordings are performed at the internal popliteal sciatic nerves or the posterior tibial nerves. This technique allows monitoring of the overall spinal cord. In 1988, recording neurogenic evoked potentials from peripheral nerves in lower extremities after spinal cord stimulation was suggested[12] to monitor spinal motor pathways. It is now widely revealed that these potentials contain at least a significant antidromical sensory component[13-15]. Neurophysiological collision studies have shown that the biphasic component corresponds to antidromical activation of the sensory pathways, whereas the polyphasic component corresponds to activation of the motor pathways. Neurogenic MEPs provide combined sensory and motor spinal pathway monitoring[16,17].

Muscle MEP (or myogenic MEP)

Motor potentials are evoked with transcranial electrodes which are placed on the scalp over the motor cortex area of the skull. The stimulus points are C3, C4, C1, C2, Cz and a point 6 cm in front of Cz (international 10-20 system)[11]. Muscle MEPs are derived from transcranial electrical stimulation (five to seven pulses, 2-4 ms apart; intensity, 250-750 V; duration of each pulse, 0.5 ms) over the same electrodes as for the D-wave. The technique is called the "multipulse technique" or "train stimulus technique". Compound muscle action potentials (CMAP) are recorded with needle electrodes from target belly muscles in all four limbs. Muscles are selected based on the surgical procedure and spinal levels involved. Typical muscles for arm MEP recordings include the abductor pollicis brevis (thenar muscle); the 1st dorsal interosseous and hypothenar muscles are alternatives. Typical muscles for leg MEP recordings include the tibialis anterior (TA) and abductor hallucis (AH). Other muscles, such as the quadriceps, deltoids, biceps, even the diaphragm, and the external anal sphincter can be selected. Muscle MEPs allow selective and specific analysis of the functional integrity of descending motor tracts, from the motor cortex to muscles. Recordings are lateralized for each limb. Muscle MEPs do not require averaging and can be repeated at a rate of 0.5-2 Hz. A reduction of more than 50% of the baseline amplitude can be an alarm point for postoperative motor deficit. However, even though muscle MEPs are lost, there may be a transient deficit but no permanent postoperative deficit if the D wave is preserved[18]. A temporary postoperative motor deficit can occur when muscle MEP amplitude is lost but D wave amplitude preserved. In this situation, surgeons can continue the resection or stop and wait for recordings to recover, which they often do. Muscle MEP loss without D wave changes or the D wave decrease without muscle MEP changes in muscle MEP occurs. A D wave maintained over 50% of the baseline indicates that the neurons of the corticospinal tract which controls delicate voluntary movements remain. In any event, if the D wave was preserved over 50% of the baseline value, it is considered that the voluntary motor control in the lower extremities are preserved[19]. A decrease of the amplitude of muscle MEP is not always associated with postoperative neurological deficit; however, it is valuable to evaluate the early ischemic or mechanical damage to the spinal cord. Despite several reports that refer the accuracy of D-wave monitoring during surgeries for intramedullary spinal cord tumors, muscle MEP monitoring is maintained as a valuable tool. This is because muscle MEP does not need an epidural electrode, has a higher generation rate of MEP and it is more accurate in monitoring for scoliosis surgery[20].

ANESTHETIC CONSIDERATIONS

Both SSEP and MEPs are affected by various pharmacological and physiological factors. Any drug or

physical parameter that influences electrical conduction along an axon may alter the evoked potential waveform. In general, the longer with more synapses tracts are, the more sensitive they are. Furthermore, a greater number of pulses will be needed for lower extremity recordings compared with upper extremity sites because it is easier to obtain signals from the upper extremity than from the lower extremity. This is because the hand area occupies a larger representation on the motor cortex[21]. Inhaled anesthetics reduce the amplitude and increase latency, while intravenous anesthetics have the same effect but to a lesser degree. Halogenated or nitrous oxide-based agents influence SSEP amplitude and latency. MEPs are generally more sensitive to anesthetics than SSEPs. Total intravenous anesthesia without neuromuscular blockade is material to muscle MEPs to allow CMAP monitoring. Typically, induction with short-acting muscle relaxants, a continuous infusion of propofol and fentanyl and low level nitrous oxide use (not exceeding 50% by volume) are mandatory for MEP monitoring. In our institute, when we need IOM for the surgery, anesthesia is maintained with a continuous infusion of propofol (10 mg/kg per hour) and remifentanil (0.25 mg/kg per minute). At induction, a single bolus of non-depolarizing short acting muscle relaxant (rocuronium) is given to facilitate tracheal intubation and ventilation. The level of neuromuscular block is monitored by recording the CMAP to a train of 4 stimuli.

ELECTROMYOGRAPHY

Spontaneous electromyography

Spontaneous or free-running electromyography (EMG) is widely applied to monitor selective nerve root function during spinal cord surgery. Unlike SEP and SSEP data, EMG is "real-time" recording from peripheral musculature. Spontaneous EMG can help to prevent postoperative radiculopathy during spinal instrumentation surgery, including pedicle screw placement. This technique does not require stimulation and can be recorded continuously from preselected muscle groups based on the nerve roots at risk[22]. One muscle group per nerve is generally considered appropriate. Common EMG recording sites by spinal levels are as follows: C4 - supraspinatus; C5 - deltoid and biceps; C6 - biceps and wrist extensors; C7 - triceps, wrist flexors and finger extensors; C8 - hand intrinsics and finger flexors; T1 - hand intrinsics; T6-12 - rectus abdominis; L1 - iliopsoas; L2 - adductor longus; L3 - adductor longus and vastus medialis; L4 - vastus medialis and vastus lateralis; L5 - TA and extensor hallucis longus; S1 - medial gastrocnemius and peroneus longus; S2-5 - perianal musculature and urethral sphincter. However, in case of cervical spinal surgery, many surgeons favor monitoring 2 muscle groups, deltoid (predominantly C5, also C6) and biceps brachii (predominantly C6, also C5), due to the risk of C5 palsy[23]. At baseline, no muscle activity is recorded from an intact nerve root. Surgical manipulations such as pulling, stretching or compression of nerves provokes spikes or bursts of activity termed neurotonic discharges, resulting in activity in the corresponding innervated muscle(s). Spontaneous EMG is quite sensitive to irritation of the nerve root, such as retraction of spinal cord or nerve root, saline irrigation and manipulation during surgery. However, false spontaneous EMG activation commonly occurs during irrigation with cold water, cauterization and use of a high-speed drill because it is sensitive to temperature changes.

Spontaneous EMG trains are continuous, repetitive EMG firing caused by continuous mechanical stress on the nerve root. Trains of higher frequency and/or amplitude are likely to indicate a high probability of nerve injury unless a prompt corrective management is performed. On the other hand, spontaneous EMG spikes and bursts indicate the proximity of the nerve root.

It is also important to note that EMG signals are interfered with in patients with various neurological disorders, such as myasthenia gravis, botulinum toxin treatments for dystonia and muscular dystrophy.

Pedicle screw testing by triggered EMG

The introduction of triggered EMG for evaluating the integrity of lumbar pedicles during screw placement and the accuracy of pedicle screw placement was first described by Calancie *et al*[24] in 1992 using a porcine model. The concept of triggered EMG is that intact cortical bone should be electrical insulation for a well-placed pedicle screw from the adjacent nerve root. In contrast, the pedicle screw would be relatively poorly insulated when medial pedicle breach occurred[22]. Intraoperative triggered EMG detects root irritation or the post injury condition of the root after medial pedicle breach. An irritated or damaged nerve root causes a decrease in electric threshold followed by sudden appearance of CMAPs of the specific muscles of the myotome after stimulation *via* the screw[25]. Each pedicle screw is electrically stimulated with an increasing intensity from 5 to 30 mA (duration, 0.2 ms; frequency, 0.8 Hz). Recordings are made at the level of the lower limb muscles with or without the rectus abdominis muscles (depending on the root levels to test). The recording of muscle activity at an intensity under 10 mA (the classically accepted threshold) argues in favor of a medial breach (close proximity of the screw to the nerve root).

PATTERNS OF MEP CHANGES DURING SURGICAL PROCEDURES

MEP changes occur most frequently towards the end of the tumor resection when the interface between the tumor and normal tissue comes close. Some of the authors of this study have previously reported that the type of muscle recorded affects the changing patterns and prognostic values of muscle MEP[26]. Muscle MEPs recorded from the AH muscle were relatively resistant to perioperative neural damage, otherwise the

muscle MEPs from the TA were relatively vulnerable to perioperative neural damage at an earlier time and/or more sensitive compared with the single-muscle recordings in the AH. Thus, the loss of muscle MEP in the TA, even though muscle MEPs in the AH were preserved, should be considered a potential early warning sign for possible postoperative neurological deficit. This result is a meaningful point of view in that using a combination of muscle MEPs from different muscles with individual sensitivities and clinical significances will improve intraoperative muscle MEP monitoring interpretations and surgical strategies.

ACTIONS TO RECOVER DETERIORATED MEP

There are some procedures useful for promoting the recovery of deteriorated or lost MEPs during spinal surgery[8,10,11,27,28]. First, transient stopping the surgical manipulations immediately after MEP and observation may recover MEP spontaneously. Second, irrigation of the surgical field with warm saline solution generally removes irritating blood products and metabolites. It is believed that accumulated extracellular potassium which is derived from local tissue damage by surgery acts as a strong axonal blocking agent. Third, local application of papaverine and increasing the mean arterial pressure (MAP) more than 90 mmHg can facilitate local perfusion to resist local ischemia. Sustained hypotension may affect MEPs and may result in an unfavorable postoperative outcome. Temporary moderate elevation of MAP may restore blood flow and may lead to improving both D-waves and muscle MEPs successfully if ischemia due to insufficient MAP is the primary cause. Fourth, when dissection in a particular location results in MEP changes, the resection at a different site can proceed without further aggravation. Fifth, increasing body temperature also may help recover MEPs because deep hypothermia obliterates muscle MEPs. Sixth, when all the previous methods have failed to regain MEP, applied correction is reduced or anchoring hardware removed in case of the correction of the spinal deformity. If there is still no significant signal recovery, a steroid bolus (methylprednisolone or dexamethasone) could be considered. Finally, if there is no noticeable neurophysiological improvement in response to all methods described above, consider removing the spinal implant or discontinuing tumor resection.

IOM IN PRACTICE

For many years, only SEPs were monitored during spinal cord surgeries before MEP techniques were developed. Since the multipulse technique was introduced in the mid-1990s, combined muscle MEP and SEP monitoring have been routinely used intraoperatively in various spinal operations, including from deformity correction to intramedullary cord tumors. Many authors have reported that combined SEP/MEP monitoring provided higher sensitivity and higher positive/negative predictive values than single-modality monitoring techniques and that optimal monitoring requires both SEPs and MEPs[27-30].

The reliability of intraoperative MEP to identify impending motor deficits has been improved, mainly as a result of accumulated knowledge interpreting the MEP changes. Monitoring muscle MEPs became the gold standard due to their increased sensitivity and the importance of motor function. It has been believed most widely that MEP recordings are stable if changes were less than 50% in amplitude and less than 10% in latency. However, there is no definite alarm point. Various different alarm points have been reported. From a surgical viewpoint, the 50% criterion could have the effect that the surgical correction of the deformity is performed incompletely or tumor resection is forsaken too early and the 80% criterion that the operation proceeded too aggressively[30]. The benefit of more sensitive MEP criteria and the risk of stopping resection too early should be always considered in parallel. This is important especially for tumors of which the most important prognostic factor is complete resection, such as spinal cord ependymomas.

Some authors have attempted to establish a more sensitive and specific warning criteria recently[31]. They recommend an alarm point of a 70% decrease in amplitude for routine spinal cord monitoring, particularly during surgery for spinal deformity, ossification of posterior longitudinal ligament and extramedullary spinal cord tumor, but not in cases of intramedullary spinal cord tumor. Different MEP methods and warning criteria still exist (muscle MEP, D-wave, absence/presence criteria, amplitude criteria and morphology criteria, *etc*.) and neither definite monitoring method nor definite warning criteria have been established. Future study should establish a more confident and accurate IOM method or criteria which prosecutes an aggressive tumor removal while preserving function of the spinal cord.

Reliable IOM enables surgeons to perform more difficult and challenging surgical procedures to the spine and spinal cord safely. Its role is to accurately identify the topography of neural structures and to avoid surgical insults by giving real-time alarms to the surgical team so that there is a response immediately. The role of IOM is increasing not only in deformity correction and intramedullary tumors but also in various spinal surgeries. It is well known that a rapid decompression of cervical medulla or cervical cord could result in neurological deficits such as C5 palsy, paresis or even plegia. It is possible to have a stretching of the lumbar roots during the reduction of the high dysplastic lumbar spondylolisthesis. IOM can help the surgical team accomplish a safe and successful outcome in spinal surgery which affects the spinal cord or spinal roots directly or indirectly. Multimodal IOM is a useful method to prevent spinal cord injury during neck positioning in cervical spine surgical procedures. It should not only be

considered for detecting intra-operative warnings, but also during positioning[32].

Case illustration

A 17-year-old girl visited our institute with back pain. She was diagnosed as a scoliosis associated with neurofibromatosis (Figure 1). We planned to perform a deformity correction by posterior column osteotomies and posterior segmental spinal instrumented fusion with intraoperative combined MEP and SSEP monitoring. When we applied the rod to the screw heads using a derotation maneuver and cantilever maneuver, the amplitude of MEP at both lower extremities decreased more than 50% compared with the baseline amplitude (Figure 2A). However, SSEP showed no change compared with the baseline amplitude (Figure 3). The amplitude of MEP recovered after correction release by removal of the rods and set screws (Figure 2B). The amplitude of MEP re-deteriorated after reassembly of the implants (Figure 2C). The amplitude of MEP recovered finally after raising MAP and administration of dexamethasone (Figure 2D). After the corrective surgery (Figure 1), she woke up without any postoperative neurological deficit and was discharged from the hospital on foot.

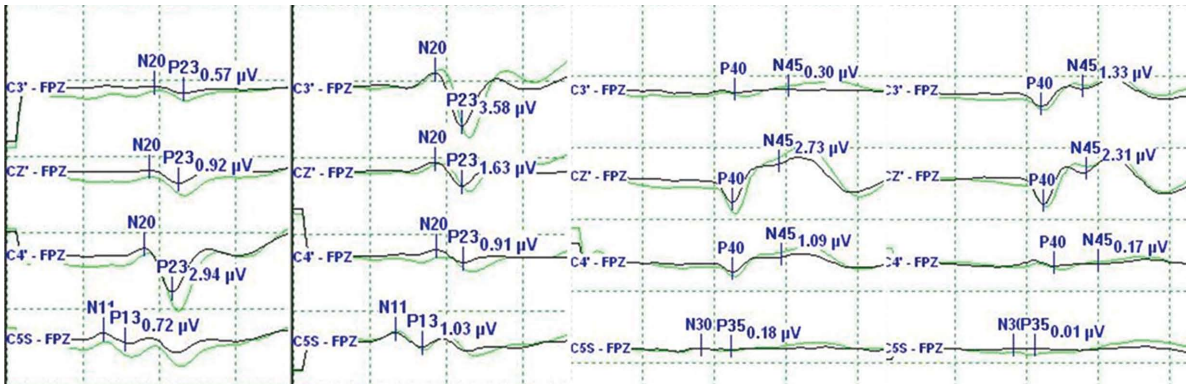

Figure 3 Spinal somatosensory evoked potential showed no change compared with the baseline amplitude (green line).

CONCLUSION

Although we cannot monitor every function of the spinal cord during spinal surgery, the technology of IOM has markedly developed. It is certain that the significance and utilization of IOM during spinal surgery will increase because of medicolegal issues as well as its usefulness. Spinal surgeons should understand the concept of the monitoring techniques and interpret monitoring records adequately to use IOM for decision making during the surgery for safe surgery, favorable surgical outcome and the surgeon's medicolegal safety.

Abstract

Esthesioneuroblastoma (ENB) is a rare malignant neoplasm arising from the olfactory neuroepithelium. ENB constitutes only 3% of all malignant intranasal neoplasm. Because of the rarity, the number of patients of ENB treated in individual departments is small. Most of these patients presents in locally advanced stages and require multimodality treatment in form of surgery, chemotherapy and radiotherapy. Multimodality approach with a risk-adapted strategy is required to achieve good control rates while minimizing treatment related toxicity.

Key words: Surgery; Radiotherapy; Chemotherapy; Esthesioneuroblastoma

Core tip: This article is a comprehensive review of literature of a rare and aggressive neoplasm. This article outlines the various newer details of diagnosis, staging and treatment aspects of esthesioneuroblastoma (ENB). The importance of multimodality approach in management of ENB is reviewed in detail.

INTRODUCTION

Esthesioneuroblastoma (ENB) is a rare malignant neoplasm arising from the olfactory neuroepithelium, including the superior one third of the nasal septum, cribriform plate, and superior turbinates, extending to base of the skull and to the intracranial space[1]. ENB was first described by Berger *et al*[2] in 1924. Because of uncertainty regarding the precise histological origin of the tumour, it has been described using various names in the literature, but the commonly used terms in recent publications are ENB and olfactory neuroblastoma. It constitutes only 3% of all intranasal neoplasms and its etiology remains unclear[3]. ENB manifests across all ages, with peaks in the second and sixth decades of

Table 1 Hyams histopathological grading

Grade	Lobular architecture preservation	Mitotic index	Nuclear polymorphism	Fibrillary matrix	Rosettes	Necrosis
Ⅰ	+	Zero	None	Prominent	HW rosettes	None
Ⅱ	+	Low	Low	Present	HW rosettes	None
Ⅲ	+/-	Moderate	Moderate	Low	FW rosettes	Rare
Ⅳ	+/-	High	High	Absent	None	Frequent

life[4].

CLINICAL PRESENTATION

ENB have varying biological behaviour, ranging from slow indolent growth to a highly aggressive neoplasm with rapid widespread metastasis resulting in poor survival[5]. The most common presentation is unilateral nasal obstruction followed by epistaxis. Other clinical features develops with local spread of tumor like proptosis (infiltration into orbital canal), cranial nerve palsies (infiltration into cranial foramens and brain), swelling in neck (neck nodes) and metastatic symptoms[6].

PATHOLOGY

Light microscopy features consists of homogeneous small cells having uniform round to oval nuclei. Rosette or pseudorosette formation, and eosinophilic fibrillary intercellular background material is seen. However, in undifferentiated tumors, with anaplastic hyperchromatic small cells showing many mitotic figures and scant cytoplasm, differentiation from other small-cell nasal neoplasms is difficult with light microscopy[7]. Hyams Grading system is routinely used for histopathological grading and it consists of four grades (Ⅰ-Ⅳ)[8]. Hyams grading takes into account the architectural pattern, mitosis, nuclear pleomorphism, fibrillary matrix, rosettes and necrosis (Table 1). On immunohistochemistry (IHC), the tumour is positive for neuron specific enolase (NSE), synaptophysin, chromogranin and S-100 protein, but most cases are negative for cytokeratin, vimentin, desmin, actin, glial fibrillary acidic protein, UMB45, and leucocytic common antigen[7]. Electron microscopy is reliable in visualising uniform round nuclei, dense core neurosecretory granules, neuronal processes with microtubules and neurofilaments, and rare synapses[7]. The closest histopathological differential diagnosis is neuroblastoma. The neuroblastoma stains positive for NSE, synaptophysin, Leu7, and neurofilament protein. Elevated serum catecholamines are also suggestive of neuroblastoma.

INVESTIGATIVE WORK-UP

The gold standard of diagnosis is biopsy of the lesion showing characteristic histopathological features along with IHC. Fine needle aspiration cytology of suspected lymph nodes in neck is recommended to rule out nodal spread. Local extension of the tumor is evaluated using contrast enhanced computed tomography (CECT) of the face and neck (Figure 1). Magnetic resonance imaging (MRI) is better in evaluating sinonasal, intraorbital or intracerebral extension (Figure 2). As computed tomography (CT) can better demonstrate bony erosions, both studies are usually required in most of the patients[9]. Chest X ray, Ultrasound abdomen and CECT chest and abdomen is helpful in detecting systemic metastasis. Baseline hemogram, renal function tests and liver function tests are done for further treatment planning. Positron emission tomography is not routinely recommended for staging evaluation but can be used as an adjunct to CT and MRI.

STAGING

Tumor staging is an important guide for prognosis and therapy. Several staging systems, including Hymans, Kadish, and tumor, node, metastasis (TNM) systems, have been proposed as a guide to choosing treatment modalities. Staging for ENB was first proposed by Kadish *et al*[10] and the tumors were staged as three group categories. Group A is limited to tumors of the nasal cavity; group B is extension to the paranasal sinuses; and group C is extension beyond the paranasal sinuses and nasal cavity. Morita *et al*[11] in 1993 published a revised Kadish system that redefined stage C (consisting of local disease spreading beyond the paranasal sinuses) and included a stage D (distant metastasis) (Table 2). In 1992, Dulguerov *et al*[6] proposed TNM staging system based on the TNM system, determined on pre-treatment CT and MRI findings (Table 3). However, modified Kadish staging system is the most widely used staging system.

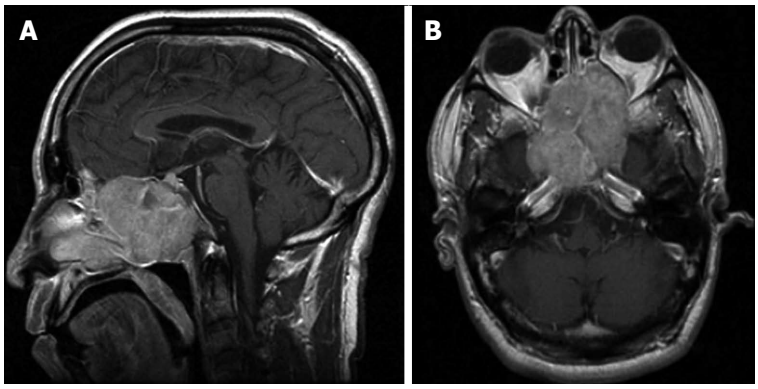

Figure 2 T1 W sagital section (A) and axial section (B) magnetic resonance imaging showing locally advanced esthesioneuroblastoma. Table 2 Modified kadish staging

Stage A: Tumour limited to the nasal fossa
Stage B: Tumour extension into the paranasal sinuses
Stage C: Tumour extension beyond the paranasal sinuses and nasal cavity
Stage D: Distant metastasis

Table 3 Tumor, node, metastasis staging system

T1	Tumour involving the nasal cavity and/or paranasal sinuses (excluding sphenoid), sparing the most superior ethmoidal cells
T2	Tumour involving the nasal cavity and/or paranasal sinuses (including the sphenoid) with extension to or erosion of the cribriform plate
T3	Tumour extending into the orbit or protruding into the anterior cranial fossa, without dural invasion
T4	Tumour involving the brain
N0	No cervical lymph-node metastasis
N1	Any form of cervical lymph-node metastasis
M0	No metastases
M1	Distant metastasis

TREATMENT MODALITIES

The various treatment modalities used in the management of ENB are surgery, chemotherapy, radiation therapy (RT) and palliative care. Nowadays, the multimodal approach is recommended for improved survival and quality of life of the patients.

Surgery

The mainstay of the treatment is surgery. The advantage of surgery is tumor removal, immediate improvement in compressive symptoms, proper tissue for histopathological and prognostic evaluation. Intracranial extension and close proximity to the cribriform plate and ethmoidal roof requires a combined transfacial and neurosurgical approach[12]. For T1 tumors, craniotomy is not justified when there is clear radiological evidence of a normal cribriform plate and upper ethmoid cells. All other patients should be managed by combined craniofacial approach. Dulguerov *et al*[5] showed 100% local control with craniofacial resection as compared to 40% local control with other surgical resections. Similarly, Spaulding *et al*[13] at the University of Virginia showed reduction of 20% local recurrence rate with the craniofacial resection as compared to non-craniofacial approach. An international collaborative study of 17 centres reported the role of craniofacial resection in ENB in 2012. Five-year overall survival was 78% and 5-year recurrence-free survival was 64%[14]. Craniofacial resection allows *en bloc* resection of the tumour with better assessment of intracranial extension and protection of the brain and optic nerves. The current accepted practice is open or endoscopic craniofacial surgical resection.

RT

Specimens from the nasal cavity and paranasal sinuses, even en bloc, are difficult to orient, and surgical margins are difficult to analyze properly. Due to locally infiltrative nature of the disease, surgically clear margins are difficult to achieve. Thus there is a role of adjuvant RT to minimize the risk of local recurrence[12,15]. Adjuvant RT is indicated for Kadish stage B and C, whereas Kadish A disease can be managed with surgery alone. RT is delivered to the tumor bed and local extension with nodal irradiation reserved for involved nodes. Elective nodal irradiation is not practiced routinely. The RT doses have varied from 50 to 60 Gy in the literature[16,17]. With higher RT doses, there is always a risk of long term neural toxicity. But with advancement in technologies in delivery of RT with Intensity modulated RT (IMRT), Image guided RT and proton therapy, the long term neural toxicities can be minimized. RT is also used in neoadjuvant settings in locally advanced tumors and in palliation in metastatic settings. In small local recurrences, stereotactic radiosurgery and stereotactic radiotherapy can be used even for re-radiation[18].

Chemotherapy

The role of chemotherapy is not very clear in adjuvant settings in early tumors, but in locally advanced and metastatic tumors it has a definitive role. It decreases the chances of systemic failure by acting on systemic micro-

metastasis[19]. In neoadjuvant settings, it decreases the size of tumor, decreases compressive symptoms and helps in further complete removal of the tumour. It can be combined with RT in both neoadjuvant and adjuvant settings for better results[20]. The common drugs used are cisplatin, etoposide, adriamycin, vincristine and cyclophosphamide. Initial literature in support of neoadjuvant CT (NACT) comes from the University of Virginia, where Kadish C stage patients received 2 cycles of NACT with vincristine and cyclophosphamide with or without doxorubicin, followed by RT dose of 50 Gy, followed by craniofacial resection[21]. The 5-year and 10-year actuarial survival was 72% and 60% repectively. Subsequently, Cisplatin-based regimens became the preferred CT regimen in ENB at the Mayo Clinic, Gustave-Roussy Institute and Harvard Medical Institute[22-24]. Presently, the preferred chemotherapy regimen is cisplatin (33 mg/m^2 daily) and etoposide (100 mg/m^2 daily) for 3 Da.

Management of neck

Neck metastases at presentation in seen in 5% of patients[25]. In such patients, neck should be addressed by neck dissection or radiotherapy. Delayed neck metastases has been reported in 16% of patients in older series[25]. But with newer investigative, surgical, CT and RT techniques, these incidences are better managed. Patients with advanced local disease should be evaluated radiologically for neck metastases and regional treatment in form of neck dissection or neck RT should be offered in case of positive neck nodes.

STAGE WISE TREATMENT

Kadish A

Surgery alone with clear margins is sufficient in Kadish A staged tumors. Adjuvant RT is indicated in close and positive margins or with residual disease. No role of adjuvant chemotherapy.

Kadish B

Surgery followed by adjuvant RT is the treatment of choice. Role of adjuvant CT is controversial. Recent reports shows use of adjuvant CT. Neoadjuvant CT or RT can be used in inoperable cases.

Kadish C

Kadish C staged tumors requires all the three modalities. Neoadjuvant approach (CT/RT/concurrent CT-RT) is preferred. Definitive role of adjuvant CT in these settings.

Kadish D

Systemic chemotherapy and palliative RT to local site and metastatic sites are advised. Palliative care should be incorporated for improving the quality of life.

RECURRENCE

Local recurrence and/or distant metastases remain the main problem in the management of ENB. Salvage treatment consists of surgery, surgery and postoperative RT, RT alone, palliative chemotherapy (CCT), or supportive care. The management options depend upon the type of relapse and initial treatment received by the patient. Bachar *et al*[26] reported local recurrence was documented in 30.7%, regional recurrence in 17.9%, and distant metastasis in 7.7% of patients. In a metaanalysis by Dulguerov *et al*[6], local regional, and distant recurrence rates were reported in 29%, 16%, and 17%, respectively.

PROGNOSIS

The most important prognostic factors influencing the outcome reported in ENB are Hyams grade, positive lymph nodes, Kadish stage, extent of resection and postoperative RT with atleast 54 Gy[27-29].

ENB IN CHILDREN

In pediatric population upto 15 years of age, the incidence of ENB is 0.1/100000[30]. In younger patients, the tumors have a more aggressive presentation and advanced disease. Bisogno *et al*[31] reported 9 young patients of ENB managed with combined modality approach. The 5-year progression-free survival and overall survival were 77.8% and 88.9% respectively[31]. El Kababri *et al*[32] reported 11 children and adolescents treated with combined modality approach between 1982 and 2002. The 5-year actuarial disease-free survival and overall survival rate was 91% with ten patients being long term survivors[32]. Thus, pediatric ENB has an aggressive presentation but has good clinical results with combined modality approach.

CONCLUSION

Most of the patients of ENB present in locally advanced stage and the optimal management depends on the cooperation between clinicians, surgeons, radiologists and pathologists from establishing diagnosis to organizing the therapeutic strategy. Novel strategies including combined CCT with RT and/or dose escalation with advanced RT techniques such as IMRT and proton therapy should be prospectively investigated to improve the survival results in ENB.

Abstract

Gingival enlargement is one of the frequent features of gingival diseases. However due to their varied presentations, the diagnosis of these entities becomes challenging for the clinician. They can be categorized based on their etiopathogenesis, location, size, extent, *etc*. Based on the existing knowledge and clinical experience, a differential diagnosis can be formulated. Subsequently, after detailed investigation, clinician makes a final diagnosis or diagnosis of exclusion. A perfect diagnosis is critically important, since the management of these lesions and prevention of their recurrence is completely dependent on it. Furthermore, in some cases where gingival enlargement could be the primary sign of potentially lethal systemic diseases, a correct diagnosis of these enlargements could prove life saving for the patient or at least initiate early treatment and improve the quality of life. The purpose of this review article is to highlight significant findings of different types of gingival enlargement which would help clinician to differentiate between them. A detailed decision tree is also designed for the practitioners, which will help them arrive at a diagnosis in a systematic manner. There still could be some lesions which may present in an unusual manner and make the diagnosis challenging. By knowing the existence of common and rare presentations of gingival enlargement, one can keep a broad view when formulating a differential diagnosis of localized (isolated, discrete, regional) or generalized gingival enlargement.

Key words: Differential diagnosis; Gingival hyperplasia; Gingival overgrowth; Gingival diseases; Decision tree

Core tip: In clinical dentistry, patients frequently report with isolated/regional or generalized gingival enlargements, which could fall under varied presentations. The diagnosis of these lesions is essential for their successful management and of the patient as a whole. This article revises the existing knowledge of different types of enlargements and highlights some important diagnostic features. A customized decision tree is designed, which will help clinicians to keep a broad view when formulating a differential diagnosis of localized (isolated, discrete, regional) or generalized gingival enlargement and arrive at a particular diagnosis is an easy and systematic manner.

Agrawal AA. Gingival enlargements: Differential diagnosis and review of literature. *World J Clin Cases* 2015; 3(9): 779-788 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/779.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.779

INTRODUCTION

Gingival enlargement or gingival overgrowth, a common trait of gingival disease, is characterized by an increase in the size of gingiva. Pertinent management depends on precisely diagnosing the origin of enlargement. However, the skills of a clinician is put to test when arriving at a particular diagnosis among the myriad of gingival enlargements that can be classified according to etiologic factors and pathologic changes, according to location and distribution and/or according to the degree of enlargement. Based on etiopathogenesis, enlargements could be inflammatory, drug influenced, those associated with systemic conditions or diseases, neoplastic or false enlargements. According to location, enlargements could be marginal, papillary or diffuse. Based on distribution they can be localized or generalized. Localized enlargements could be further divided into three sub-types, *viz.*, "isolated, discrete" or "regional". "Isolated" enlargements are those limited to gingiva adjacent to single or two teeth (*e.g.,* gingival/periodontal abscess). "Discrete" lesions are isolated sessile or pedunculated, tumor-like enlargements (*e.g.,* fibroma/pyogenic granuloma). "Regional" enlargements refer to involvement of gingiva around three or more teeth in one or multiple areas of the mouth (*e.g.,* inflammatory enlargement associated with mouth breathing in maxillary and mandibular anterior region). "Generalized" enlargement refers to involvement of gingiva adjacent to almost all the teeth present (*e.g.,* drug influenced gingival overgrowth). Inglés *et al*[1] summarized different methods and presented their clinical index to measure the degree of gingival enlargements.

The purpose of this article is to highlight significant findings of different types of gingival enlargement which would help clinician to differentiate between them. For the purpose of clinical diagnosis, enlargements mentioned in this review are grossly are divided into isolated lesions (epulis) and regional or generalized gingival enlargements. Among these, diagnostic points are discussed for the more commonly occurring lesions and the very rare and unusual presentation are listed as per the category to which they belong.

ISOLATED REACTIVE LESIONS OF THE GINGIVA

Localized enlargement of gingiva, historically termed as edulis[2], refers to any solitary/discrete, pedunculated or sessile swellings of the gingiva with no histologic characterization of a particular lesion. A corrective term "reactive lesion of the gingiva"[3], seems to be more appropriate for these category of swellings. Frequent diagnosis in this category is inflammatory rather than neoplastic and may fall in one of the following group of reactive lesions: fibrous epulis/peripheral fibroma, angiogranuloma/pyogenic granuloma and the peripheral giant cell lesion/granuloma.

Fibrous epulis/peripheral fibroma

In adults, this lesion frequently represents as firm, pink, un-inflammed mass, and it seems to grow from below the free gingival margin/interdental papilla (Figure 1A). Most often the lesion is painless. Pain may be associated due to secondary traumata *via* brushing, flossing or chewing. Histologically, the fibroma may show additional focus of calcification (peripheral calcifying fibroma), foci of cementicles (peripheral cementifying fibroma, Figure 1B) or trabeculae of bone (peripheral ossifying fibroma, Figure 1C).

Angiogranuloma/pyogenic granuloma

Presents in adults as smooth surfaced mass, often ulcerated and grows from beneath the gingival margin. These reddish/bluish color mass are highly vascular, compressible and could bleed readily. Typically they grow rapidly within first few weeks and then slowly. The mass may penetrate interdentally and present as bilobular (buccal and lingual) mass connected through the col area, but bone erosion in uncommon (Figure 2A). Angiogranuloma which appears during pregnancy are termed as pregnancy epulis/tumor or granuloma gravidarum (Figure 2B).

Histologically, the stratified squamous epithelium is thickened, with prominent rete pegs and some degree of intracellular and extracellular edema, prominent intercellular bridges and leukocytic infiltration.

Peripheral giant cell granuloma

They occur particularly in anterior region in young patients or in posterior mouth during mixed dentition phase and in adults. They are very aggressive lesions with significant growth potential. The high vascularity of these lesions can be understood by their purplish-red color and tendency to bleed. They also tend to penetrate interdentally and erosion of adjacent bone along with separation of adjacent teeth is a common occurrence (Figure 3).

Gingival cysts

Gingival cysts are unusual cysts of odontogenic source. They are frequently found in females in their 50's or 60's. A greater number of these are found on the labial attached gingiva of the mandibular anterior teeth. Presence of fluid may give them a bluish hue and they may lead to resorption of the labial bone due to pressure. Radiographically, its radiolucency may sometimes lead to confusion with lateral periodontal cyst. Excisional biopsy is the best management for these lesions[4].

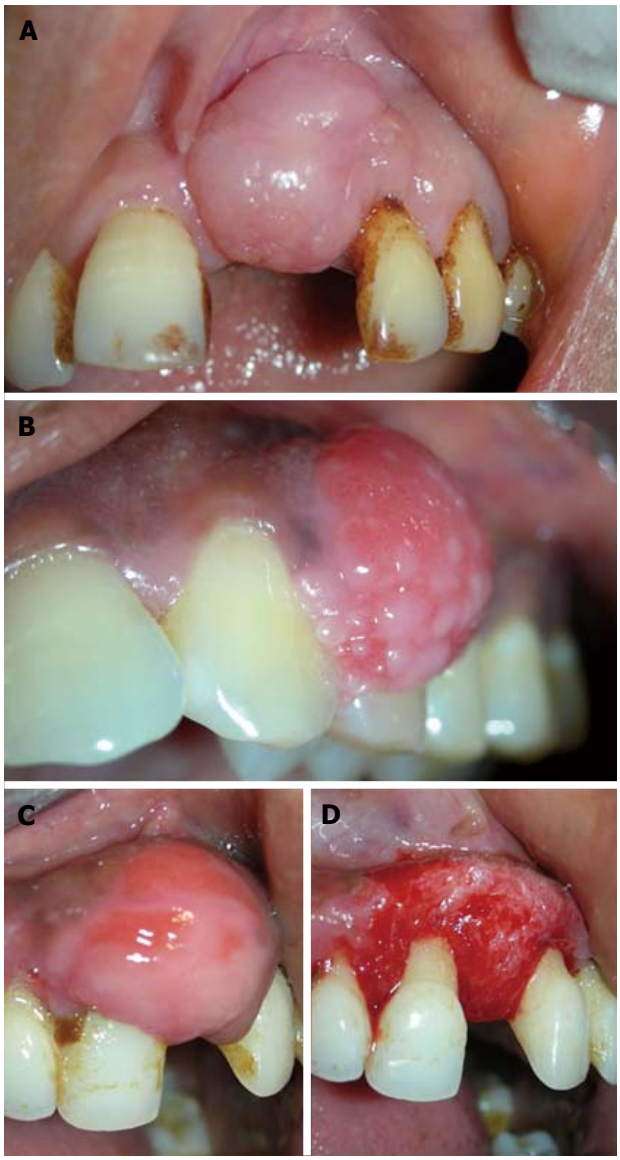

Figure 1 Fibrous epulis and its subtypes. A: Peripheral fibroma, presenting as pink firm, uninflammed mass growing from under the gingiva; B: Peripheral cementifying fibroma, a subcategory of fibroma, shows additional foci of cementicles; C and D: Surgical exposure of the lesion showing extensive bone formation in the core of the lesion. Also presence of bony trabeculae was seen histologically.

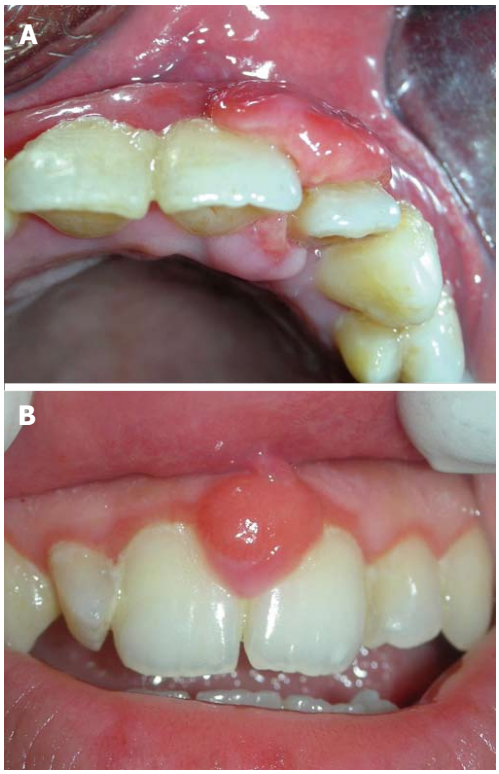

Figure 2 Angiogranulomas may present as: Pyogenic granuloma, a bilobular mass connected through the col area (A), and similar lesion occurring during pregnancy is termed as "pregnancy epulis" (B).

Figure 3 Lesion of peripheral giant cell granuloma. This highly vascular lesion is characterized by purplish red-color and its tendency to bleed.

Neoplastic

The localized epulis like lesions can also be classified as being benign or malignant. Benign masses could be, fibroma, peripheral giant cell granuloma, central giant cell granuloma, papilloma, leukoplakia, nevus[5], myoblastoma[6], hemangioma (Figure 4A)[7,8] neurilemoma[9], neurofibroma[10], ameloblastoma[11]. Malignant tumors could be squamous cell carcinoma or melanoma. Among sarcomas, Kaposi's sarcoma[12] is more common, and fibrosacroma, lymphosarcoma and reticulum cell sarcoma are rarely reported[13]. Other rare lesions (< 2% prevalence) include angioma, osteofibroma, myxoma, fibropapilloma, adenoma and lipoma[14].

Others

Some other localized chronic lesions that can be misdiagnosed as epulis would be palatal mucocele (Figure 4B), a lateral periodontal cyst projecting on labial/lingual surface (Figure 4C and D), *etc.*

Acute

The acute form of isolated gingival enlargement could be various abscesses such as gingival, periodontal, periapical or pericoronal. They can be differentiated from their location and vitality of the associated tooth. It could be located near gingival margin or papilla (gingival abscess) (Figure 5A), or may be diffuse and forms significant portion of attached gingiva (periodontal abscess) (Figure 5B). When the associated tooth is non-vital the lesion may be originated from an endodontic

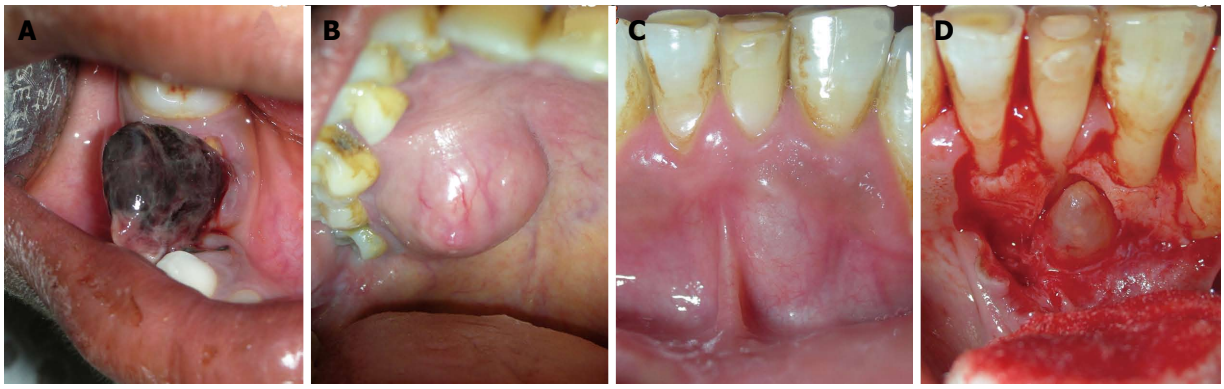

Figure 4 Other uncommon localized gingival enalargements which could be misdiagnosed as epulis. A: Hemangioma located in mandibular right quadrant; B: Mucocele associated with palatal minor salivary gland; C and D: A lateral periodontal cyst projecting labially and causing localized gingival enlargement.

problem (periapical abscess/endo-perio lesion) (Figure 5C). Often the pericoronal flap covering distal most mandibular teeth might become inflamed and swollen. Abscess of these pericoronal flaps could eventually develop if the inflammation persists (Figure 5D).

Histopathological examination of gingival/periodontal/pericoronal abscess may present purulent focus in the connective tissue, surrounded by diffuse infiltration of polymorphonuclear leukocytes, edematous tissue and vascular engorgement. The surface epithelium has varying degrees of intra- and extracellular edema, invasion by leukocytes, and sometimes ulceration.

CHARACTERISTIC FEATURES OF GENERALIZED GINGIVAL ENLARGEMENT

More commonly, gingival disease manifests as regional or generalized gingival enlargement, which might fall into one of the different types.

Inflammatory gingival enlargement

These are inflammatory response to local irritant associated with gingiva. The irritant could be microbial deposits (plaque and calculus) (Figure 6A), fractured tooth, overhanging restorations, ill-fitting prosthesis (Figure 6B), orthodontic brackets (Figure 6C), *etc.* The presentation begins as slight ballooning of the papilla or marginal gingiva, depending upon the location of the irritant. The bulge may progressively increase in size and extent to become generalized. Clinical they may appear bluish or deep red. They are frequently friable and soft with a smooth shiny surface and they usually bleed easily. Occasionally, chronic inflammatory enlargement may also present as firm, resilient, pink and fibrotic enlargement which histologically show abundance of fibroblasts and collagen fibers.

Gingival enlargement in mouth breathers

Although considered as inflammatory, the exact mechanism of enlargement in mouth breathers is not clear. It is thought to be due to alternate wetting and drying of the gingival surface. The gingiva appears red and edematous with diffuse shiny surface. A diagnostic feature of this type of enlargement would be presence of significant enlargement in maxillary and mandibular anterior regions and no involvement of posteriors. In a typical bimaxillary protrusion case, the enlargement will be limited to palatal aspect of maxillary anteriors and labial aspect of mandibular anteriors. Patients present with mouth breathing habit that may be due to short upper lip, hyperactive labii superioris, proclined incisors, rhinitis, *etc.*

Fibrotic

Drug induced gingival enlargement: There are many anticonvulsants, immuno-suppressants and calcium channel blockers that may lead to gingival enlargement in varied presentations (Table 1 and Figure 7). Signs and symptoms related to gingival enlargement are seen within 2-4 mo of initiation of drug intake. Usually at the initial presentation there is no pain. The enlargement starts as beadlike enlargement of the interdental papilla and eventually may involve marginal gingiva. When not involved by secondary inflammation, the enlargement looks like mulberry shape, firm, pink and resilient with minute lobulations and no bleeding on probing. Although it may involve the gingiva around all teeth, it is more prominent in maxillary and mandibular anteriors. It will be absent in edentulous areas and will disappear in areas where teeth are extracted. When infected secondarily, there is increase in the size of existing enlargement and adds characteristic features of inflammatory enlargement. Among commonly encountered drug induced gingival enlargement (DIGO), those due to immunosuppressive agent like cyclosporine, appear more vascularized than phenytoin induced[17].

When patients are in combination therapy, in which two or more drugs are known to cause gingival enlargement, then, which should be attributed to the diagnosis of DIGO, is a puzzle. One way to arrive at a diagnosis in such cases is to consult the patient's physician, request him to substitute/stop one drug at a time, starting with the one that would have least effect on patient's routine schedule. Frequently, patient gives history of related medications (antihypertensives/anticonvulsants/immune-

Figure 5 Abscess presenting as localized gingival enlargement. A: Gingival abscess, near gingival margin or papilla; B: In periodontal abscess, the swelling is diffuse; C: Periapical abscess, near apex of concerned tooth; D: Abscess of pericoronal flap.

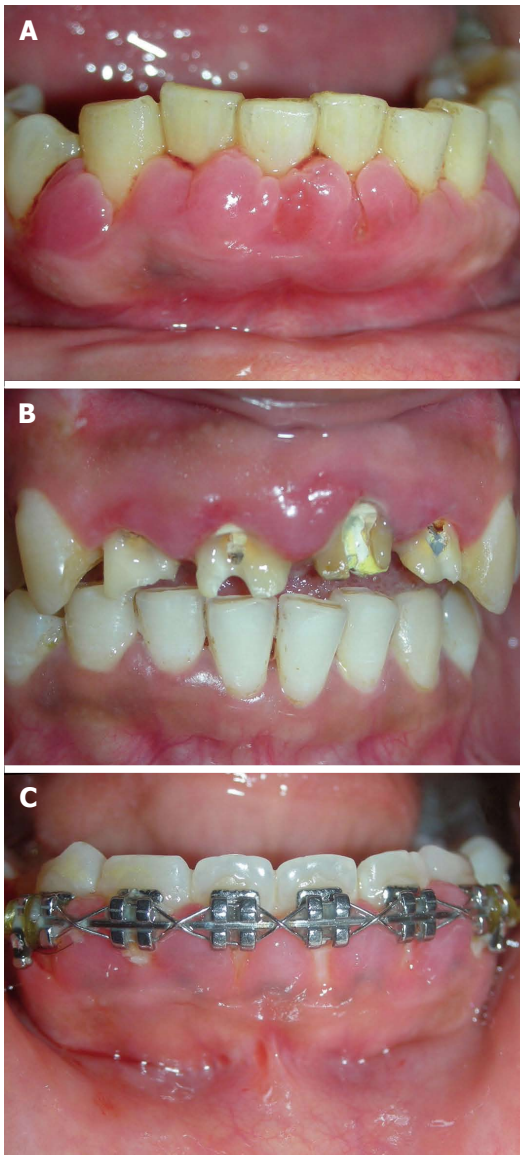

Figure 6 Inflammatory gingival enlargement. A: Plaque and calculus; B: Ill-fitting prosthesis; C: Orthodontic brackets.

Table 1 Different drugs known to predispose to gingival enlargements

Anticonvulsants[15,16]		Immunosuppressants[17]	Calcium channel blockers[15]
Phenytoin	Vigabatrin	Cyclosporine	Nifidipine
Ethotoin	Ethosuximide	Tacrolimus	Diltiazem
Mephenytoin	Topiramate	Sirolimus	Felodipine
Phenobarbital	Pyrimidinone		Nitrendipine
Lamotrigine			Verapamil
			Amlodipine

suppressants) since many years but enlargement was noted since few months. In these cases, it becomes difficult to associate duration of occurrence of enlargement with related drug history. Specific query related to recent change in type/dose of drug will help to associate both.

Genetic disorders associated with gingival enlargement: They can be divided into 4 primary categories based on their etiology, clinical features and histology. Namely, idiopathic gingival enlargement, lysosomal storage disorders, vascular disorders and

Table 2 Gingival enlargement associated with syndromes in different types of genetic disorders

Syndromes associated with heriditary gingival fibromatosis	
Zimmerman-Laband syndrome[18]	Abnormal fingers, nails, nose and ears, splenomegaly, hepatomegaly, hyperextensible metacarpophalangeal joints
Ramon syndrome[19]	Cherubism, seizures, mental deficiency, hypertrichosis, stunted growth, juvenile rheumatoid arthritis
Systemic Hyalinosis[20]	Painful joint contractures, diffuse thickening of the skin with pearly papules and fleshy nodules and failure to thrive
Jones syndrome[21]	Progressive sensorineural deafness
Rutherford syndrome[22]	Corneal opacity, mental retardation and aggressive behavior, failure of tooth eruption
Cross syndrome[23]	Hypopigmentation, mental retardation and writhing movement of hand and legs
Schinzel-Giedion syndrome[24]	Severe mid face retraction, severe mental retardation and congenital heart defect, patient usually die under 10 yr of age
Costello syndrome[25]	Macrostomia, redundant skin of neck, hands and feet, nasal and perioral papillomas, enlargement within first years of life
Syndromes associated with lysosomal storage diseases	
Hurler syndrome[26]	Dwarfism, flexion contractures, hernias, corneal clouding, macroglossia, short mandibular rami, peg-shaped teeth
Maroteaux-Lamy syndrome[27]	Enlargement of skull, corneal opacities, short peg-shaped poorly formed teeth, hypertrophy of alveolar ridges, anterior open bite
Neimann-Pick disease[28]	Thick lips, macroglossia and widely spaced teeth
Anderson-Fabry disease[29,30]	Painful crises on extremities and abdomen, angiokeratomas of skin, labial mucosa and buccal mucosa
Cowden syndrome[31]	Cobblestone papules of gingiva and buccal mucosa, macrocephaly, multiple hamartomas, learning disabilities, autism
Gingival enlargement associated with vascular disorders	
Sturge-Weber syndrome[32]	Unilateral cutaneous nevi, unilateral vascular hyperplasia, neurological manifestations and ocular complications
Klippel-Trenaunay syndrome[33]	Capillary hemangiomas, increased size of lips, tongue, teeth malformations, delayed exfoliation of teeth, calcified roots
Gingival enlargement associated with characteristic dental abnormalities	
Wilson syndrome[34]	Enamel hypoplasia, multiple small red papules of lips, early onset periodontitis and repeated oral candidiasis, signs of cirrhosis
GoltzGorlin syndrome[35]	Partial anodontia, hypoplastic teeth, atrophy and linear pigmentation of skin, herniation of fat, multiple papillomas, digital anomalies

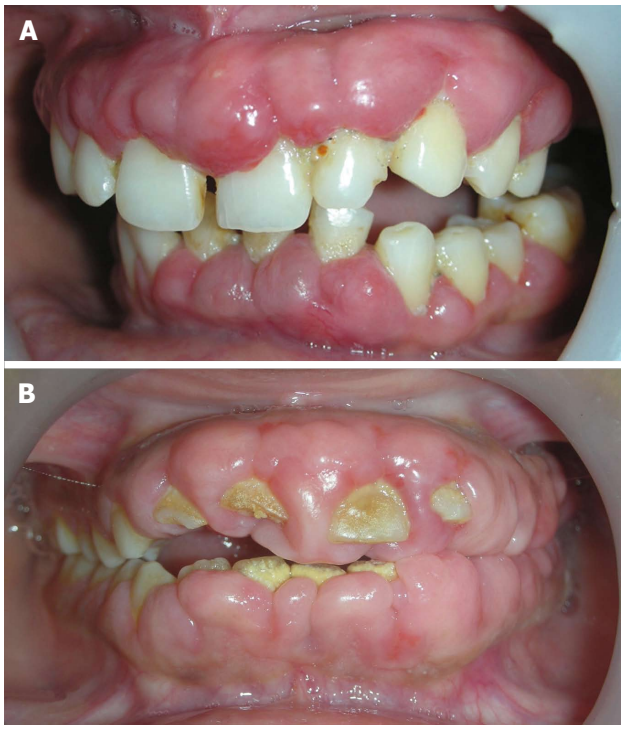

Figure 7 Drug influenced gingival overgrowth. A: Superimposed with secondary inflammation; B: Fibrotic and leathery.

those associated with characteristic dental abnormalities (Table 2). Idiopathic gingival enlargement is also referred to as congenital familial fibromatosis, gingivomatosis, idiopathic fibromatosis, elephantiasis and hereditary gingival hyperplasia. It presents as unusual fibrotic gingival enlargement of localized or generalized extent. It may present as a specific entity or as a part of syndrome. Diagnosis can be made by a positive family history of gingival enlargement. It usually begins with the eruption of the primary or permanent dentition. A frequent finding could be presence of firm bulky enlargement of gingiva restricted to maxillary and mandibular second and third molar areas only. The enlarged mass may be pink or reddish and may be firm/nodular on palpation. Alveolar bone is rarely affected, but presence of pseudo-pockets and difficulty in maintaining oral hygiene may lead to some periodontal problems. Extensive overgrowths can lead to esthetic and functional concerns to the patient (Figure 8).

Conditioned gingival enlargement

Hormonal: Generalized gingival hyperplasia, during pregnancy and puberty, is influenced by hormonal changes that pretentious the response to local irritants. The interproximal gingiva shows more prominent enlargement than the facial and/or lingual surfaces (Figure 9). The enlarged gingiva usually is soft and friable, bright red or magenta, with a smooth, shiny surface. Bleeding may occur extemporaneously or on mild stimulation. The enlargement may reduce spontaneously after the delivery, but complete elimination may require the removal of all local irritants and additional surgical intervention of any fibrotic remnants.

Figure 8 Unusual firm fibrotic gingival enlargements in a patient with hereditary gingival fibromatosis.

Figure 9 Typical multiple interproximal enlargements in a pregnant patient.

Figure 10 Appearance of gingiva in patient with plasma cell gingival enlargement. The color is reddish and involves almost complete attached gingiva and slightly granular appearance.

Vitamin C deficiency: Deficiency of vitamin C is defined as a serum ascorbic acid level < 2 μg/mL. Diabetes, stress and smoking are the commonly labeled factors leading to mild vitamin C deficiency. The gingiva, of vitamin C deficiency associated enlargement, is bluish red, soft and friable with a smooth, shiny surface. Bleeding may occur spontaneously or on slight irritation. Surface necrosis with pseudomembrane formation are also frequently seen[36]. Kubota *et al*[37] pointed out that high-sensitivity C-reactive protein (hs-CRP) levels were inversely proportionate with serum vitamin C concentration, and therefore, hs-CRP blood level may be elevated in these patients.

Plasma cell gingivitis: The etiology of this entity is difficult to establish, but it is considered to be a hypersensitivity reaction with affluent plasma cells seen histologically. Usual allergens known to be associated with this lesion could be, *e.g.,* toothpaste, khat, food product particularly cinnamon, chewing gum or unknown origin. It might bleed on provocation. Patients usually complain about burning sensation on eating hot and spicy food. Appearance is reddish in color, involves almost complete attached gingiva, slight granular surface appearance is typical (Figure 10).

Gingival enlargement associated with systemic disease

Leukemia: Generalized gingival enlargement associated with leukemia is due to the massive infiltration of leukemic cells in the gingival connective tissue. Clinically it may mimic inflammatory origin. Apart from gingival enlargement other associated features could be oral ulceration, spontaneous gingival bleeding, petechiae, mucosal pallor, herpetic infections and candidiasis. Rarely, uncommon features such numbness in chin and/or tooth pain has been reported[38]. The most serious condition associated with gingival enlargement in this category would be acute myeloid leukemia. It can be associated with signs and symptoms of bone marrow failure, such as ecchymoses, night sweats, recent infections and lethargy. An expeditious diagnosis can be made by a simple full blood count. A rare case of gingival hyperplasia secondary to acute lymphoblastic leukemia has also been reported[39].

Wegener's Granulomatosis: "Strawberry gingivitis", formed by reddish-purple exophytic gingival swelling with patechial haemorrhages, is a characteristic sign of Wegener's granulomatosis. The oral lesions could be of great help in timely diagnosis of this potentially fatal condition, because they persists for a long time before multi-organ involvement occurs (Figure 11)[40,41]. At least two of the following conditions should be fulfilled to diagnose the condition as Wegener's granulomatosis: (1) ulcerative lesions of oral mucosa or nasal bleeding or inflammation; (2) nodules, fixed infiltrates or cavities in chest radiograph; (3) abnormal urinary sediment; and (4) granulomatous inflammation on biopsy[40].

Crohn's disease: The gingiva is pink, firm and almost leathery in consistency, with a characteristic minutely pebbled surface. Signs and symptoms of these conditions must be strenuously trailed in these patients. It is normally associated with swelling of lips, bowel disorders, fever and ulcers. A consultation with gastroenterologist will prove to be helpful.

Sarcoidosis: Sarcoidosis is a multiorgan disorder. The

Figure 11 Gingival condition in patient with Wegenersgranulomatosis, presents as reddish purple, exophytic gingival overgrowth.

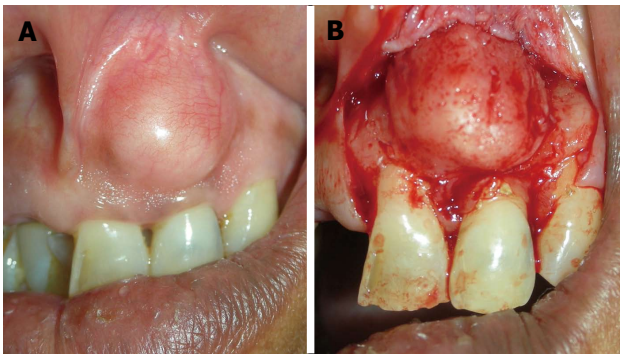

Figure 12 Case of false enlargement wherein. A: The overlying gingiva presents with no abnormal clinical features except the massive increase in size of the area; B: Formed completely by underlying bone.

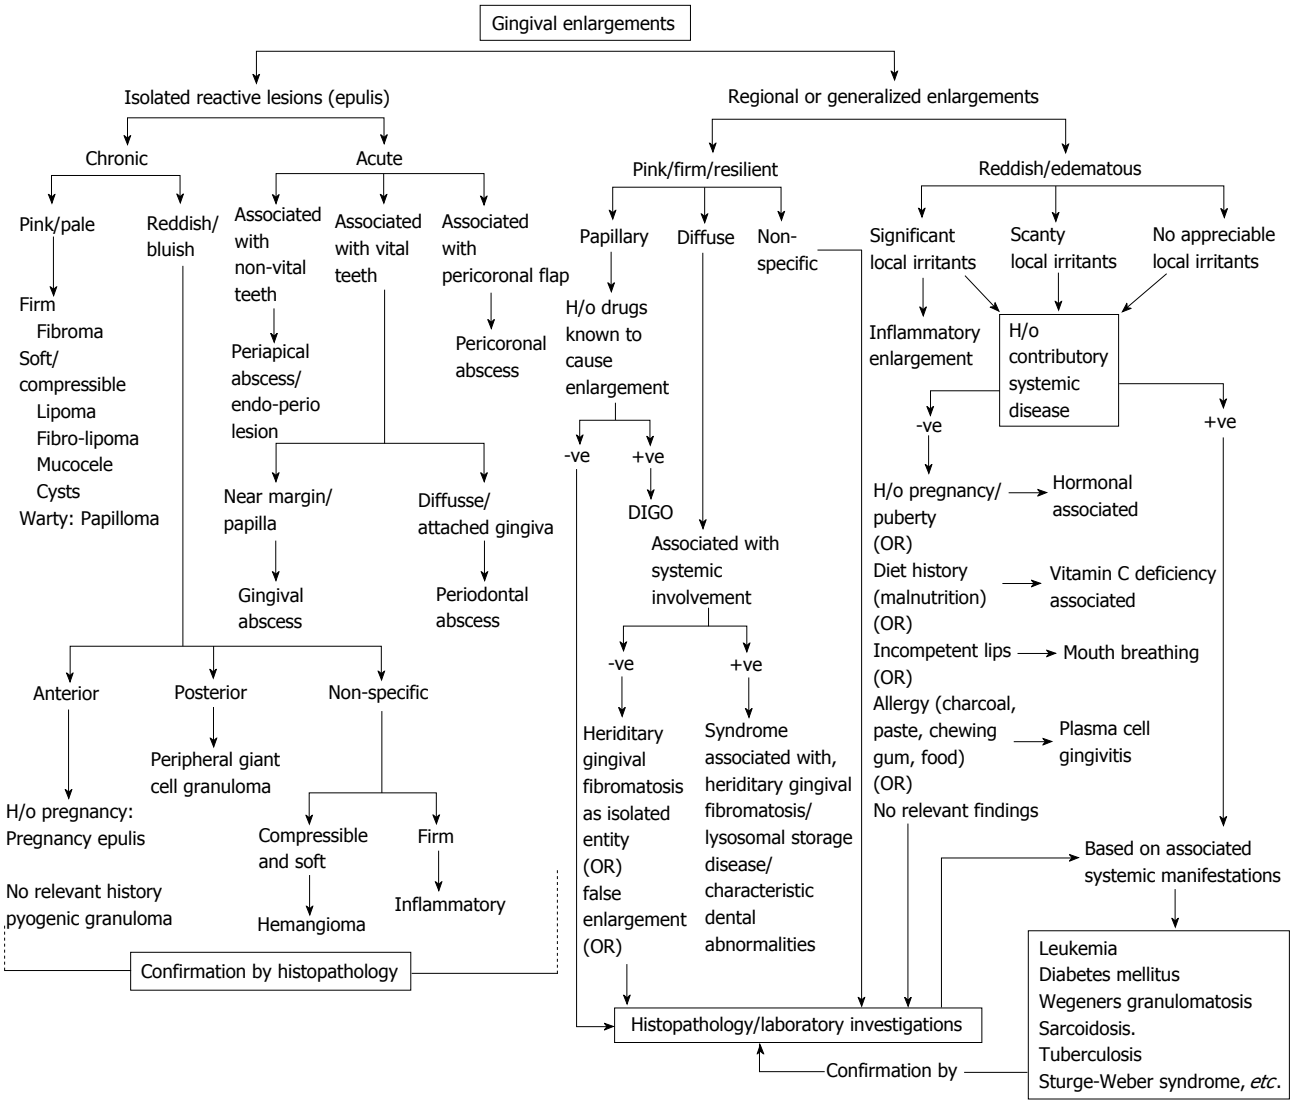

Figure 13 Decision tree for differential diagnosis of isolated, regional and generalized gingival enlargement. DIGO: Drug induced gingival enlargement.

most common presentation consists of pulmonary infiltration and hilar lymphadenopathy, dermal and ocular lesions[42], however oral involvement is uncommon. There are no specific tests for sarcoidosis. Diagnosis of sarcoidosis is mainly based on exclusion of other non-caseating granulomas forming conditions and other laboratory tests[42,43]. Eosinophil count might be significantly increased (normal range 0%-4%), and serum angiotensin converting enzyme levels can also be significantly raised (normal range less than 670 nkat/L).

Chest X-ray might show hilar lymphadenopathy[44].

Tuberculous gingival enlargement: Primary oral tuberculous lesions are very rare, but when they occur they are usually seen in younger age. The lesions themselves remain painless in most cases, however associated caseation of the dependent lymph nodes may be seen[45,46]. Furthermore, primary tuberculosis manifesting solely as gingival enlargement is extremely rare which can be diagnosed based on history of fever, weakness, loss of appetite and weight loss[47]. The diagnosis can be confirmed based on histopathology, complete blood count and polymerase chain reaction[47]. In contrast, secondary oral tuberculosis can be seen in 0.05% to 1.5% of cases and the prevalence is more in older adults[48,49].

Unusual presentations: Generalized gingival enlargement has been rarely reported with amelogenesis imperfecta[50], Hashimoto's thyroiditis[51], I-cell disease[52] and Multiple myeloma[53].

False enlargement: These pseudo-enlargements appears as a result of increase in size of underlying osseous (tori, exostosis, Paget's disease, cherubism, osteoma, *etc.*) or dental tissues (during tooth eruption). The overlying gingiva presents with no abnormal clinical features except the massive increase in size of the area (Figure 12).

Decision tree: Differential diagnosis of gingival enlargement requires thorough dental and medical history, careful evaluation of the type, nature and extent of enlargement and identification of etiologic or predisposing factors. A decision tree (Figure 13) is specially designed to get a broad overview of different possible diagnosis for localized or generalized gingival enlargements. This systematic presentation would be very helpful for the clinicians to arrive at a particular diagnosis. Furthermore, laboratory investigations and/or biopsy specimens may be required to confirm the diagnosis or make a diagnosis of exclusion.

CONCLUSION

Inspite of a myriad of etiology, gingival enlargements can often be diagnosed by a careful history (*e.g.,* drug influenced or hormonal influenced gingival enlargement), by location (*e.g.,* mouth-breathing enlargement around anterior teeth) or by the clinical presentation (*e.g.,* strawberry gingivitis). Presence of local irritants (plaque and calculus) could be primary or associated cause of gingival enlargements. Hence, plaque control is an essential aspect of management in all the patients. An excisional/incisional biopsy and/or hematologic/histologic examination may be needed occasionally to correctly diagnose the uncommon cases of gingival enlargement. The clinician should have an open mind and consider all possibilities before coming to the final diagnosis of the condition at hand.

Abstract

Hernia is a common problem of the modern world with its incidence more in developing countries. Inguinal hernia is the most common groin hernia repaired worldwide. With advancement in technology operative techniques of repair have also evolved. A PubMed and COCHRANE database search was accomplished in this regard to establish the current status of laparoscopic inguinal hernia repair in view of recent published literature. Published literature support that laparoscopic hernia repair is best suited for recurrent and bilateral inguinal hernia although it may be offered for primary inguinal hernia if expertise is available.

Key words: Laparoscopic hernia repair; Lichtenstein repair; Day care surgery; Open hernia repair; Inguinal groin hernia

Core tip: This review compares the laparoscopic hernia repair to conventional open hernia repair techniques in terms of cost, recurrence, procedure related morbidity and quality of life of the patient. Recent published literature has been included in this regard to focus on if any supremacy exists between the two approaches.

INTRODUCTION

Hernia is a common problem of the modern world with an incidence ranging from 5%-7%. The prevalence of hernia is far greater in developing countries like India amounting to a major health care burden. Of all groin hernias, around 75% are inguinal hernias[1,2]. The repair of the groin hernia is therefore a commonly performed surgery worldwide.

Operative techniques have evolved continuously over the past decades establishing tension free mesh repair as standard of care for inguinal hernia management. A PubMed and COCHRANE database search was accomplished in this regard to establish the current status of laparoscopic inguinal hernia repair in view of recent published literature.

The groin is a naturally occuring defect in the ante-

rior abdominal wall. This weak muscular area in the inguinal region has been named after surgeon and anatomist Henri Fruchaud. The anatominal extents of this myopectineal orifice are as follows: cranially and medially this is bordered by the conjoined tendon and the rectus abdominis muscle, laterally by the iliopsoas muscle and caudally by the superior ramus of the os-pubis. This area is covered by the fascia transversalis, split in two by the inguinal ligament, and penetrated by the spermatic cord (in men)/round ligament (in women) and femoral vessels. The integrity of the area is hence primarily depends on fascia transversalis, whose failure to sustain the preperitoneal fat and varying intraabdominal pressure is therefore the fundamental cause for formation of congenital or acquired inguinal hernia. Inguinal hernias are treated by repairing the fascial defect in the myopectineal orifice of Fruchaud or by strengthening the weakened fascia transversalis by placement of a prosthesis (mesh).

CONSERVATIVE TRIAL *VS* SURGERY

Inguinal hernia is a disease of benign nature and follows a fixed course but their complications are dramatic and frequent. Surgical repair done under emergency conditions has higher recurrence and is associated with increased morbidity and mortality[3,4]. Hence, a repair in elective setting is always preferred. Open repairs applying principles of Pascal's law include tension free like Lichtenstein repair, which can be done under regional anaesthesia in a safe and economic way[5,6]. Recently with advancement in laparoscopy, endoscopic repairs seems to offer better quality of life, decreasing hospital stay and early return to work. Henceforth every possible attempt should be made for early repair of inguinal hernia if no addded comorbidity is present[7,8]. A few of asymptomatic elderly individual, not fit for surgery can be advised conservative management.

ANAESTHESIA

Till date all anaesthetic techniques have been used to undertake the operative repair safely. General anaesthesia was the most common method used in early days but in recent past it has been replaced by regional anaesthesia[9]. Few benefits of regional anaesthesia include: (1) A conscious patient at the operating table. Patient can cough to increase the intra-abdominal pressure thereby checking the effectiveness or repair; and (2) Lesser time spent in the operating room, lower incidence of nausea, fewer requirements of post operative analgesia and early discharge on a day care basis[10].

However general anaesthesia is still the method of choice for undertaking endoscopic/laparoscopic inguinal hernia repairs.

TYPES OF REPAIR

Herniorrhaphy techniques include: Bassini repair; Shouldice repair; McVay repair.

Hernioplasty techniques include: Anterior (Lichtenstein repair; Plug and patch repairs; Double layer hernia repair); Posterior (pre-peritoneal) repairs {Rieves repair; Stoppa repair; Laparoscopic/endoscopic repair [Total extra peritoneal repair (TEP); Trans abdominal pre peritoneal repair (TAPP)]}.

Among these various methods prosthetic repairs have established their supremacy over repairs withour using prosthesis. A recent metaanalysis published in cochrane has revealed that Shouldice herniorrhaphy is the favoured non prosthetic technique comparing recurrence but it lacks favour on terms of operational time and hosptial stay[11,12]. Concluding, lower recuurence rates have been established for mesh repair techniques compared to tissue repair techniques alone.

Recent European hernia society guidelines state that none of the alternative mesh techniques except for Lichtenstein and endoscopic techniques have received sufficient scientific evaluation to be recommended[13]. American college of surgeons and National Institute of Clinical Excellence consider Lichtenstein repair as gold standard open repair[4,14,15]. However tissue repairs are a viable alternative in females because of the more durable transversalis fascia[16] and in emergency repairs where use of mesh is associated with increased surgical site infections[17,18].

Minimal access surgical repairs also provide very promising results if surgeon has technical expertise. It results in minimum postoperative pain, reduced wound infection and early return to work[19]. A Cochrane review between TEP and TAPP repair found the above said approaches are equal in terms of considering duration of operation, hematoma, length of hospital stay and rate of recurrence[20]. European hernia society guidelines promote TEP as a preferred method of repair to TAPP in the case of minimal access (endoscopic) surgery[13].

LAPAROSCOPIC REPAIR *VS* OPEN SURGERY

In recent times a rousing debate is brewing between open and endoscopic prosthesis repairs for the preferred approach status. Open and minimal access surgcal (laparoscopic/endoscopic) techniques have been compared in a number of studies in published literature. To begin with, cost factor remains a burning issue in pulling down the laparoscopic repairs as thery involve high cost compares to open repair. Hynes *et al*[21] has stated that laparoscopic repair amounts to an average of $638 more compared to open surigcal techniques in North America. Similarly, McCormack *et al*[22] showed that laparoscopic repair is exorbitant to the health service compared to open surgical repair by approximately 300-350 pounds per patient. A Swedish study has demonstrated that the total hospital cost was 710.6 Euro higher for TEP repair which would increase to 795.1 Euro when the added bills due to recurrences and complications within 5 years were acknowledged[23].

Similarly Khajanchee *et al*[24] reported a cost difference of $128.58 for a TEP repair. The cost-minimization analysis, including complications, reoperations and community costs during follow-up of 5 years, in a randomized trial showed that laparoscopic inguinal hernia repair had a small but significant increase in overall costs compared with open repair[23]. Above all financial burden on the patient and high infrastructal cost has been a limiting factor specially in developing countries.

A systematic review by McCormack *et al*[22] comparing laparoscopic and open repairs has revealed no apparent difference in recurrence. Laparoscopy seems to cause less persisting pain and numbness. Return to normal day to day activities is also faster[25]. However, operation time using laparoscopy technique is longer and there appears to be a higher risk of serious complication rate in respect of visceral (especially bladder) and vascular injuries[26].

In the similar systematic review, on further comparing complications of laparoscopic repair to open repair, it was evident that laparoscopic repairs are associated with overall more incidence of seroma formation. On the other hand there are less frequent chances of hematoma formation (more in TEP patients) and wound/superficial infections but there has been a heterogenity in data to deduce a final statement[26]. Other complications related to laparoscopic hernia repair, although in lower frequency, include trocar site hemorrhage and/or herniation, and injury to the epigastric or gonadal vessels[25]. Complications related to use of laparoscopy and less to surgeon technique are hypotension secondary to elevated intra-abdominal pressure, hypercapnia, subcutaneous emphysema, pneumothorax, and increased peak airway pressures[25].

A large number of hernia repairs are still done with open technique as endoscopic repairs have a steep learning curve and requires costlier infrastructure[27]. Despite a few hurdles, endoscopic repair is becoming a preferred approach specially for bilateral and recurrent hernias.

TYPES OF MESH

Types of mesh includes synthetic: Heavy weight (density > 100 g/m^2) [Polypropylene; Polyester; Light weight (density 35-50 g/m^2); Non absorbable (Plain polypropylene; Coated polypropylene; Partially absorbable: Polypropylene + polygalactin; Polypropylene + polyglycaprone)] and Biological.

Use of meshes has decreased the rate of recurrence to a significant extent but complications related to these prostheses have been reported in published literature.

Since mesh is a foreign antigen, theoritical reasoning supports the notion of increased chances of infection but practically this complication is well taken care of. Standard polypropylene mesh is most frequently used because of low cost, easily availability and reasonable strength to avoid recurrence[28].

Foreign body sensation and chronic postoperative pain have discouraged the regular use of established polypropylene mesh. Newer light meshes have been developed to overcome these problems but they are fairly expensive and only reduce the foreign body sensation without significant difference in recurrence rate compared to heavyweight mesh[29-31]. Biologic meshes, on the other hand may gain importance in future as they have been proposed to be advantageous in contaminated areas but they are extremely expensive, not widely available and studies supporting use of biologic meshes is limited which needs further in depth analysis[32,33].

Hence conentional polypropylene mesh is a trustworthy option for inguinal hernioplasty. On the other hand, lightweight meshes may be considered based on patient's affordability and surgeon's discretion.

CONCLUSION

Patients with no atendent comorbidities with asympatomatic inguinal hernia at presentation should be offered hernia repair. Laparoscopic hernia repair is best suited for recurrent and bilateral inguinal hernia although it may be offered for primary inguinal hernia.

Mesh Repair is associated with the lowest recurrence rates with pain being the most common complication of hernia surgery.

Abstract

AIM: To determine the role of leukocyte function-associated antigen-1 (LFA-1) in polymicrobial sepsis model in mice.

METHODS: Cecal ligation and puncture model was used to study polymicrobial sepsis in wild type and LFA-1 knockout (KO) (= CD11a KO) mice. Their survivals were examined. Neutrophil recruitment to the abdominal cavity, bacterial tissue load and bacterial killing by neutrophils, tissue cytokine profiles, and serum cytokines were examined. Apoptosis of tissues was assessed using cleaved-caspase 3 and TUNNEL staining. The recruitment of neutrophils to various tissues was assessed using myeloperoxidase staining or measuring myeloperoxidase activity.

RESULTS: LFA-1 deficiency significantly decreased survival (P = 0.0024) with the reduction of neutrophil recruitment to the abdominal cavity and higher bacterial load in blood. It was also associated with increased apoptosis in spleen and more organ injuries probed by interleukin-6 mRNA level. However, the deficiency of LFA-1 did not prevent neutrophil recruitment to lung, liver, spleen or kidney, which suggested the existence of LFA-1 independent recruitment mechanism in these organs.

CONCLUSION: LFA-1 deficiency did not attenuate neutrophil recruitment to various organs to adequately mitigate secondary tissue injury in sepsis. It was associated with decreased neutrophil recruitment to

the abdominal cavity, higher bacterial load, leading to increased mortality in an abdominal, polymicrobial sepsis.

Key words: Leukocyte function-associated antigen-1; Tissue injury; Neutrophil recruitment; Polymicrobial sepsis; Apoptosis

Core tip: We report our result on the role of leukocyte function-associated antigen-1 (LFA-1) in polymicrobial abdominal sepsis model induced by cecal ligation and puncture. LFA-1 is a key player in neutrophil migration, but its role in neutrophil migration to tissues in polymicrobial sepsis is yet to be determined. This study demonstrated that LFA-1 deficiency blocked neutrophil migration to the abdominal cavity, but maintained migration to other organs, and reduced survival in sepsis.

INTRODUCTION

Sepsis remains to be associated with high morbidity and mortality and accounts for a large expenditure in public health. The recent study demonstrated that the mortality was still over 30% in Europe and the United States despite the implementation of sepsis management protocols[1]. This suggests that our understanding of the pathophysiology of sepsis remains quite limited.

Accumulating evidence demonstrated that the innate immune system is activated and works as the first line of defense against sepsis. This inflammatory response is characterized by leukocyte infiltration into the extravascular space. Leukocytes are not only bactericidal but also mediate local tissue damage and alternations in microvascular perfusion. Adhesion molecules present on leukocytes and endothelial cells control leukocyte adhesion and extravasation.

Leukocyte-function associated antigen-1 (LFA-1, CD11aCD18) is an adhesion molecule expressed ubiquitously on the surface of all leukocytes and plays a central role in leukocyte recruitment. LFA-1 is composed of two subunits CD11a and CD18 and binds to their counter ligands, intercellular adhesion molecule-1 and -2 (ICAM-1 and ICAM-2). While LFA-1 does not bind its ligands in a resting state, in inflammation it becomes active and binds them. The interactions between them facilitate leukocyte rolling, arrest on the blood vessels and transmigration to facilitate leukocyte recruitment. This is a critical, immunological process to fight against and reduce infection.

The role of LFA-1 in infection has been examined in several *in vivo* models with mixed results. Deficiency of LFA-1 worsened the outcome of *Streptococcus pneumoniae* infection[2] and *Mycobacterium tuberculosis*[3], but was protective in listeriosis[4] and lipopolysaccharide shock[5]. Specifically neutrophils are innate immune cells for the first-line defense against infection. Their bactericidal properties emanates from phagocytosis and release of proteases and reactive oxygen species. However, these indiscriminant processes can also harm host tissues[6]. Sepsis often results in an exaggerated inflammatory response that leads to secondary tissue injury and organ dysfunction. We hypothesize that the LFA-1 deficiency will attenuate tissue injury and ameliorate bacterial sepsis. To test this hypothesis we used cecal ligation and puncture (CLP) model, an abdominal polymicrobial model which mimics human sepsis physiology[7] and measured the extent of histopathological damage and cytokine response in LFA-1 deficient and wild-type (WT) mice.

MATERIALS AND METHODS

Mice

All the mice were purchased from Jackson laboratory (Bar Harbor, Maine, United States) and inbred in the Boston Children's Hospital animal facility. CD11a knockout (KO) mice (LFA-1 KO mice) have been previously described[8]. Male mice on the C57BL/6J background aged 8-10 wk were used for the current experiments. They were housed under 12 h day and night cycles and specific pathogen free conditions.

CLP model and animal care use

All the experimental protocols were approved by the Review Board in Boston Children's Hospital and followed the Animal Research: Reporting of *in vivo* experiments guidelines. All the appropriate measures were taken to minimize pain and discomfort as described below. Polymicrobial sepsis was induced by cecal ligation and puncture model as described in our previous report for the details[7]. The mice were anesthetized with ketamine 60 mg/kg and xylazine 5 mg/kg. The cecum was punctured through and through using a 18-G needle. Following the completion of CLP surgery, 0.1 mL/kg of warmed saline was given subcutaneously. Postoperative surgery pain was treated with buprenorphine. Activity levels were recorded as follows: 5 = full response and activity (baseline activity), 4 = little less than full response and activity, 3 = responsive, active, but decreased appetite, 2 = responds, but barely reacts, 1 = barely responsive, and 0 = no response. In some of the experiments, LFA-1 blocking antibody (M17/4; BioXcell, West Lebanon, NH, United States) 2 mg/kg was given intravenously prior to CLP surgery.

Peritoneal leukocyte count

Peritoneal lavage samples were collected at 6 and 12 h after CLP as described in our previous report[7]. The

TNF: Tumor necrosis factor; IL: Interleukin; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

number and differential of peritoneal leukocytes was assessed using TURK blood diluting fluid and Giemsa staining.

Quantitative blood and organ culture

The residual bacterial loads in the organs and blood were determined by loading serially diluted tissue homogenates and blood on agar plates as described in our previous report[7].

Bacterial killing assays

As previously described[9], we isolated neutrophils from mouse bone marrow. We performed bacterial killing assays as described in our previous report[7]. Briefly, 50% diluted plasma from either WT or CD11a KO mice was mixed with 5×10^5 CFU of bacteria derived from tissues after CLP for opsonization. Then 5×10^4 of neutrophils were added and kept for one hour in a shaker at 37 ℃, and then the number of residual bacteria was determined by plating on blood agar.

Complete blood count, serum cytokine level measurement and immunoglobulin level measurement

VetScan HM2 (Abaxis, Union City, CA, United States) was used for complete blood count counts. Levels of various serum cytokines except interleukin-6 (IL-6) were determined by using mouse Th1/Th2 kit (Meso Scale Discovery; Gaithersburg, MD, United States). Serum IL-6 was measured using mouse IL-6 enzyme-linked immunosorbent assay (ELISA) kit (Life Technologies, Grand Island, NY, United States). Serum mouse immunoglobulin levels were measured with a commercially available ELISA kit (BD, Sparks, MD, United States).

Reverse transcription and real time quantitative polymerase chain reaction

Following the harvest, tissues were snap frozen and stored at -80 ℃ for a short period. Total RNA was extracted using TRIzol reagent (Life Technologies) and subject to DNase digestion. 1 μg of RNA were subject to reverse transcription using Superscript Ⅲ RNase reverse transcriptase (life technologies). Real time quantitative polymerase chain reaction (PCR) was performed using SYBR green master mix (Applied Biosystems, South Francisco, CA, United States). As examples of proinflammatory and anti-inflammatory cytokines, we quantitated mRNA level of tumor necrosis factor (TNF)-α, IL-1β, IL-6 and IL-10. glyceraldehyde-3-phosphate dehydrogenase was used as housekeeping gene. The sequences of primers used for this assay were listed in Table 1.

Histology

Mice tissues were fixed using 4% paraformaldehyde. Tissues for histology analysis were prepared in Boston Children's Hospital pathology core.

The determination of tissue apoptosis

The degree of splenic apoptosis was determined by Western blot analysis and immunohistochmistory probed by anti-cleaved caspase-3 antibody and TUNEL staining as we previously described for details[7,10]. For Western blot analysis, the total protein extracted from spleen was used. For immunohistochemistry analysis, anti-cleaved caspase 3 antibody was probed with biotin-labeled anti-rabbit IgG and peroxidase-conjugated streptavidin. 3,3'-diaminobenzidine (DAB) was used for a chromogenic reaction. TUNEL staining was performed according to the company protocol (Millipore, Serological Corporation, Norcross, GA, United States).

Myeloperoxidase staining

The degree of neutrophil recruitment to various organs was assessed by probing myeloperoxidase activity (MPO) in the tissues. Histology sections were deparaffinized as we previously described[7] and probed with anti-myeloperoxidase antibody, which was captured by anti-rabbit IgG-HRP and DAB.

Leukocyte counts in bronchoalveolar lavag fluid

Bronchoalveolar lavag fluid was obtained as described in our previous report[7]. The number and differential of leukocytes was determined with TURK blood diluting fluid and Giemsa staining.

MPO assay of lung

MPO level was measure in lung samples obtained from mice at 12 h after CLP. MPO assay was well described in the past[11]. Briefly, MPO was extracted from tissues into the supernatant by homogenization in 50 mmol/L KPO_4 buffer containing 0.05% hexadecyltrimethlammonium bromide, followed by repeated freeze and thaw, and centrifugation. O-dianisodine and H_2O_2 were added to the supernatant. The wave length of 450 nm was used for absorbance measurement.

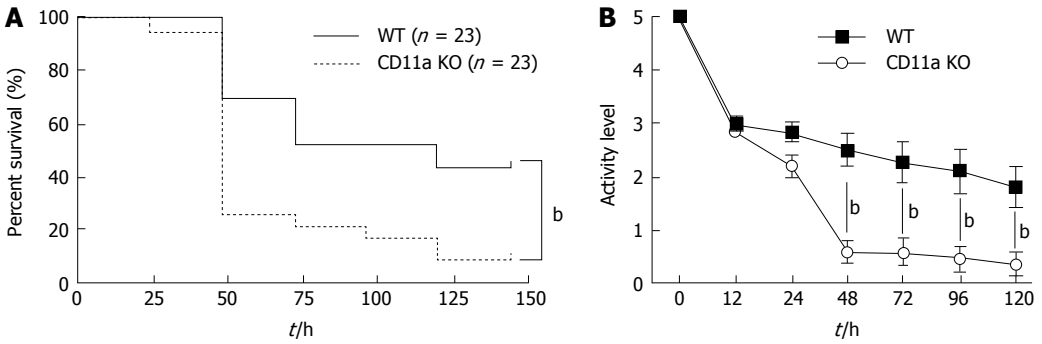

Figure 1 The outcome and activity level of CD11a knockout mice in polymicrobial sepsis. A: The outcome of polymicrobial sepsis in wild-type (WT) and CD11a knockout mice. Statistical significance was evaluated using Log-rank test (P = 0.0024). The activity level of WT and CD11a mice following polymicrobial sepsis is shown; B: Activity was numbered from 0 to 5 based on responsiveness and appetite as described in Methods. Statistical analysis was performed using two-way analysis of variance with Bonferroni post hoc analysis. In both (A) and (B), $^{b}P < 0.01$, respectively. KO: Knockout.

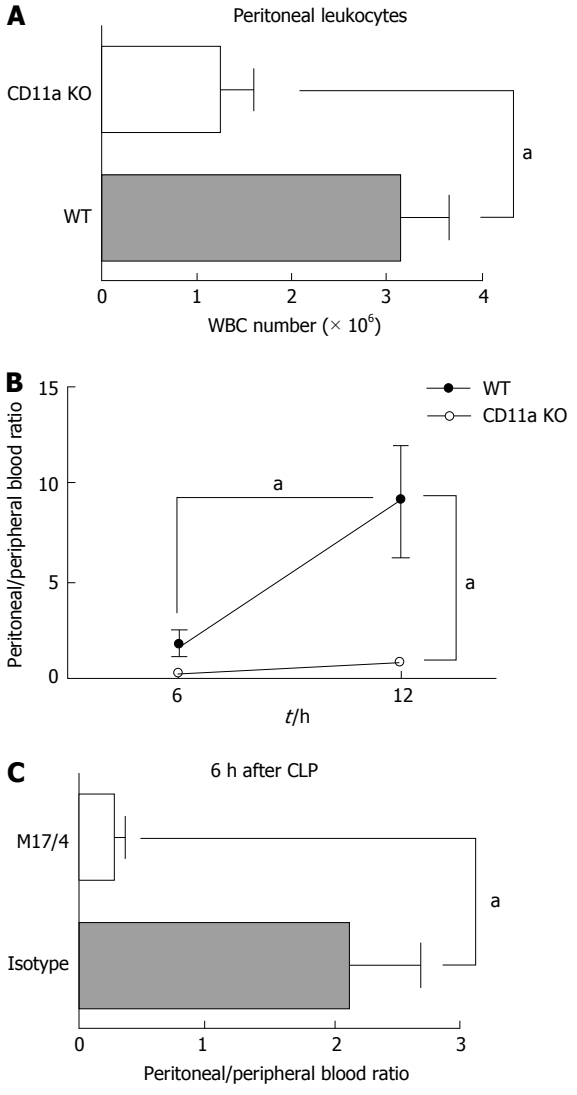

Figure 2 Leukocyte migration to the peritoneal cavity. A: Total numbers of peritoneal leukocytes in both wild-type (WT) and CD11a knockout (KO) mice at 6 h after cecal ligation and puncture (CLP) were compared. Statistical analysis was performed using two-tailed Student's *t*-test; B: The peritoneal emigration ratio defined as in the manuscript were shown at 6 and 12 h after CLP. Data represent mean ± SD of 4 mice. Statistical analysis was performed using one-way analysis of variance with Tukey's post hoc analysis; C: The peritoneal emigration ratio was shown at 6 h after CLP in both isotype-control injected WT group and CD11a blocking antibody M17/4 injected WT group. Data represent mean ± SD of 4 mice. Statistical analysis was performed using two-tailed student's *t*-test. $^{a}P < 0.05$.

Statistical analysis

The data were shown as mean ± SD. Differences were statistically analyzed using PRISM software (GraphPad software, Inc. La, CA, United States). The statistical methods used were detailed in corresponding figure legends. $P < 0.05$ was used for a statistical significance. The statistical methods of this study were reviewed by Amber Hall, MPH (Boston Childrens Hospital).

RESULTS

The outcome of polymicrobial sepsis

In the previous study using less severe CLP model (survival about 80%), administration of LFA-1 blocking antibody did not improve survival despite the attenuation of lung injury[12]. The use of blocking antibody carries the potential problem because (1) in the case of physical approximation of LFA-1 with an other surface receptor, anti-LFA-1 antibody may directly interfere with the receptor, and (2) blocking antibody may activate Fc receptors and induce functional changes in neutrophils[13]. Therefore, we studied using CD11a KO mice here.

Contrary to our hypothesis that LFA-1 deficiency would attenuate sepsis, KO mice had significantly higher mortality (Figure 1A). Their activity level was significantly reduced 48 h after CLP compared to WT mice (Figure 1B), which was in line with the observed pattern of mortality.

Leukocyte infiltration to the abdominal cavity

LFA-1 plays an important role in leukocyte recruitment. Now we evaluated the degree of leukocyte recruitment to the peritoneal space. The total number of peritoneal leukocytes was greater in WT mice (Figure 2A), which were primarily neutrophils (data not shown). Previously, the peritoneal emigration ratio was defined as (peritoneal leukocyte number)/(peripheral leukocyte number) by Prince *et al*[2]. When we compared this parameter, KO mice had much lower peritoneal emigration ratio than WT mice (Figure 2B), suggesting that leukocyte recruitment to the peritoneal cavity was significantly reduced in the former. Similarly, the administration of the blocking antibody was associated with lower peritoneal

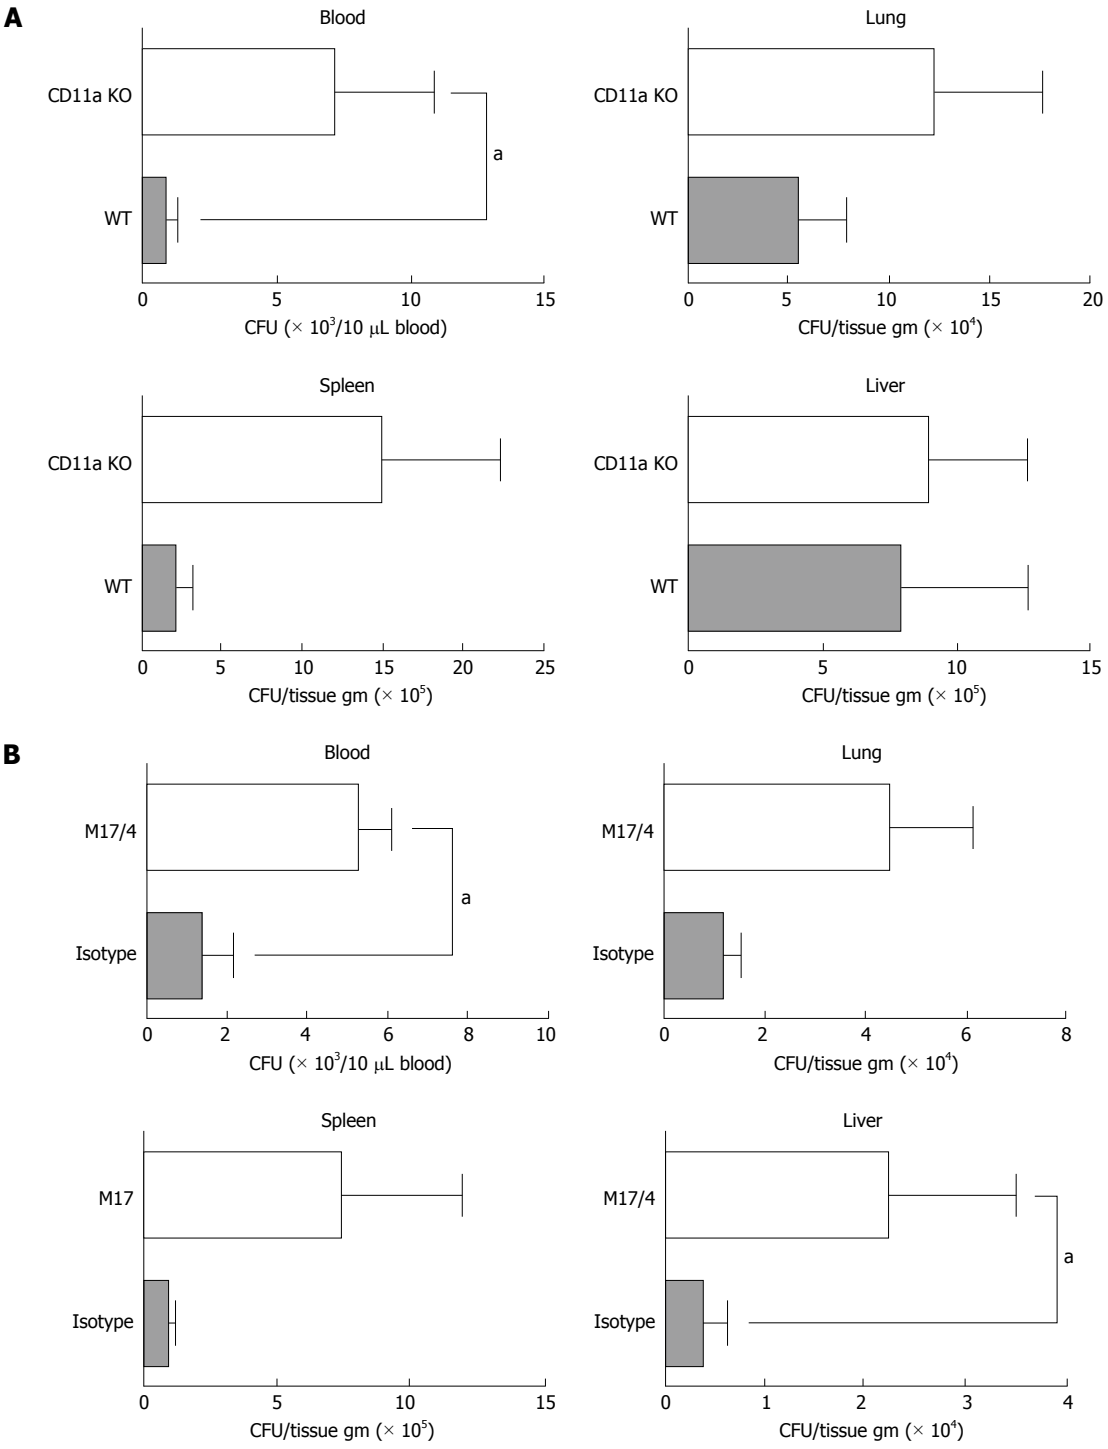

Figure 3 Tissue bacterial load. A: The comparison between wild-type and CD11a knockout (KO) mice. The tissue bacterial load was studied and shown as mean ± SD of 8 mice. Statistical analysis was performed using two-tailed Mann-Whitney test; B: The comparison between isotype-control injected group and CD11a blocking antibody M17/4 injected group. emigration ratio than isotype control (Figure 2C). This observation is compatible with thioglycollate-induced peritonitis model[14] and *Streptococcus pneumoniae* abdominal infection model[2].

Bacterial loads

Since KO mice had significantly reduced leukocyte recruitment to the peritoneal cavity (site of infection), we reasoned that the higher mortality in KO mice might be due to the difference of bacterial clearance between WT and KO mice. Bacterial loads in blood and various tissues were measured. Even at 6 h after CLP surgery, the KO mice had a significantly higher bacterial load in blood than the WT (Figure 3A). Similarly the presence of CD11a blocking antibody M17/4 was associated with higher bacterial load in blood and liver than the

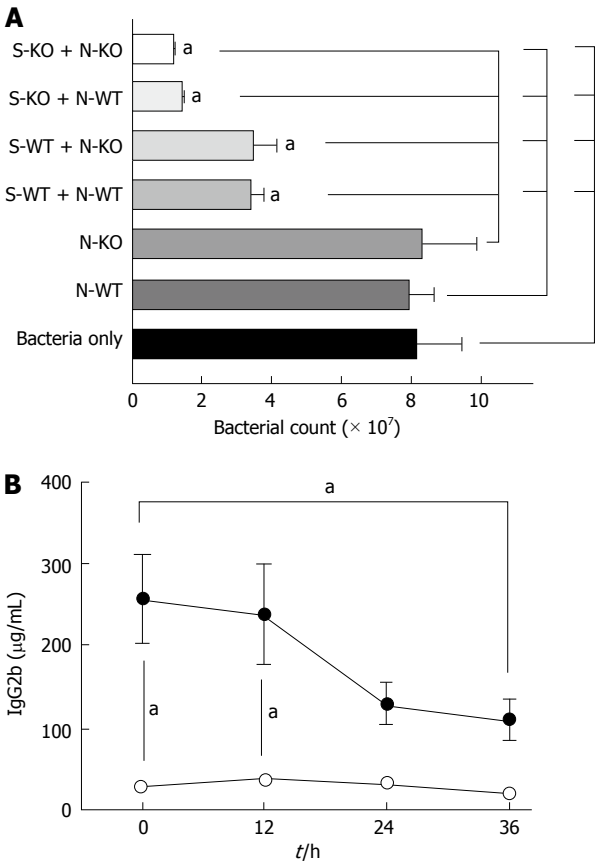

Figure 4 Bacterial killing and IgG2b level. A: Bacterial killing assay was performed using bacteria obtained from cecal culture as described in the methods. Data represent mean ± SD of 3 independent experiments. N-WT: Wild-type neutrophils; N-KO: CD11a KO neutrophils; S-WT: Wild-type serum; S-KO: CD11a KO serum.

presence of isotype-control antibody (Figure 3B).

Bacterial killing assays

Because KO mice had higher bacterial load, we assessed any alternation of bacterial killing in KO mice in addition to the reduced leukocyte recruitment to the abdominal cavity. We performed assays using bacteria derived from the cecal flora. Isolated neutrophils themselves were not bactericidal, but the addition of serum to the neutrophils effectively killed bacteria in both WT and KO mice (Figure 4A). The serum itself killed bacteria and KO serum was more efficient in bacterial killing. Furthermore neutrophils were more bactericidal with KO serum than with WT serum. Therefore, higher bacterial load in KO mice is attributed to the significantly reduced number of leukocytes at the site of infection. The observation that KO serum was more efficient in bacterial killing with and without neutrophils may suggest the possibility that KO serum have more complement activity, or it may be due to significant reduced serum IgG2b level in KO mice (Figure 4B). IgG2b can bind to inhibitory Fc receptor and impair optimal opsonization through binding to antigenic sites on the bacteria[15]. Therefore, the reduced IgG2b level may be in favor for opsonization in KO mice.

Serum cytokines

Systemic activation of the innate immune system plays an important role in the pathophysiology of sepsis. The initial immune response is proinflammatory, but this rapidly shifts to hypoinflammatory (anti-inflammatory) process[16]. The attenuation of proinflammatory cytokines was previously associated with the improved outcomes in this model[17]. Since KO mice had higher mortality, we compared proinflammatory [TNF-α, interferon (IFN)-γ, CXCL1, IL-1β, IL-2, and IL-12] and anti-inflammatory (IL-4, IL-5, and IL-10) cytokines (Figure 5). There was a slight increase of IFN-γ level in KO mice at 12 h after CLP procedure, but there was no difference at 24 and 36 h. IL-1β level of KO mice was significantly higher at 24 h after CLP procedure, but at 36 h no difference was observed. IL-6 is a cytokine with both proinflammatory and anti-inflammatory properties. Previously the serum level of IL-6 was elevated in septic patients[18] and shown to correlate with their outcomes[19,20]. Serum IL-6 level was higher at 12 h in KO mice. At 24 and 36 h, serum IL-6 level in KO mice was not statistically different (Figure 5).

Tissues injury

Next we evaluated local injury to see if there was any difference between WT and KO mice. IL-6 serves as sensitive marker of tissue inflammation (injury)[21]. In both lung and spleen, the level of IL-6 mRNA was significantly higher in KO mice than WT mice (Figure 6), suggesting that there was more tissue injury in KO mice. mRNA levels of TNF-α, IL-1β and IL-10 were not statistically significant (Figure 7).

Apoptosis

Apoptosis in the spleen is linked to the severity of sepsis[22]. Therefore, we evaluated the degree of apoptosis in our model. We first evaluated the cleaved-caspase-3 expression in spleen using western blot. The expression of cleaved caspase-3 was peaked at 12 h following CLP procedure in both WT and CD11a KO mice (Figure 8). Expression was higher in KO mice. Next we evaluated apoptosis using TUNEL stain and cleaved caspase-3 staining on the spleen histology. As predicted, apoptotic cells of spleen were present more in KO mice (Figure 9). Taken together, LFA-1 deficiency contributed to severity in tissue injuries in CLP model.

Neutrophil infiltration in the spleen, liver, kidney and lung

Since KO mice had increased tissue injury, we examined neutrophil recruitment to spleen, liver, kidney and lung. MPO is a peroxidase enzyme that is most abundantly expressed in the granules of neutrophils. We examined the expression of MPO in tissues as a surrogate of

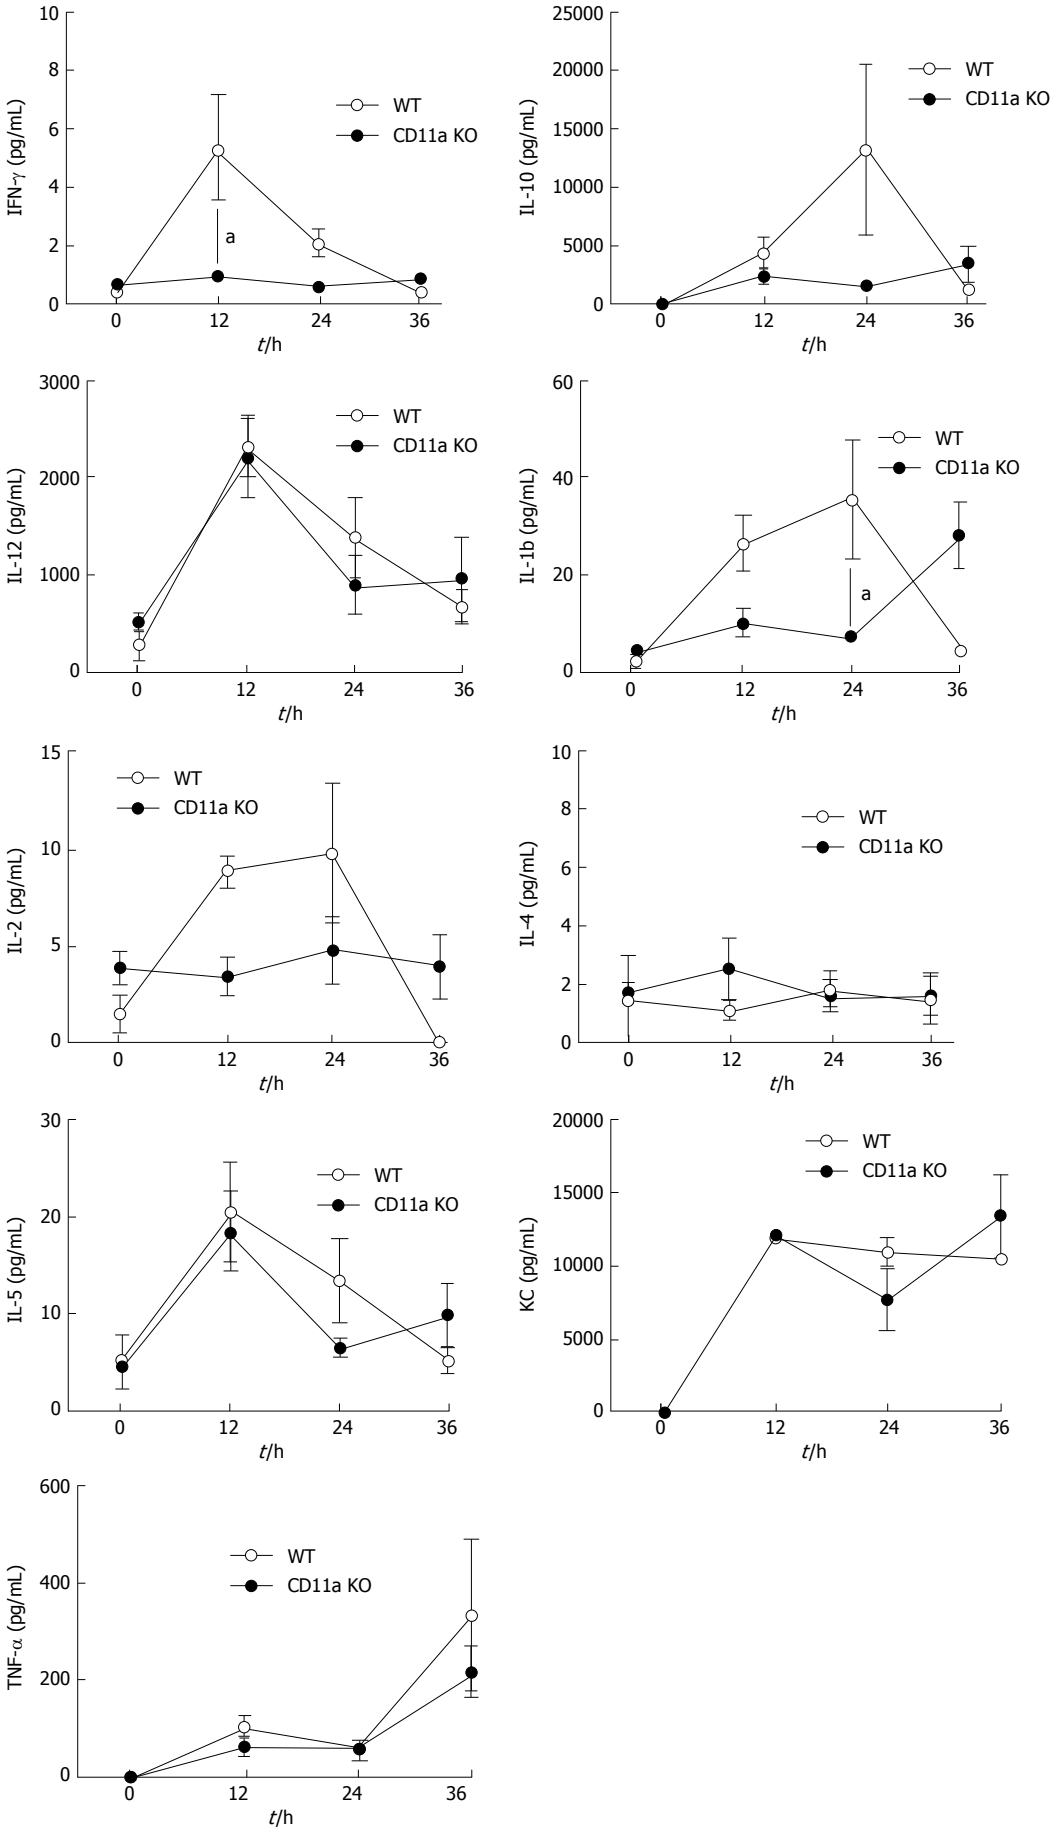

Figure 5 Serum cytokine profiles in polymicrobial sepsis. The cytokine profiles of wild-type (WT) and CD11a knockout mice were compared. The data represents mean ± SD of 8 mice. Statistical analysis was performed using two-way analysis of variance with Tukey post hoc analysis. $^{a}P < 0.05$.

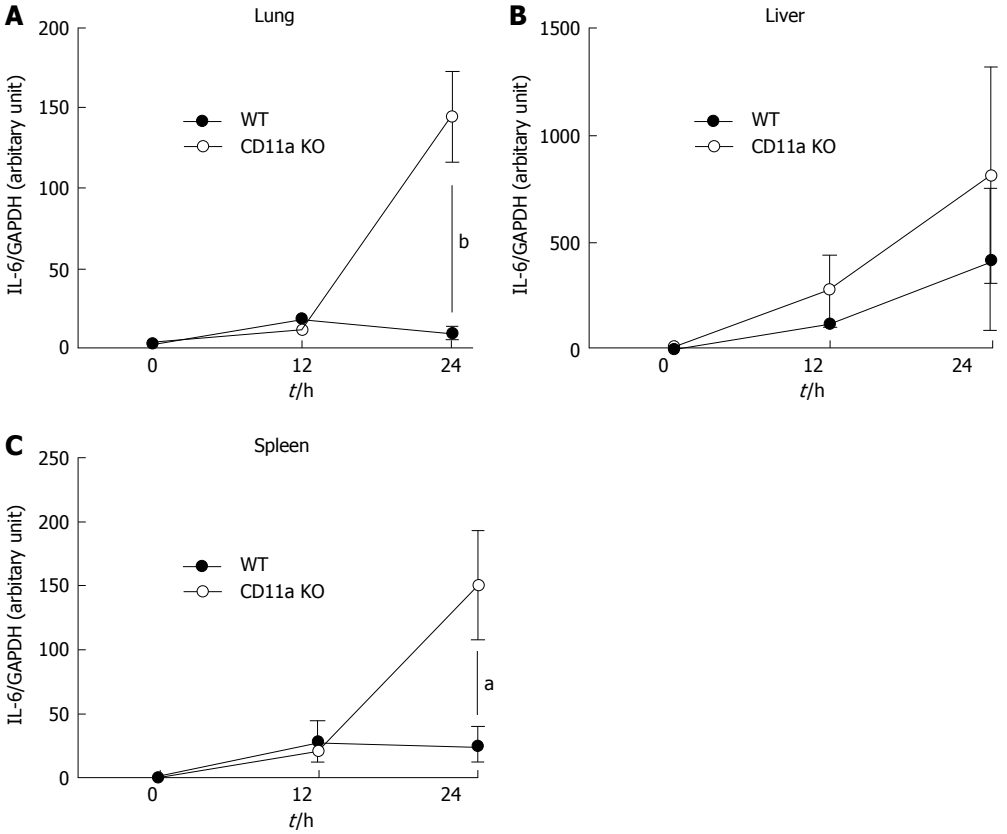

Figure 6 Tissues interleukin-6 mRNA level. Interleukin-6 (IL-6) expression at various tissues was examined using real-time quantitative polymerase chain reaction (A-C). Data represent mean ± SD of 4 independent experiments. Statistical analysis was performed using two-way analysis of variance with Tukey post hoc analysis. $^{a}P < 0.05$ and $^{b}P < 0.01$, respectively.

neutrophil number. There were more MPO positive cells on tissues of KO mice in organs tested after CLP (Figure 10). Activated leukocytes are often trapped in lung in sepsis, causing lung injury. The number of leukocytes in bronchial lavage fluid was not statistically different between WT and KO mice (Figure 11A). The majority of the population was neutrophils (data not shown). However, MPO value was significantly higher in lung tissue in KO mice than in WT mice (Figure 11B), suggesting that neutrophils in KO mice were trapped in lung tissue with less migration out into the alveolar space. Although the baseline neutrophil count was higher in KO mice as previously reported due to the elevated level in G-CSF level[23], there was no difference at 12 h after CLP (Figure 12). This larger reduction in peripheral neutrophil counts could be well explained by more neutrophil recruitment to the tissues in KO mice. In addition, we tested neutrophil recruitment to lung using LFA-1 blocking antibody M17/4. The result demonstrated more neutrophil recruitment to lung in the group that received LFA-1 blocking antibody, consistent with our KO mice data (Figure 11C). These results suggested that neutrophils migrated in a LFA-1 independent fashion to the tissues tested.

DISCUSSION

Here we demonstrated that both LFA-1 blockade and deficiency were detrimental in polymicrobial sepsis. CD11a KO mice demonstrated higher mortality with more bacterial load in blood than WT mice in CLP model. The reduction of available leukocytes at the site of infection (the abdominal cavity) was significant. Contrary to our hypothesis, LFA-1 deficiency did not attenuate neutrophil recruitment to various organs, suggesting that tissue damage by neutrophils was not attenuated. Therefore, we conclude that the loss of LFA-1 did not alleviate organ injury in this experimental model of abdominal sepsis.

Neutrophil phagocytosis of a certain bacteria strain (such as Streptococcus pyogenes) was previously reported to be potentiated by LFA-1/ICAM-1 interaction[24]. The capability of bacteria killing was not different between WT and KO mice, suggesting that neutrophils devoid of LFA-1 could phagocytize bacteria effectively. Reduction of leukocyte recruitment to the abdominal cavity can certainly reduce the efficiency of bacteria killing. Therefore, higher bacteria load in blood may be simply due to the impaired recruitment of neutrophils to the abdominal cavity.

The process of leukocyte (neutrophil) recruitment to organs was previously assumed to uniformly follow an orchestrated progression consisting of initial tethering and rolling by selectins, firm adhesion by integrins such as LFA-1 and macrophage-1 antigen (Mac-1, CD11bCD18) and transmigration. Molecules involved in the recruit-

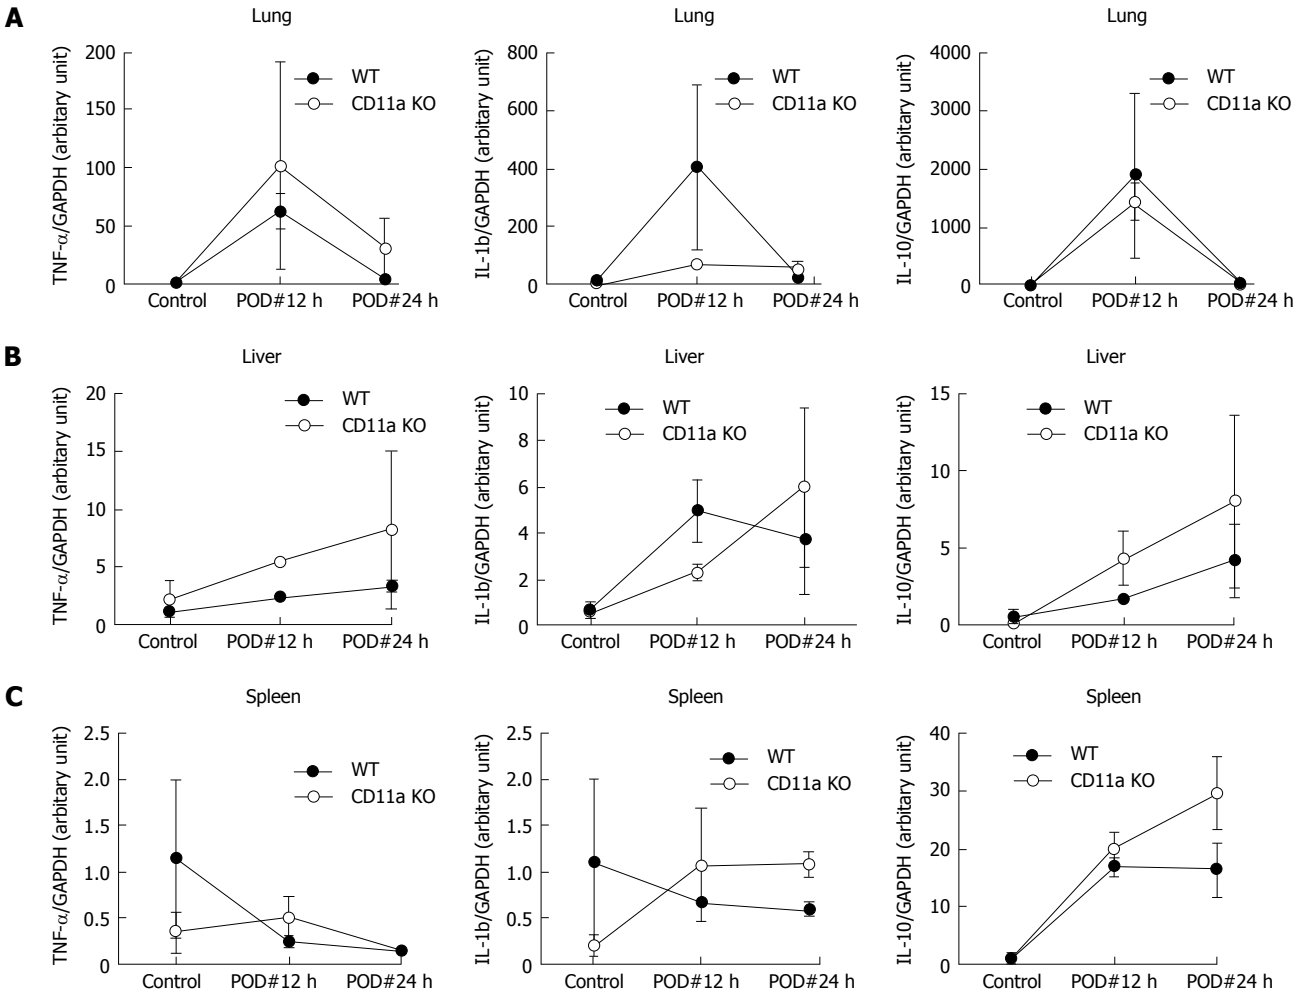

Figure 7 Tissues tumor necrosis factor-α, interleukin-1b and interleukin-10 levels. Various tissues of IL-6 expression were examined using real-time quantitative polymerase chain reaction. Statistical analysis was performed using two-tailed Student's *t* test. There was no statistical significance (P = 0.1158); B and C: Neutrophil recruitment to the lung was examined by measuring myeloperoxidase level. In the figure, control means no cecal ligation and puncture surgery, and CLP means cecal ligation and puncture model. Data represent mean ± SD of 4 different samples. Statistical analysis was performed using one-way analysis of variance with Tukey post hoc analysis. $^{a}P < 0.05$. Isotype means isotype control antibody. M17/4 is anti-CD11a blocking antibody. KO: Knockout; CLP: Cecal ligation and puncture; MPO: Myeloperoxidase; WT: Wild type.

ment of leukocytes to the abdominal cavity were examined in thioglycollate-induced inflammation[25]. The study demonstrated that two integrins LFA-1 and α4β1 contributed to neutrophil recruitment. In our study migration of leukocytes to the peritoneal cavity was much less in CD11a KO mice than WT mice, suggesting that LFA-1 played a major role. Microcirculation of peritoneum seems to fit this traditional scheme. Microcirculation in tissues such as mesentery, skeletal muscle, and skin also follow the original scheme[26]. In contrast, LFA-1 deficiency did not have an effect on neutrophil recruitment to liver, kidney, spleen and lung in our model, suggesting that other processes are involved.

Recruited leukocytes are predominantly neutrophils early in sepsis. Neutrophils efficiently kill bacteria *via* various methods, but the secondary damage by neutrophils could be detrimental. The importance of early, enhanced neutrophil recruitment by the chemokines CXCL1 (= KC) and CXCL2 (macrophage inflammatory protein 2; MIP-2) administration in peritonitis-induced sepsis was previously shown to improve bacterial clearance and survival[27]. However, blockade of CXCL2 was associated with the reduced percentage of neutrophils in the peritoneal fluid but with better survival[28]. Furthermore, leukotriene B4 receptor (BLT1) deficiency was associated with reduction of neutrophils migration to the abdominal cavity with a better survival[29]. The impact of these molecules on other effects such as neutrophils recruitment to various tissues and cytokine productions were not fully explored in these studies. However the completely opposite outcomes despite similarly reduced neutrophil recruitment to the abdominal cavity suggested that there are important factors other than local infection control. The function of CXCL2 includes the activation of neutrophils. Blockade of CXCL2 or BLT1 deficiency may possibly reduce neutrophil migration to various organs outside of the abdominal cavity, limiting organ injury. It is important to understand how we modulate the behavior of neutrophils (leukocytes) in the whole body rather than simple control of neutrophils to the site of infection.

In the present report we demonstrated that in CD11a KO mice, neutrophil recruitment seems organ specific. Neutrophil recruitment to liver in lipopolysaccharide shock was previously shown to be independent on LFA-1 and dependent on CD44[5,30]. Interestingly, neutrophil utilizes Mac-1 when fMLP was injected locally in liver, suggesting that main players can change depending on circumstances[30]. Lung microvasculature is a network of thin capillaries. Neutrophils have to deform to pass through these small capillaries, which may make selectins and integrins unnecessary[31]. However, the other report suggests that integrins play a significant role in leukocyte recruitment to lung[12,32]. In the study by Asaduzzaman *et al*[12], the administration of LFA-1 blocking antibody did not change the outcome of mice in mild CLP model (survival around 80% in both vehicle and blocking antibody injected groups) despite the less neutrophil recruitment to lung. In our more severe model, LFA-1 blocking antibody did not attenuate neutrophil recruitment to lung. Whether or not the pattern of neutrophil recruitment to lung varies in different disease processes as well as severity of diseases remains to be clarified. In kidney, Mac-1 is shown to be involved in neutrophil recruitment[33]. Various insights into neutrophil recruitment at various organs start to emerge. However, it is required to have further investigations on clear mechanism of neutrophil recruitment to each organ in the future. Our study highlighted the importance of this approach.

Since LFA-1 works by interacting with its ligands, it

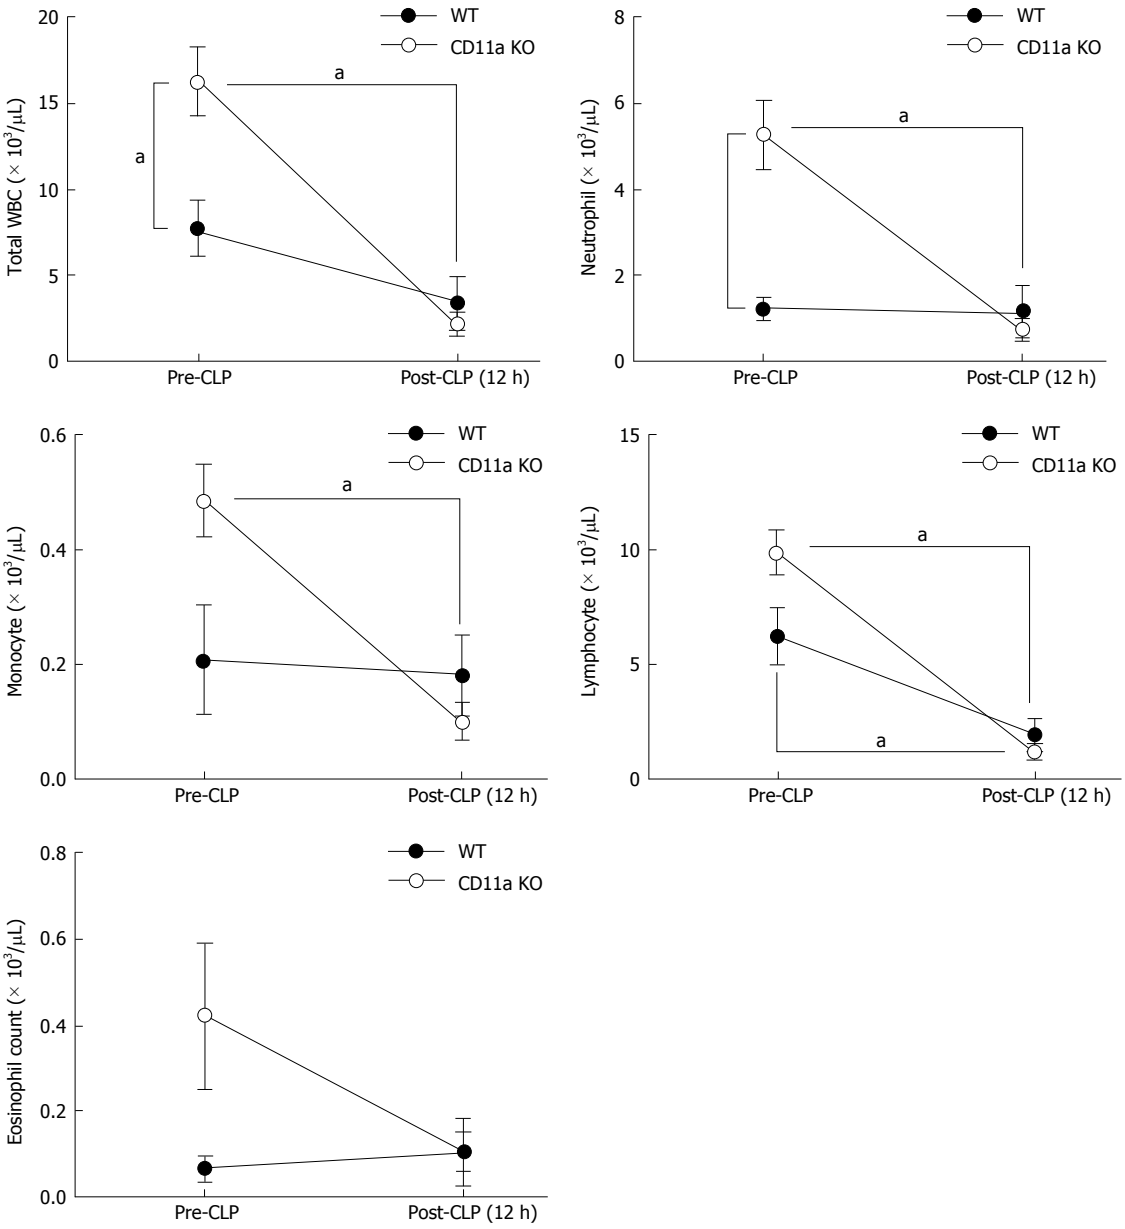

Figure 12 The changes of peripheral leukocyte counts in septic mice. The number of leukocytes was examined. The data represent mean ± SD of 4 independent experiments. Statistical analysis was performed using one-way analysis of variance with Tukey's post hoc analysis. $^{a}P < 0.05$.

is important to study the role of ICAM-1 and ICAM-2, both of which are ligands for LFA-1. They are expressed on leukocytes, epithelial cells, endothelial cells, and fibroblasts. ICAM-1 is uniformly expressed on the surface of resting endothelium at low level and its expression is upregulated by inflammatory cytokines. On the other hand, ICAM-2 shows high expression constitutively, particularly at endothelial cell junctions. The predominant role of ICAM-1 is to establish stable leukocyte adhesion while ICAM-2 mediates trans-migration[34]. The role of ICAM-2 in polymicrobial sepsis has not been studied. ICAM-1 KO mice subjected to CLP surgery had reduction of serum TNF-α, IL-1β, IL-6 and IL-10 levels as well as leukocyte migration to liver and lung, and had significantly higher survival over WT mice in CLP model[35]. The degree of leukocyte migration to the abdominal cavity and bacterial tissue load were not assessed in this study, but it is highly likely that neutrophils recruitment to the abdominal cavity was reduced by disrupted LFA-1/ICAM-1 interaction. The significantly lower cytokine levels and attenuation of leukocyte migration to organs such as liver in ICAM-1 KO mice might reduce their mortality. In our study, we did not see a significant difference of cytokine levels between WT and CD11a KO mice. Because ICAM-1 also binds to Mac-1 and p150,90, the elimination of interaction of ICAM-1 with these targets other than LFA-1 might contribute to this paradoxical result in ICAM-1 KO mice. The recruitment of neutrophils to liver is dependent on Mac-1[31], and the reduction of leukocyte recruitment to liver might be due to the abolishment of Mac-1 interaction. It is interesting to investigate in the future if ICAM-1 KO mice have less neutrophil recruitment to the abdominal cavity as well as other

organs.

We tried to address the degree of tissue injury by measuring IL-6 levels. IL-6 is induced by various signals including IL-1β, TNF-α, IL-2 and endotoxin, and it was reported as a marker of severity in sepsis and correlated with the outcome of patients. Remick *et al*[21] stated it as a sensitive marker for tissue injury. We demonstrated that IL-6 mRNA levels in various tissues were more elevated in CD11a KO mice. This was in line with our result of more neutrophil recruitment to various organs in KO mice. It remains to be studied whether or not other markers suit better for this purpose.

In conclusion, we demonstrated that LFA-1 blockade selectively reduced neutrophil recruitment to the site of infection without attenuating various organ injuries. Blockade of LFA-1 may not have a therapeutic implication in the setting of abdominal polymicrobial sepsis.

COMMENTS

Background

Neutrophils are the double-edge swords in sepsis because they eradicate bacteria as the first-line innate cells, but cause tissue injury. Leukocyte function-associated antigen-1 (LFA-1) is an important adhesion molecule in leukocyte recruitment. The effect of LFA-1 deficiency on leukocyte recruitment and tissue injury has not been well characterized in polymicrobial sepsis model.

Research frontiers

The author aimed to study the role of LFA-1 in neutrophil migration to various organs in polymicrobial sepsis model.

Innovations and breakthroughs

To illustrate the contribution of LFA-1 in neutrophil migration to various tissues so as to understand the impact of LFA-1 deficiency (or blockade) in polymicrobial sepsis model.

Applications

The author hypothesized that LFA-1 deficiency would reduce neutrophil recruitment to various organs, thereby reducing tissue injury and improving the outcome in polymicrobial sepsis model. However, the authors results showed that LFA-1 reduced neutrophil migration to the abdominal cavity, but did not reduce to other organs. The blockade of LFA-1 does not likely improve sepsis outcomes.

Terminology

LFA-1 is an adhesion molecule expressed on neutrophils and binds to its ligands such as intercellular adhesion molecule-1 on the endothelium, allowing neutrophils to stop on the blood vessel. Traditionally, this step is considered to be a critical step in neutrophil migration.

Peer-review

This is a clear cut study using LFA-1 knockout mice. The authors revealed that the absence of LFA-1 results in survival disadvantage in polymicrobial sepsis. The experiments were performed properly, and the paper is well-written with reasonable discussions.

Abstract

AIM: To analyze the host genetics factors influencing the clinical course and the response to antiviral treatment in patients with chronic hepatitis C (CHC).

METHODS: We conducted an electronic search on the PubMed and MEDLINE (2000-2014) databases and Cochrane library (2000-2014). A total of 73 articles were retrieved and their data were extensively evaluated and discussed by the authors and then analyzed in this review article.

RESULTS: Several studies associated polymorphisms in the interleukin 28B gene on chromosome 19 (19q13.13) with a spontaneous viral clearance in acute hepatitis C and with the response to pegylated interferon (Peg-IFN)-based treatment in chronic hepatitis C patients. Other investigations demonstrated that inosine triphosphate pyrophosphatase genetic variants protect hepatitis C virus-genotype-1 CHC patients from ribavirin-induced anemia, and other studies that a polymorphism in the patatin-like phospholipase domain-containing protein 3 was associated with hepatic steatosis in CHC patients. Although not conclusive, some investigations suggested that the vitamin D-associated polymorphisms play an important role in the achievement of sustained virologic response in CHC patients treated with Peg-IFN-based antiviral therapy. Several other polymorphisms have been investigated to ascertain their possible impact on the natural history and on the response to treatment in patients with CHC, but the data are preliminary and warrant confirmation.

CONCLUSION: Several genetic polymorphisms seem to influence the clinical course and the response to antiviral treatment in patients with CHC, suggesting individualized follow up and treatment strategies.

Key words: Single nucleotide polymorphism; Hepatitis

C virus infection; Interleukin 28B; Inosine triphosphate pyrophosphatase; Patatin-like phospholipase domain-containing protein 3

Core tip: Some single nucleotide polymorphisms have been associated with the clinical presentation and/or response to antiviral treatment in subjects with chronic hepatitis C (CHC). In this review article the effect of old and new host genetics factors [interleukin 28B, inosine triphosphate pyrophosphatase, patatin-like phospholipase domain, cannabinoid receptor type 2 (CB2-63), vitamin D associated polymorphisms, *etc*.] on the outcome of CHC and the response to antiviral treatment will be presented, analyzed and discussed, to provide some guidance for individualized therapies in clinical practice.

INTRODUCTION

The World Health Organization estimates that 130-170 million people are infected with hepatitis C virus (HCV) worldwide and that more than 350000 people die of HCV-related liver diseases each year[1]. In addition, HCV chronic infection is recognized as the most common cause of end-stage liver diseases in Western countries[2]. Primary infection causes asymptomatic acute hepatitis C (AHC) in most cases, which, however, progresses to chronicity in about two thirds of the cases, whereas about one third clear the virus spontaneously and recover[3-9]. Patients with chronic hepatitis C (CHC) frequently show the increasing severity of liver fibrosis over time, which leads to liver cirrhosis in nearly a quarter of cases. Hepatocellular carcinoma (HCC) develops in HCV-related liver cirrhosis with a yearly rate around 3%[10-18].

The combination of pegylated interferon (Peg-IFN) and ribavirin (RBV) has been recommended as the treatment of choice for CHC for nearly a decade[19-24]. This treatment provides a sustained clearance of circulating HCV [sustained viral response (SVR)] in nearly half of the patients with CHC due to HCV genotype 1 and in nearly 70% of those with HCV genotype 2 or 3. Several predictors of a favorable/unfavorable response to treatment have been identified. Some viral factors (HCV genotype 1/4 and an on-treatment slow or absent viral clearance) and host factors (male sex, older age, insulin resistance, diabetes, Afro-American ethnicity, presence of cirrhosis and/or steatosis, and high body mass index) have been associated with a poor response to Peg-IFN plus RBV treatment.

More recently, genome-wide association studies (GWAS) investigated the association between single nucleotide polymorphisms (SNPs) and the clinical presentation, course of the disease and response to antiviral treatment. Several studies have associated polymorphisms in the interleukin 28B (*IL28B*) gene on chromosome 19 (19q13.13) with a spontaneous clearance of HCV in AHC and with the response to Peg-IFN plus RBV treatment in CHC[25-28].

Some investigations demonstrated that inosine triphosphate pyrophosphatase (ITPA) genetic variants protect HCV-genotype-1 patients from RBV-induced anemia[29-31] and some other studies that a polymorphism in the patatin-like phospholipase domain (PNPLA3) is associated with hepatic steatosis[32,33].

The addition of a direct-acting antiviral (DAA) NS3 protease inhibitor boceprevir or telaprevir to the traditional combination of Peg-IFN plus RBV has increased the SVR rate in CHC patients with HCV genotype 1% to 70%[34-38], and the replacement of these first generation protease inhibitors with the recently developed second or third generation DAAs to nearly 90%[39-43]. In addition, some IFN-free treatments recently investigated have been shown to eradicate HCV infection in 90% or more of CHC patients. These high rates of HCV eradication should reduce the clinical value of most predictors of response to treatment so far considered, at least in countries where the high cost of second and third generation DAAs will not be an obstacle to their use. Nevertheless, the low toxicity of IFN-free DAA regimens allow the treatment of patients with comorbidities for which IFN-based treatments are contraindicated, those with advanced or decompensated liver cirrhosis and liver transplant recipients, who are all patients who may require individualized treatment possibly based on predictors of a favorable response.

MATERIALS AND METHODS

In this review article we focus on old and new host genetic factors influencing the outcome of CHC and the response to antiviral treatment to offer some guidance for individualized therapy in clinical practice. We conducted an electronic search on the PubMed and MEDLINE (2000-2014) databases and Cochrane library (2000-2014). A total of 73 articles were retrieved and their data were extensively evaluated and discussed by the authors and then analyzed in this review article.

RESULTS

Host IL28B and HCV infection

Several studies performed in the last 4-5 years have demonstrated that two SNPs, the rs12979860C/T and rs8099917T/G, located in the *IL28B* gene in chromosome 19 have a substantial impact on the clinical course of HCV-related liver diseases and on the response

to Peg-IFN-based treatment in CHC. The *IL28B* gene region encodes for an endogenous antiviral cytokine interferon-λ3 involved in both the early stage of the host innate immune response to HCV infection[25,44,45] and, by binding to a cellular class Ⅱ cytokine receptor complex, in the activation of interferon stimulating genes through the JAK-STAT pathway[44,45]. Thus, there is an immunological and virological explanation for the protective effect of the rs12979860CC[25] and rs8099917TT[28] genotypes on the natural course of primary HCV infection and on the response to IFN-based treatment[26-28,46].

IL28B and AHC

AHC has an asymptomatic course in 50%-90% of cases[3], but primary HCV infection becomes chronic in two-third of the cases, more frequently in men[47] and in asymptomatic cases[48]. Viral factors (genotype, subtypes and quasispecies)[49-53] and host factors (route of transmission, presence or absence of symptoms, initial immune response) have been described as playing a role in the natural history of the illness[25,28,46,54-57]. More recently, the rs12979860CC and rs8099917TT SNPs have been described as independently associated with a spontaneous clearance of HCV[25,28,58,59]. A recent meta-analysis of 8 studies on 2460 patients with HCV chronic infection and 1052 with a spontaneous HCV clearance, 7 studies investigating rs12979860 and 3 rs8099917, confirmed that, at least in Caucasian populations, rs12979860CC and rs8099917TT favor a spontaneous HCV clearance[60].

Early short-term IFN treatment prevents the progression to CHC in the majority of cases, whereas the results are less encouraging when treatment is started 6 mo or more after the onset of AHC[61-63]. Two controlled randomized studies recently published showed a frequent favorable response to a short Peg-IFN treatment starting three months after the onset of AHC[64,65]. Although both rs12979860CC and rs8099917TT have not been associated with a treatment-induced HCV clearance in AHC[58], some authors have suggested that treatment should be started immediately for patients with a non-CC genotype, while it can be delayed for those with the CC genotype, since these subjects may clear HCV spontaneously[59,66].

IL28B and the natural course of CHC

The influence of IL28B polymorphisms on the progression of CHC remains unclear. The rs8099917TT genotype was found to be associated with more severe liver neuroinflammation and fibrosis in a study from Japan[67], whereas it was not found to be associated with the more severe stages of liver fibrosis in an Italian prospective study[68]. In addition, an association of IL28B polymorphisms with the development of HCC in cirrhotic patients described in an Italian study[69] was not confirmed in a study from Japan showing similar prevalences of rs8099917TT genotype in 69 patients with HCC and in 442 without[70]. Further studies are needed to afford further clarification.

IL28B and response to antiviral treatment in CHC

The combination of Peg-IFN-alfa-2a or -2b and RBV has been used for nearly a decade to treat patients with CHC. More recently, the first generation DAA NS3 protease inhibitors, boceprevir or telaprevir, have been used in combination with Peg-IFN and RBV to treat patients with HCV genotype 1[34,71-73]. Second and third generation DAAs against HCV have been recently developed[74-76] and interferon-free combinations of these drugs are at present available both in the United States and in some European countries[77].

IL28B and Peg-IFN plus ribavirin treatment in patients with HCV-genotype 1: The IL28B genotype SNPs rs12979860 and rs8099917 are reliable predictors of the course of the disease after Peg-IFN and RBV treatment in CHC patients with HCV genotype 1[26-28,46]. In fact, the rs12979860-CC or rs8099917-TT genotypes are detectable in the majority of patients with a favorable response to treatment and patients with these genotypes have a twofold likelihood of achieving SVR[78-81]. These genotypes are more frequent in Asian (73%) than in Caucasian (41%), Hispanic (25%) and African American populations (13%)[26-28,46,79,80]. This different distribution strongly contributes to the racial differences in the response to therapy[79], since the favorable effects of rs12979860-CC and rs8099917-TT are similar for all ethnic groups.

IL28B and Peg-IFN plus ribavirin treatment in patients with non-1 HCV genotypes: The association between the IL28B polymorphisms and the response to Peg-INF plus RBV treatment in patients with HCV-genotype 2 and 3 has been investigated by few authors. In a recent study, Eslam *et al*[82] confirmed that rs12979860 CC and rs8099917 TT are independent predictors of SVR also in patients with HCV-genotype 2 or 3. In a study by Sarrazin *et al*[83] the rs12979860 CC genotype, HCV genotype 2 and a young age were found to be significantly associated with SVR in HCV genotype 2/3-infected patients, whereas rs8099917 and rs12980275 were not found to be associated. In addition, the achievement of SVR in patients with RVR was associated with the rs12979860 CC genotype, while no association was found for non-RVR subjects. In a recent study on the impact of SNP rs8099917 and of the amino acid substitutions in the NS5A region on the response to Peg-IFN plus RBV treatment in 286 CHC patients with HCV-genotype 2, SVR was achieved with similar rates in patients with rs8099917TT (76%) and those with TG or GG alleles (72%), whereas it was significantly less frequent in patients with the wild-type IFN sensitivity-determining region (ISDR) than in those with the mutant type (65.9% *vs* 83.5%). On multivariate analysis the only factors related to SVR were a younger age of patients and the ISDR, indicating that in patients with HCV genotype 2, the ISDR sequence variations are significantly associated with the response to Peg-IFN plus RBV treatment[84].

The SNPs rs12979860CC and rs8099917TT were found to be strongly associated with SVR in a large number of genotype-3-infected patients recently investigated by Firdaus *et al*[85].

In a retrospective study on 169 patients with genotype 4 treated with Peg-INF and RBV for 48 wk, Boglione *et al*[86] demonstrated that the combination of rs8099917/rs12979860 polymorphisms is useful to identify possible SVR patients, null-responders and relapsers. In fact, these authors achieved an 88.8% SVR in cases with rs8099917/rs12979860 TT/CC or TT/TC genotypes. Moreover, Youssef *et al*[87] underscored that alpha-fetoprotein increased the SVR predictive strength of IL28B rs12979860 CC polymorphism in Egyptian CHC patients with HCV-genotype 4.

IL28B and Peg-IFN plus ribavirin and first generation DAA triple therapy: Triple therapy with Peg-IFN, RBV and a first generation protease inhibitor boceprevir or telaprevir has increased the rates of SVR in HCV-genotype 1 CHC patients to nearly 70%, which reduces the importance of predictors of the response to therapy[71]. Nevertheless, IL28B favorable genotypes may still be useful to identify patients with a greater likelihood of achieving SVR with a first-line, low-cost Peg-IFN and RBV regimen, reserving DAA-based treatment for non-responders and relapsers[72,73], a particularly useful strategy in developing countries.

IL28B and second and third generation DAAs: The introduction of the second and third generation DAAs in IFN-based and IFN-free regimens for CHC patients has strongly reduced the need to determine the IL28B genotypes to predict the response to treatment. In fact, a favorable response was obtained in nearly 90% of patients with HCV-genotype 1 treated with sofosbuvir plus Peg-INF and RBV, this rate being slightly lower in patients with cirrhosis. In CHC patients with HCV-genotype 2, the combination of sofosbuvir and RBV given for 12 wk also resulted in SVR of 90% or more, with a slightly lower efficacy in patients with cirrhosis[76]. Other studies showed an SVR rate of nearly 95% in CHC patients treated with IFN-free regimens[74,75], independently of the IL28B status[74,75]. Guedj *et al*[88] found no effect of IL28B on the viral kinetics in HCV-genotype-1 CHC patients treated with sofosbuvir and GS-0938 given alone and in combination for 14 d.

The combination of daclatasvir plus sofosbuvir, with or without RBV, obtained SVR in 98% of both therapy-naïve or - experienced CHC patients with HCV-genotype 1a or 1b (98% and 100%, respectively), with IL28B CC or non-CC (93% and 98%, respectively) and with RBV included or excluded from combination therapy (94% and 98%, respectively)[77]. The data from the above-mentioned studies strongly indicate that we cannot evaluate the influence of *IL28B* genotypes on the response to second or third generation DAA treatments of CHC, due to the high efficacy of these treatments.

IL28B and HCV recurrence after liver transplantation

Some investigations showed an association between IL28B polymorphism and response to therapy in patients with a recurrence of HCV infection after liver transplantation. In particular, the highest SVR rates were observed when both donor and recipient showed the same rs12979860CC or rs8099917TT genotypes[89,90]. It has also been reported that the recipients with rs12979860TT genotype showed a more severe histological HCV recurrence after liver transplantation[89].

PNPLA3 polymorphism and HCV infection

The *PNPLA3* gene encodes a 481 amino acid protein called adiponutrin, which belongs to the patatin-like phospholipase family. Its progenitor, patatin, was first described in potato tubers and has non-specific lipid acyl-hydrolase activity[91]. The adiponutrin has a molecular mass of 53 kDa and is mainly expressed in both human adipocytes and hepatocytes[92]. The protein presents a sequence similar to that of adipose tissue triglyceride lipase, and has both triglyceride lipase and transcylase activity.

In 2008 two GWAS[32,33] showed a correlation between the rs738409 polymorphism of PNPLA3 and non-alcoholic fatty liver disease. In fact, a C to G mutation causes the substitution of isoleucin at codon 148 with a methionine, whose hydrophobic side-chain inhibits the binding of the substrate to the catalytic site, leading to a reduction in the enzymatic activity of the protein towards glycerolipids. Consequently, triglycerides accumulate, resulting in the development of macrovesicular steatosis.

Hepatic steatosis, frequent in patients with CHC and with the highest rates in those with genotype 3[93], has been associated with a more rapid progression of liver fibrosis[94] and a poor response to IFN-based treatments[95]. Due to these associations several authors investigated the impact of the rs738409 polymorphism of PNPLA3 on the clinical presentation and natural history of CHC (Table 1). The I148M mutation was found to be associated with the degree of steatosis and with the development of cirrhosis in two independent cross-sectional studies investigating, respectively, 537 and 819 patients with CHC[96,97]. These data were confirmed by the Swiss Hepatitis C Cohort Study Group on 626 patients with CHC for all HCV genotypes except genotype 3[98]. Zampino *et al*[99] found a stronger correlation between waist circumference and liver steatosis in homozygous 148M Italian CHC patients carrying non-3 HCV genotypes, but not with carotid atherosclerosis[100]. In addition, the association between another PNPLA3 polymorphism, the rs2896019, and the presence of any degree of steatosis, even severe, was demonstrated in a cross-sectional investigation[101] on 972 patients. Instead, Nakamura *et al*[102] did not find any association between the I148M mutation and the presence of steatosis or cirrhosis development in 260 Japanese patients with CHC; in this study, however, liver

Zampino *et al*[99]	166	Italy	Cross-sectional	Chronic hepatitis	Mean steatosis score GG: 1.94 ± 1.6, CG: 1.25 ± 1.2, CC: 1 ± 1.1, P < 0.05				

[1]GG + GC *vs* CC non-genotype 3; [2]Steatosis > 5%; [3]Rs2896019 GG + GT *vs* TT genotype 1; [4]Steatosis > 32%; [5]GG + GC *vs* CC donors; [6]Occurrence of Ishak staging ⩾ 3, acute cellular rejection, chronic rejection or fibrosing cholestatic hepatitis during a 620-d (IQR 317-975) follow-up; [7]226 patients; [8]GG+GC *vs* CC, United States diagnosis of steatosis and cirrhosis; [9]F3 or F4; [10]470 patients; [11]325 patients. SVR: Sustained viral response; HCC: Hepatocellular carcinoma.

steatosis was detected only by ultrasound. Interestingly, Dunn *et al*[103] found the I148M mutation to be independently associated with fibrosis progression and graft loss in a prospective study on 101 CHC patients who underwent liver transplantation.

An independent association between the I148M mutation and a poor response to IFN-based therapy was described by Valenti *et al*[97] in 470 patients with CHC; in the same paper these Authors described an association between this SNP and the development of hepatocellular carcinoma. An association between the I148M mutation and HCC development was found in a case-control study on 160 German patients with alcohol-related cirrhosis, but not in a group of 162 patients with HCV-related end-stage liver disease[104]. While confirming this association in alcoholic liver disease, Guyot *et al*[105] found no association between the rs738409 polymorphism and HCC occurrence or between this SNP and the SVR rate of IFN-based therapy in a prospective study on 253 patients with HCV-related cirrhosis. However, a recent meta-analysis including 2503 European patients with cirrhosis, particularly HCV - and alcohol-related, indicated that rs738409 exerts a marked influence on hepatocarcinogenesis[106].

Concluding on this point, further studies are needed to confirm the association between the I148M mutation and a poor response to IFN-based therapy and to establish the mechanisms relating to the role of PNAPL3 on the development of HCC.

ITPA polymorphisms and HCV infection

Ribavirin has made a strong contribution to the success of old and new combination treatments to eradicate HCV infection[107,108].

This drug, however, induces a dose-related hemolytic anemia that impairs the patients' quality of life and frequently entails a dosage reduction and lowered SVR rates[109-112]. This adverse reaction has been reported as more frequent during the administration of triple combination therapy with Peg-IFN, RBV and telaprevir or boceprevir[108,113].

Erythrocyte hemolysis is considered the main cause of RBV-induced anemia[114]. By reducing adenosine triphosphate (ATP) levels in human erythrocytes, RBV induces a guanosine triphosphate (GTP) depletion followed by the inhibition of the ATP-dependent oxidative metabolism, membrane damage and premature hemolysis of erythrocytes[115,116].

In patients with reduced ITPA activity, however, inosine triphosphate (ITP) accumulates in erythro-

cytes[117-120], replacing the GTP activity and producing adenosine monophosphate[121], thus avoiding the inhibition of the ATP-dependent oxidative metabolism and erythrocyte hemolysis. Therefore, RBV-induced anemia seems primarily to be due to the reduced levels of ATP in erythrocytes consequent to the effect of the drug on GTP[121], and resistance against RBV-related anemia is due to a reduced ITPA activity[115,116].

The genetic bases of these phenomena were first identified in 2010 by Fellay *et al*[29], who in a GWAS found a strong association between the single nucleotide polymorphism rs6051702 and the quantitative hemoglobin reduction at week 4 of Peg-IFN plus RBV treatment. The association was explained by 2 functional variants in the *ITPA* gene (encoding inosinetriphosphatase-ITPase) on chromosome 20: a missense variant in exon 2 (rs1127354, P32T) and a splice-altering single nucleotide polymorphism in intron 2 (rs7270101). The polymorphisms rs1127354 and rs7270101 were found to be associated with a hemoglobin reduction at week 4 of treatment in 304 genotype-1 CHC patients receiving Peg-IFN plus RBV, while the minor alleles of each variant protected against hemoglobin reduction; in particular, a 3g reduction in hemoglobin levels was a rare occurrence in 22 (2%) patients with a reduction in the ITPA activity of less than 30% and in 45% of 212 with normal enzyme activity[30]. These data were confirmed in other investigations both in HCV-genotype-1 patients[31,122-127] and in those with HCV-non-1 genotypes (Table 2)[116,128-132].

There are contrasting opinions on the impact of ITPA polymorphisms in patients treated with telaprevir-based triple therapy since some studies reported an impact of the ITPA polymorphism similar to that observed in patients receiving Peg-IFN plus RBV double therapy (Table 2)[133-135], whereas a recent study did not find ITPA deficiency useful to predict early anemia in patients with advanced fibrosis receiving telaprevir[135]. No information is so far available on the impact of ITPA polymorphisms in patients with CHC treated with a boceprevir-based triple therapy.

Polymorphisms influencing the vitamin D metabolism and HCV infection

Vitamin D is a steroid hormone exerting its primary role in bone mineral homeostasis. The main source of vitamin D comes from the synthesis of its inactive precursor 7-dehydrocholesterol in the skin during an ultraviolet-B radiation-dependent reaction, whereas only small amounts of vitamin D_2 and D_3 come from food. Vitamin D from both sources undergoes 25-hydroxylation by hepatic microsomal enzymes and, through a series of other enzymatic reactions, 1,25-dihydroxy-vitamin D_3 (calcitriol), the active form of vitamin D, is obtained. A vitamin D receptor (VDR) is expressed in several human cells. It binds to its ligand and plays the role of a transcription factor for numerous target genes. Consequently, vitamin D exerts its effect on several tissues.

An anti-inflammatory and anti-fibrotic role of vitamin D in chronic liver diseases has only recently been hypothesized, mostly on the basis of the observation that nearly two thirds of patients with chronic liver disease present low serum levels of vitamin D[136] associated with a high fibrosis score and low response to Peg-IFN-based therapy[137,138]. A case-control study on 110 patients with CHC showed a significant correlation between the CYP27B1-1260 promoter polymorphism rs10877012 and the SVR rate (Table 3)[139]. Falleti *et al*[140] found a significantly higher likelihood of response to antiviral treatment in patients with a higher "vitamin D pathway functional score", a genetic model they constructed considering for each patient the sum of every functional allele associated with the achievement of SVR, including the rs10877012 and another three polymorphisms, the rs7041 and rs4588 of the *GC* gene and the rs10741657 of CYP2R1. These Authors also demonstrated that the achievement of SVR with Peg-IFN plus RBV treatment in CHC patients with difficult-to-treat HCV genotypes is predicted both by the carriage of the GC-globulin WT isoform and by normal levels of serum vitamin D at the baseline[141]. Baur *et al*[142,143] demonstrated a correlation between the carriage of the *VDR* gene bAt (CCA) genotype, comprising three different polymorphisms of the *VDR* gene, and the SVR rate and cirrhosis development. These data were confirmed in another cross-sectional study, which also showed a relationship between another *VDR* gene polymorphism and the likelihood of response to therapy[144].

Concluding on this point, the studies mentioned above do not allow conclusions to be drawn at present, but they certainly suggest that the vitamin D-associated polymorphisms play an important role in the achievement of SVR with Peg-IFN based treatment in CHC patients.

Other polymorphisms and HCV infection

Several other polymorphisms have been investigated to ascertain their possible impact on the clinical presentation and natural history of CHC (Table 4). Huang *et al*[145] proposed a risk score based on 7 different SNPs that were highly predictive of the development of cirrhosis in two retrospective series of 420 and 154 Caucasian patients (a training and validation cohort, respectively). This score was demonstrated to be effective in these series of patients and in subsequent large prospective[146,147] and retrospective[148] studies carried out in patients with mild or moderate chronic hepatitis, human immunodeficiency virus (HIV)-HCV coinfected patients[149] and liver transplant recipients[150].

Interesting data also come from studies investigating the genes regulating the immune system. Yee *et al*[151] showed that patients with chronic hepatitis C carrying the IL-6 rs1800795 G allele have a reduced chance of achieving SVR when treated with Peg-IFN plus RBV. These data are in disagreement with those of a previous study[152], which, however, enrolled only HIV-HCV coinfected patients. This polymorphism was also associated with the higher degrees of liver necroin-

flammation[153] and fibrosis[154]. In addition, spontaneous and treatment-induced HCV viral clearance have been found to be associated with the rs2069707 G allele of the *IFN-γ* gene[155] and with KIR2DL3 and HLAC1 haplotypes[156,157].

More recently, an association between the polymorphism at codon 63 of the cannabinoid receptor 2 gene (*CB2*) and HCV infection was suggested[158,159]. This polymorphism leads to the substitution of glutamine, Gln (Q), with arginine, Arg (R), causing a different polarization state of the protein. The CB2 variants have been demonstrated to affect differently the ability of the CB2 receptor to exert its inhibitory function[160]. Specifically, *in-vitro* T lymphocytes from CB2-63 RR homozygotes showed an approximately two-fold reduction in the endocannabinoid-induced inhibition of proliferation compared to cells from CB2-63 QQ homozygotes[161]. In a cohort of 169 biopsy-proven CHC patients, the CB2-63 QQ variant was found to be independently associated with more extensive neuroinflammation[160], whereas in 253 patients with HCV chronic infection this variant was found to be independently associated with a persistently normal aminotransferase status identified by the Authors as the end-stage of the necroinflammatory activity[159]. Further investigations are needed to better define the role of the CB2 variants.

DISCUSSION

Several genetic polymorphisms seem to influence the outcome of CHC and the response to antiviral treatment, which allows individualized strategies to be devised for monitoring the course of the disease and for the choice of treatment. The recent introduction of second and third generation DAAs in Peg-IFN-based and IFN-free treatments have certainly reduced the clinical importance of these predictors, which, however, may still be useful with difficult-to-treat patients and in developing countries

where the cost of the new DAAs is at present a serious obstacle to their use.

COMMENTS

Background

Chronic hepatitis C (CHC) is a life-threatening disease since nearly a quarter of patients progress to liver cirrhosis and nearly 3% of hepatitis C virus (HCV) cirrhotic patients per year develop hepatocellular carcinoma.

Research frontiers

Genome-wide association studies have recently shown that some nucleotide polymorphisms may influence the clinical course and the response to antiviral treatment in patients with chronic hepatitis C.

Innovations and breakthroughs

Several studies associated the polymorphisms in the interleukin 28B (*IL28B*) gene on chromosome 19 (19q13.13) with a spontaneous viral clearance in acute hepatitis C and with the response to the pegylated interferon (Peg-IFN)-based treatments in CHC patients. The achievement of sustained virological response in CHC patients treated with Peg-IFN-based antiviral therapy has been also associated with the vitamin D-associated polymorphisms in some preliminary investigations. Other studies demonstrated that inosine triphosphate pyrophosphatase (ITPA) genetic variants protect HCV-genotype-1 CHC patients from ribavirin-induced anemia. Evidence of an association between a polymorphism in the patatin-like phospholipase domain (PNPLA3) with hepatic steatosis in CHC patients has been also given in recent studies. Several other polymorphisms have been investigated to assess their possible impact on the natural history and response to treatment in patients with CHC, but the results are preliminary and further confirmation is needed.

Applications

In this review article the authors focus on old and new host genetic factors influencing the outcome of CHC and the response to antiviral treatment to offer some guidance for individualized follow up and therapy in clinical practice.

Terminology

The *IL28B* gene region encodes for an endogenous antiviral cytokine interferon-λ3 involved in both the early stage of the host innate immune response to HCV infection and, by binding to a cellular class Ⅱ cytokine receptor complex, in the activation of interferon stimulating genes through the JAK-STAT pathway. The *PNPLA3* gene encodes for a 481 amino acid protein called adiponutrin, which belongs to the patatin-like phospholipase family and is mainly expressed in both human adipocytes and hepatocytes. The protein presents a sequence similar to that of adipose tissue triglyceride lipase, and has both triglyceride lipase and transcylase activity. In patients with reduced ITPA activity, inosine triphosphate accumulates in erythrocytes, replacing the GTP activity and producing adenosine monophosphate, thus avoiding the inhibition of the ATP-dependent oxidative metabolism and erythrocyte hemolysis by ribavirin. An anti-inflammatory and anti-fibrotic role of vitamin D in chronic liver diseases has been hypothesized only recently.

Peer-review

Good work, which comprehensive summary of genetic polymorphisms that effect on the CHC.

Abstract

AIM: To investigate the association between sports hernias and femoroacetabular impingement (FAI) in athletes.

METHODS: PubMed, MEDLINE, CINAHL, Embase, Cochrane Controlled Trials Register, and Google Scholar databases were electronically searched for articles relating to sports hernia, athletic pubalgia, groin pain, long-standing adductor-related groin pain, Gilmore groin, adductor pain syndrome, and FAI. The initial search identified 196 studies, of which only articles reporting on the association of sports hernia and FAI or laparoscopic treatment of sports hernia were selected for systematic review. Finally, 24 studies were reviewed to evaluate the prevalence of FAI in cases of sports hernia and examine treatment outcomes and evidence for a common underlying pathogenic mechanism.

RESULTS: FAI has been reported in as few as 12% to as high as 94% of patients with sports hernias, athletic pubalgia or adductor-related groin pain. Cam-type impingement is proposed to lead to increased symphyseal motion with overload on the surrounding extra-articular structures and muscle, which can result in the development of sports hernia and athletic pubalgia. Laparoscopic repair of sports hernias, *via* either the transabdominal preperitoneal or extraperitoneal approach, has a high success rate and earlier recovery of full sports activity compared to open surgery or conservative treatment. For patients with FAI and sports hernia, the surgical management of both pathologies is more effective than sports pubalgia treatment or hip arthroscopy alone (89% *vs* 33% of cases). As sports hernias and FAI are typically treated by general and orthopedic surgeons, respectively, a multidisciplinary approach for diagnosis and treatment is recommended for optimal treatment of patients with these injuries.

CONCLUSION: The restriction in range of motion due to FAI likely contributes to sports hernias; therefore, surgical treatment of both pathologies represents an optimal therapy.

Key words: Athletic pubalgia; Groin pain; Laparoscopic treatment; Femoroacetabular impingement; Sports hernia

Core tip: Sports hernia and femoroacetabular impingement (FAI) are two pathologies frequently reported in athletes, which are independently treated by general surgeons and orthopedists, respectively. An association between these two entities has recently been recognized, and this review was conducted to define the prevalence of FAI in patients with sports hernia and evaluate the proposed pathogenic mechanism connecting them. Although the range of terms used to describe groin pain throughout the literature is varied, there is a high prevalence of FAI with sports hernias, for which the treatment of both pathologies is optimal.

Munegato D, Bigoni M, Gridavilla G, Olmi S, Cesana G, Zatti G. Sports hernia and femoroacetabular impingement in athletes: A systematic review. *World J Clin Cases* 2015; 3(9): 823-830 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/823.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.823

INTRODUCTION

Groin injuries are a common occurrence in elite-level athletes, representing up to 6% of all athletic injuries[1-5]. These injuries occur as a result of running, kicking, cutting movements, or explosive turns and changes in direction, and thus impact 10%-28% of male soccer players[6-8]. One type of groin injury, called sports hernia, has been reported in 50% of athletes with groin pain lasting longer than 8 wk[9]. The most common operative finding in sports hernia is deficiency of the posterior wall of the inguinal canal[10-12], which is a consequence of underlying conjoint tendon dysfunction. Thus, demonstration of a dynamic bulge of the posterior wall on abdominal straining is a criterion for diagnosis of sports hernia. Real-time ultrasound for dynamic evaluation of the inguinal canal is currently the preferred diagnostic technique and provides good assessment of the conjoint tendon[13-15]. A bulging inguinal wall can also be imaged by dynamic computed tomography[16], though magnetic resonance imaging is more useful for detecting musculotendinous disease, osteitis pubis, and hip pathologies.

Risk factors for sports hernia include muscle imbalance[17,18] and significant limb length discrepancy (> 5 mm)[19]. In addition, labral tears, as well as decreased external and internal rotation of the hip joint may be related[20], which have been detected in pre-season soccer players[21-24], Gaelic football athletes[25], professional Australian Football League players[24], and athletes with chronic groin injury or osteitis pubis[26]. Garvey *et al*[13] found that half of the cases of sports hernia were associated with other conditions, including rectus abdominis wasting, osteitis pubis, conjoint tendinopathy, osteoarthritis, and neuralgia. Indeed, multiple co-existing pathologies have been reported in 27%-95% of cases of sports hernia[9,27-29], including adductor tendinosis[30] and adductor pain associated with either lower abdominal or inguinal pain[13]. Feeley *et al*[31] described the sports hip triad (labral tear, adductor strain, and rectus strain) as a common injury pattern in the elite athlete.

Femoroacetabular impingement (FAI) is a hip pathology where the bones of the hip are abnormally shaped. FAI reportedly occurs in a very high percentage of elite-level athletes examined for chronic groin and/or hip pain[32-34]. This suggests that the presence of FAI may be a predisposing factor for developing groin-related sports injuries or indicate a common underlying pathogenic mechanism. To more comprehensively investigate this, a systematic review was performed. Specifically, the prevalence of the concomitant presentation of FAI and sports hernias and their treatments were assessed.

MATERIALS AND METHODS

PubMed, MEDLINE, CINAHL, Embase, Cochrane Controlled Trials Register, and Google Scholar databases were electronically searched using the following search terms: sports hernia, athletic pubalgia, groin pain, long-standing adductor-related groin pain, Gilmore groin, adductor pain syndrome, and FAI. After reading the titles and abstracts, a total of 196 studies, published before August 2014, were identified as potentially relevant. No formal exclusion criteria were applied but, from these studies, only articles concerning the association of sports hernia and FAI or laparoscopic treatment of sports hernia were selected. Finally, 24 studies were included in this review. The terms athletic pubalgia, long-standing adductor-related groin pain, adductor strain, and adductor pain syndrome were considered synonymous with sports hernia because conjoint and adductor tendinopathies and nerve entrapment are frequently associated with sports hernias and similarly result from pelvic instability; this pattern is frequently identified as "groin disruption injury"[14].

RESULTS

Prevalence

The results of the systematic review demonstrate that the prevalence of FAI and the associated restricted internal rotation varies widely among cases of athletic-related groin pain (Table 1)[13,32,34-38]. Whereas Meyers *et al*[35] found an overlap of athletic pubalgia and hip

Table 1 Prevalence of femoroacetabular impingement in patients with sports hernia and groin disruption

Table 2 Laparoscopic mesh repair treatment for sports hernias

Ref.	Treatment	Results	Recurrence
Diaco *et al*[42]	Preperitoneal approach (n = 96)	Return to active participation within 3-6 wk in 92/96 patients	-
Edelman *et al*[43]	Preperitoneal approach (n = 10)	Return to full activity within 4 wk in 9/10 patients	None
Ingoldby[44]	Laparoscopic *vs* conventional (n = 14 each)	Laparoscopic treatment superior: return to training in 4 wk (13/14 *vs* 9/14), resume full contact (3 wk *vs* 5 wk; $P < 0.05$)	Conventional: hernia, n = 1 after 22 mo; laparoscopic: pain, n = 1 after 5 mo
Susmallian *et al*[10]	Preperitoneal approach (n = 35)	Return to full activity in 34/35 patients	-
Srinivasan *et al*[45]	Extraperitoneal approach (n = 15)	Return to full activity within 4 wk in 13/15 patients	None
Genitsaris *et al*[46]	Transabdominal preperitoneal approach (n = 131)	100% of patients returned to full activity within 2-3 wk	Pain, n = 4; hernia, n = 1 after 7 yr
Paajanen *et al*[47]	Extraperitoneal approach *vs* conventional treatment (n = 30 each)	Laparoscopic treatment superior: return to full activity within 3 mo (27/30 *vs* 8/30)	-
Paajanen *et al*[48]	Extraperitoneal approach (n = 41)	Return to full activity within 4 wk in 39/41 patients	-
van Veen *et al*[49]	Extraperitoneal approach (n = 55)	100% of patients returned to full activity within 3 mo	-
Kluin *et al*[4]	Preperitoneal approach (n = 17)	Return to full activity within 3 mo in 13/17 patients	Minor symptoms, n = 2 after 1 yr
Ziprin *et al*[50]	Transabdominal preperitoneal approach (n = 17)	Return to full activity in 16/17 patients within a median of 42 d	Mild pain, n = 5

pathology in 27% of hockey players, Larson *et al*[39] reported that 90% of collegiate football players with hip and groin pain participating in a National Football League combine showed radiologic signs of cam- or pincer-type FAI. FAI was also found in patients with adductor tendinopathies, and Sansone *et al*[37] reported that, although most (75%) patients were satisfied with the results of tenotomy, the prevalence of FAI was greater in patients who were not satisfied when assessed after a median follow-up of six years.

Pathophysiology

Verrall *et al*[24] postulated that chronic groin injuries result from increased loading and mechanical stress on the pubis symphysis and surrounding structures caused by reduced hip range of motion. Furthermore, Larson *et al*[39,40] hypothesized that the decreased hip range of motion from an underlying FAI promotes compensatory extra-articular patterns, which subsequently lead to osteitis pubis and athletic pubalgia. Birmingham *et al*[41] analyzed the three-dimensional motion of the pubic symphysis in six fresh-frozen human cadaveric pelvises to compare native and simulated cam lesion hips. They found that rotational motion was significantly increased by cam-type lesions due to the repetitive loading of the symphysis, which is one possible precursor to athletic pubalgia.

Treatment

Laparoscopic mesh repair for the treatment of sports hernias can be performed using either a transabdominal preperitoneal or total extraperitoneal approach. Most studies demonstrate a > 90% success rate with these treatments, with return to full activities within 1-3 mo (Table 2)[4,10,42-50].

Only one case report and one retrospective case series reported on combined treatment of FAI and sports hernia. Matsuda[51] reported a case report regarding an endoscopic pubic symphysectomy in a case with bilateral FAI and recalcitrant osteitis pubis with high patient satisfaction, decreased pain, improved function, and resolution of the classic waddling gait at the 12-mo follow-up. In a retrospective study of 31 patients, Larson *et al*[40] found that surgical management of both pathologies leads to a greater rate of return to full sporting activities compared with sports pubalgia surgery or hip arthroscopy alone after a mean follow-up of 29 mo (89% *vs* 33%). In this study, whether the surgeries were performed concurrently, hip arthroscopy was performed first to avoid excessive stress placed on the pubalgia repair during positioning and traction for arthroscopy. There were no differences for return to sports or

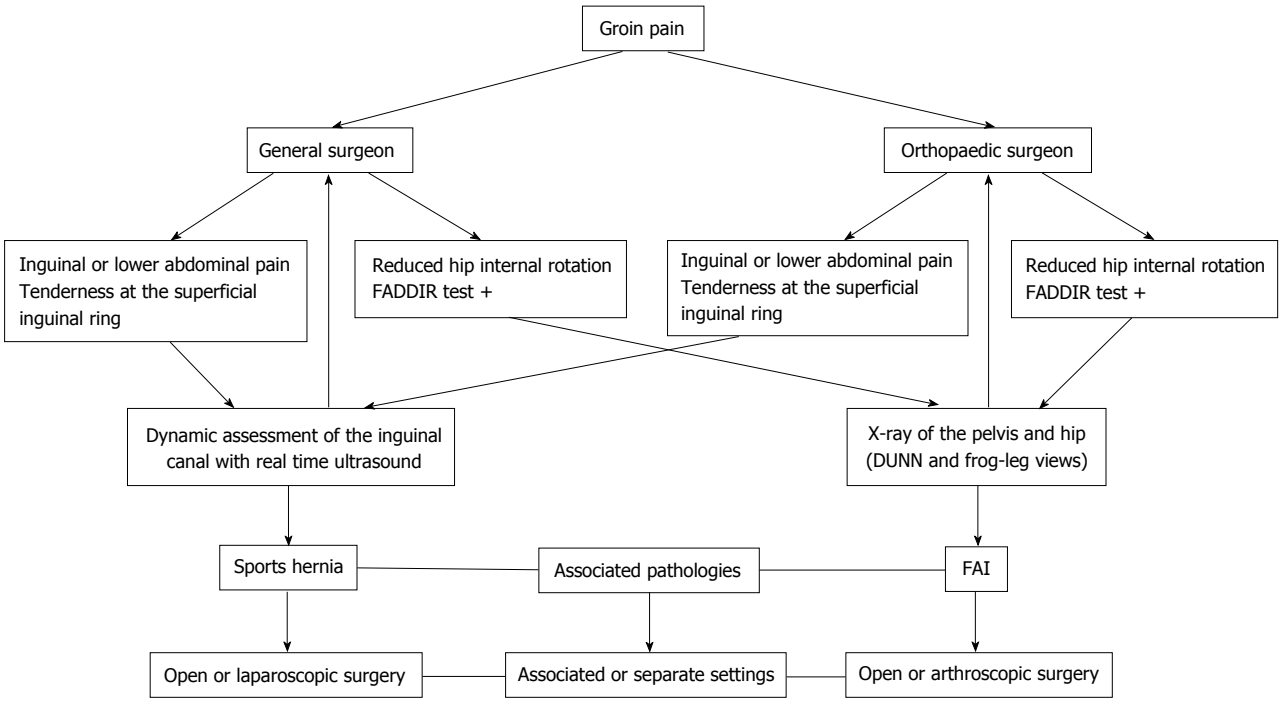

Figure 1 Diagram showing the proposed multidisciplinary approach. FADDIR: Flexion-adduction-internal rotation; FAI: Femoroacetabular impingement.

outcomes scoring for concurrent *vs* separate setting hip arthroscopy and sports hernia surgery. However, hip arthroscopy alone was sufficient to resolve sports pubalgia symptoms in four patients. It was postulated that the improved hip range of motion and function after FAI correction reduced the stress on extra-articular pelvic structures, thus alleviating the symptoms.

The presence of multiple pathologies does not dictate treatment outcome. The importance of treating both pathologies to obtain good and stable results during time is confirmed in a study of Hölmich *et al*[52], which found that active treatment of adductor-related groin pain can be effective even in the presence of morphologic changes to the hip joint. However, clinical outcome decreased over time in patients with angles > 55. A multidisciplinary approach is recommended, such as one involving orthopedic and general surgeons, to detect the presence of both pathologies in order to provide optimal treatment (Figure 1).

DISCUSSION

A wide variety of terms are used throughout the literature to describe groin pain or pubalgia, making it difficult to obtain an accurate assessment of the association between sports hernia and FAI. However, the results of this review indicate that the conditions commonly co-occur, and treatment of the underlying morphologic abnormalities can impact the sports-related symptoms.

The majority of the patients with sports hernias complain of unilateral inguinal pain or lower abdominal pain, often radiating to the pubic tubercle and the inner thigh or across the midline. Although the pain can occur after a specific event, more often the onset is insidious with exacerbation of the symptoms by activity that persists for a day or two and is temporarily relived with rest[14,53,54]. There may be pain and tenderness at the superficial inguinal ring, but without a visible or palpable lump indicative of a classical inguinal hernia. In patients with FAI, the groin pain is accompanied with pain at the greater trochanter, deep posterior buttock, and sacroiliac joint[55]. Whereas 50% of these patients reported an insidious onset, approximately 26% reported acute development of symptoms in the absence of a traumatic event. In the early stage, the pain is exacerbated with prolonged sitting or walking or with athletic activity; however, the pain becomes more constant with the progression of articular damage and osteoarthritic changes.

Upon physical examination, patients with FAI demonstrate pain with combined flexion, adduction, and internal rotation of the hip during the anterior impingement test[55-57], as well as during other tests of joint rotation[58]. These patients typically show restricted internal rotation and/or flexion in the hip range of motion, and restricted abduction or external rotation is also sometimes observed. Diagnosis of FAI is confirmed from radiographic exams showing an increased alpha-angle and/or signs of overcoverage or retroversion of the acetabulum (Figure 2)[56].

The additional stress from restricted rotation can lead to weakening or tearing of the transversalis fascia and surrounding tissues over time, resulting in tendon enthesitis of the adductor longus and/or abdominal muscles and groin pain[1,59,60]. This injury affects the external oblique aponeurosis, which can cause irritation of ilioinguinal or iliohypogastric nerves, as well as the

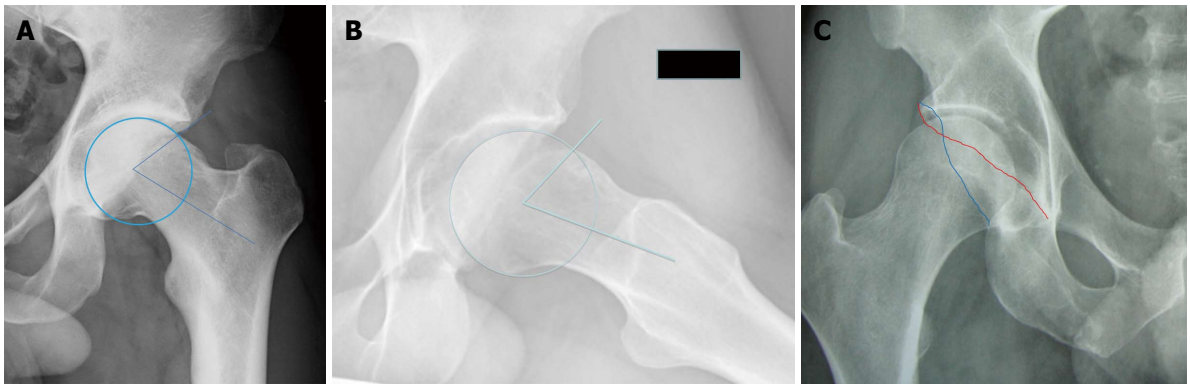

Figure 2 Radiographic findings of femoroacetabular impingement. X-ray scans of a cam-type femoroacetabular impingement (FAI) showing increased alpha-angles with bumps in the A: Superior head-neck junction; B: Anterior head-neck junction (DUNN-view 45°); C: Superior focal acetabular retroversion is observed in pincer-type FAI when the anterior wall (red line) is lateral to the posterior wall (blue line), referred to as the crossover sign.

conjoint tendon and inguinal ligament, resulting in weakness (deficiency) of the lower abdominal wall and occult hernias. Athletes performing rapid acceleration and deceleration movements and repetitive, high-speed twisting and cutting motions are especially vulnerable to these injuries[1,61].

Conservative treatment of sports hernias or FAI can be effective in a variable percentage of patients[62]. However, surgical treatment results in higher success rates, as demonstrated by Paajanen *et al*[48]. Moreover, Polglase *et al*[63] conducted a randomized clinical trial and found that appropriate repair of the posterior wall of the inguinal canal is superior to nonoperative management in athletes, effectively curing 60% of patients and providing improvement to an additional 20%. In a randomized study by Ekstrand *et al*[64], surgical treatment significantly reduced symptoms at six months compared to conservative treatment. For patients with FAI and sports hernias, surgical treatment of both pathologies appears to be the best option[40].

The surgical techniques performed to treat sports hernias are classified into three categories: open sutured repair, open mesh repair, and laparoscopic mesh repair by either transabdominal preperitoneal or extraperitoneal approaches. Sutured repairs are the most commonly performed operations for athletic pubalgia[65-68], with successful return to sport activities in 68%-100% of cases[3,5,30,60,67,69-74] and a recovery time ranging from to four weeks to three months[67,69,71,73,74]. The open anterior mesh repair technique is analogous to the Lichtenstein method of inguinal repair and is designed to reconstruct the posterior inguinal floor in a tension-free fashion. The reported success rate with this method is 77%-100%[75-79], allowing for a return to full activities within 3-4 mo[76,79]. Open or arthroscopic treatment has also been successful for treatment of FAI in athletic patients[80-83]. In addition, Dojčinović *et al*[30] used a shouldice technique and an ilioinguinal nerve neurolysis and resection of the genital branch of the genitofemoral nerve in a patient with untreated FAI.

The results of the present review indicate that newer laparoscopic techniques are as effective or better for successfully treating sports injuries and allowing patients to return to full activities more quickly. Compared to open surgeries, the recovery time was on the order of weeks, rather than months, and with rare incidences of recurrence. The results also suggest that athletes undergoing extraperitoneal repair do well in the postoperative period, even when a macroscopic abnormality is not detected, which is in keeping with the idea that strengthening the posterior wall relieves symptoms. There were few instances of recurrence with these techniques, however, most reports did not include a long-term follow-up.

The wide variety of terms used throughout the literature to describe groin pain and injuries complicates evaluation of the association between sports hernias and FAI. For the purposes of the present review, the terms sports hernia, athletic pubalgia, long-standing adductor-related groin pain, adductor strain, and adductor pain syndrome were considered as synonymous. However, groin pain is a common complaint of athletes with sports hernias and FAI, indicating that they may share an underlying pathogenic mechanism, such as the placement of excessive rotational stress on the pubic symphysis. Thus, surgical repair of both pathologies, likely provides the optimal treatment for elite-level athletes with these injuries.

COMMENTS

Background

Pubalgia and groin pain are common in athletes, and can be caused by sports hernias and femoroacetabular impingement (FAI). In the past, these were considered isolated pathologies and treated by a general or orthopedic surgeon. However, osteoarthritis and reduced hip range of movement have increasingly been observed in athletes with sports hernias, indicating that these pathologies are related.

Research frontiers

Recently, alterations in the pelvic biomechanics due to a FAI have been described. In addition, a case series concerning the combined treatment of sports hernia and FAI was published. However, the association between FAI and sports-related groin injuries is not well defined. Therefore, the objective of this study was to systematically review articles reporting on the incidence, pathophysiology, and treatment of these two pathologies.

Innovations and breakthroughs

Recent studies report a variable association between sports hernia and FAI, ranging from 12% to 94%. To explain the association, it was proposed that increased rotational stress on the symphysis pubis and the surrounding structures from FAI leads to weakness of the posterior inguinal wall, which can result in sports hernia. The optimal treatment of athletes with sports hernias may rely on a multidisciplinary approach, involving repair of both underlying pathologies to ensure a rapid and complete return to sport activities.

Applications

This review highlights the relationship between sports hernias and FAI in athletes with groin pain, and will be useful to promote the knowledge of these pathologies for both orthopedic and general surgeons. A multidisciplinary approach is proposed to optimize the diagnosis and treatment of affected patients.

Terminology

A sports hernia is defined as a dynamic bulge of the posterior wall upon abdominal straining that results from conjoint tendon dysfunction and posterior wall weakness. FAI is a hip pathology where the bones of the hip are abnormally shaped resulting in restricted rang of motion. The asphericity of the femoral head with a bump in the head-neck junction defines the cam-type impingement, whereas a deepened or retroverted acetabulum defines the pincer-type impingement. These bone abnormalities result in repetitive collision between the femoral neck and the acetabular rim, which damages the labrum and surrounding cartilage.

Peer-review

This review describes recent reports concerning FAI in cases of sports hernia. The co-occurrence of the two conditions indicates a common underlying pathology. This article provides a review of studies using laparoscopic techniques to repair sports hernias and indicates that concurrent treatment of FAI is optimal for earlier recovery and return to full activity.

Abstract

Coumadin ridge is a normal anatomic variant that is occasionally found in the left atrium. It can present as a linear or nodular mass which can undulate with cardiac motion and if particularly prominent, can easily be mistaken for a tumor or thrombus. Careful evaluation and consideration of the common variants discussed in this review can help limit misdiagnosis, as well as unnecessary workup and treatment. We present a case of coumadin ridge that was found on a patient using two-dimensional transthoracic echocardiography.

Key words: Coumadin ridge; Pseudotumor; Warfarin ridge; Left atrial pseudotumor

Core tip: As we improve imaging modalities, normal anatomic variants of the heart are coming to our attention more frequently. Coumadin ridge is an example of such a variant that is occasionally found on various imaging modalities of the heart, including transthoracic echocardiography, transesophageal echocardiography, cardiac magnetic imaging, among others. Coumadin ridge is a term that refers to a part of the left atrium that lies between the left atrial appendage and the left superior pulmonary vein. Since this is a not a common finding, and due to its shape and location, it has the potential of being misdiagnosed as a left atrial myoxma or thrombus.

Coumadin ridge: An incidental finding of a left atrial pseudotumor on transthoracic echocardiography. *World J Clin Cases* 2015; 3(9): 831-834 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/831.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.831

INTRODUCTION

As imaging modalities continue to improve in resolution and clarity, several normal anatomic variants of the heart have come to our attention. One of these normal variants is the coumadin ridge, which is found in the left atrium between the left atrial appendage and the left superior pulmonary vein. Although the coumadin ridge is a normal anatomic finding, its shape and location can cause it to be mistaken for a tumor or thrombus, leading to unnecessary, risky, and costly treatments for patients. In this case report, we present a patient in whom a coumadin ridge was found using two-dimensional transthoracic echocardiography with color Doppler.

CASE REPORT

A 58-year-old African American woman with hypertension, morbid obesity, and no remarkable history of heart disease presented to general medicine clinic with complaints of worsening exertional dyspnea with abdominal and lower extremity swelling. She denied chest pain, palpitation, orthopnea, or paroxysmal nocturnal dyspnea. Her medications included aspirin 81 mg, amlodipine 10 mg, hydrochlorothiazide 25 mg, and losartan 50 mg. She weighed 114 kg with a body mass index of 41 kg/m^2. Physical examination revealed a blood pressure of 170/88 mmHg, pulse of 72 bpm, and respiration rate of 18 breaths per minute. Lungs were clear to auscultation. There was no jugular venous distention. Normal heart sounds, no S3 or S4, no murmurs, and no rubs. No hepatomegaly or ascites was present. There was 1+ pitting edema over the dorsum of each foot. An electrocardiography showed sinus rhythm with a heart rate of 63 and left atrial abnormality (Figure 1). Given long-standing history of hypertension, worsening exertional dyspnea and lower extremity edema, a transthoracic echocardiography was performed to evaluate her cardiac anatomy and function, which showed prominent coumadin ridge in the left atrium, mild concentric left ventricular hypertrophy, grade Ⅱ left ventricular diastolic dysfunction with pseudonormalization pattern, normal valves and normal biventricular size and systolic function (Figures 2 and 3). All other workup was negative in assessing the etiology of the patient's edema and worsening exertional dyspnea, including a complete metabolic panel, thyroid stimulating hormone, pulmonary function tests, and urine analysis. The patient's serum albumin level was also within normal limits. The patient's elevated blood pressure was improved by up-titrating her losartan to 100 mg. The patient's edema improved with lifestyle changes such as keeping her feet elevated. Her worsening exertional dyspnea was attributed to her conditioning, and physical therapy was recommended.

DISCUSSION

Over the past few decades, echocardiography has become an increasingly common tool to assess cardiac anatomy and function. As imaging modalities continue to improve in resolution and clarity, we are more likely to come across normal anatomic variants of the heart. Some of these normal variants include the eustachian valve, chiari network, and crista terminalis of the right atrium, lipomatous hypertrophy of the interatrial septum, interatrial aneurysms, pectinate muscles of the right and left atriums, transverse sinus of the pericardium, moderator band of the right ventricle, Lambl's excrescence of the aortic valve, and coumadin ridge of the left atrium[1].

The coumadin ridge is a prominent, muscular ridge of tissue that lies in the left atrium in between the left superior pulmonary vein and the left atrial appendage[2]. It may often appear to be attached to the roof of the left atrial appendage, with a rounded end extending into the left atrium[2]. Due to this rounded end, the coumadin ridge is often referred to as a "Q-tip sign" on echocardiography[2]. It is important to keep in mind that it may not always appear rounded. When viewing it in the parasternal long axis view, it may appear as a linear band within the left atrium (LA)[2]. Also, when several cross sections of heart specimens were looked at along their narrowest point, 75% of the samples were shown to be round, 15% flat, and 10% pointed[3].

In our case, we used two-dimensional transthoracic echocardiography to show the coumadin ridge in its rounded and flattened shape. Due to its rounded edge, the coumadin ridge has often been mistaken for a thrombus, thereby, resulting in unnecessary anticoagulation and hence the name, Coumadin ridge. It may also be mistaken for a myxoma, leading to inappropriate surgeries[3,4]. Correct identification of these variants on cardiac imaging is crucial and will help prevent unnecessary workup and treatment. These inappropriate treatments can have a devastating impact on patients' outcomes, raise healthcare spending, and may often times result in legal repercussions for healthcare providers[4]. Knowledge of its location and features on various imaging modalities is critical in making the correct diagnosis.

Figure 2 shows the patient's coumadin ridge on an apical transthoracic echocardiography view, while Figure 3 shows it on an apical four-chamber transthoracic echocardiography view. In both of these views, the echogenicity of the ridge is similar to the surrounding cardiac tissues, suggesting this is a normal structure of the heart and not a thrombus or myxoma. Its location in the left atrium and its shape are also consistent with other reported cases. In both of the apical transthoracic echocardiography views, the coumadin ridge can be seen as a rounded "Q-tip" shape.

Two-dimensional transthoracic echocardiography can provide adequate clarity of the coumadin ridge. Additionally, fast spin echocardiography techniques with contrast can further help to clarify the diagnosis[5]. If coumadin ridge is seen using transthoracic echocardiography and question still remains about the

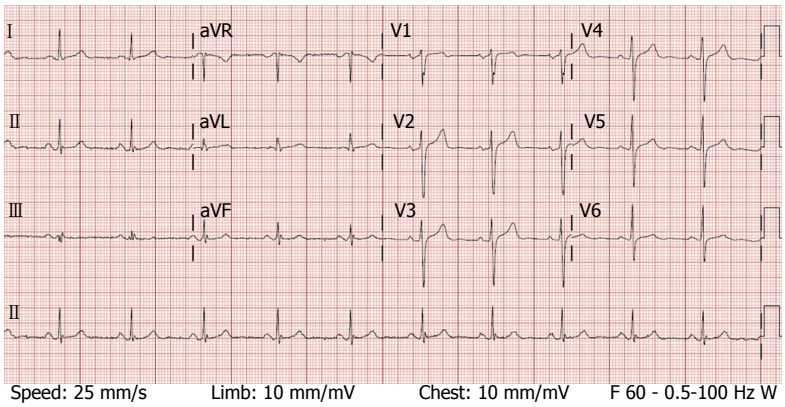

Figure 1 Electrocardiography showed sinus rhythm with a heart rate of 63 and left atrial abnormality.

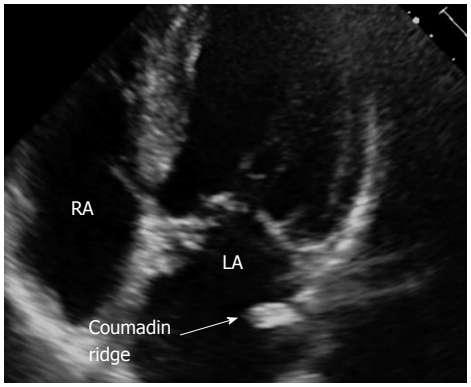

Figure 2 Apical transthoracic echocardiography view of coumadin ridge in the left atrium. RA: Right atrium; LA: Left atrium.

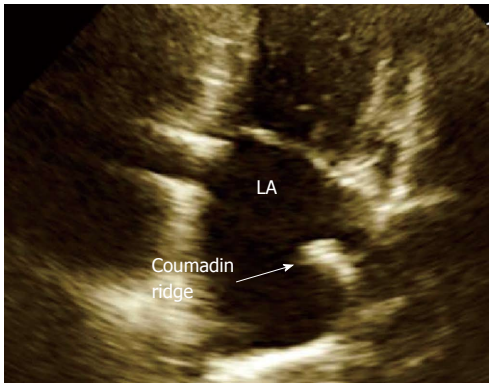

Figure 3 Apical four-chamber transthoracic echocardiography view of coumadin ridge in the left atrium. LA: Left atrium.

diagnosis, full volume three-dimensional transthoracic echocardiography with color Doppler can also provide additional clarity of the surrounding structures[2]. In other cases, transesophageal echocardiography may be needed, as the coumadin ridge is best seen using midesophageal two-chamber view[6]. In cases where it is difficult differentiating coumadin ridge from a thrombus or tumor, cardiac magnetic resonance or computed tomography may help to provide clarity to the diagnosis[4,5]. On both T1 and T2-weighted imaging, the coumadin ridge should have the same signal strength as adjacent cardiac tissue[5]. In addition, late gadolinium enhancement cardiac magnetic resonance may assist in clarifying the diagnosis; the coumadin ridge is unlikely to exhibit late enhancement[5]. Thrombus, however, will typically have low signal-strength surrounded by structures with higher signal strength on late gadolinium enhancement[5].

The usual location of the coumadin ridge is between the left superior pulmonary vein and the left atrial appendage. Along with its location, the lack of mobility and its unique linear structure with a rounded tip help differentiate this normal anatomic variant from other abnormal masses[1,6]. However, if the mass is not imaged correctly, it may appear as a free-floating structure in the left atrium or may even appear to undulate with cardiac motion (LA)[1,5]. In addition, there are a few features that help distinguish intracardiac thrombi from a coumadin ridge. Thrombi will typically have different echogenicity from adjacent tissue. Also, thrombi will have mobility with underlying tissue[1]. Thrombi are often seen in patients with atrial fibrillation, and are much less likely in patients with sinus rhythm[1]. The gold standard in assessing these thrombi is with transesophageal echocardiography using color flow and pulse wave Doppler[1]. Color flow Doppler will help in assessing if there is a low-flow risk for thrombus, which occurs when peak velocity is less than 40 cm/s[1].

Coumadin ridge may also be misinterpreted for a myoxma of the left atrium. Myxoma is the most common benign tumor in adults, and is found in the left atrium 75% of the time[1]. It is typically located on the interatrial septum and has a stalk attached to the fossa ovalis[1]. It has a smooth surface with homogeneous consistency, and can grow very large in size[1]. Midesophageal four-chamber view gives the best indication of the size and location of left atrial myxomas[1].

While there is concern that the coumadin ridge may be misinterpreted as a tumor or thrombus, one should also be careful not to overlook lesions that may be near or attached to the coumadin ridge, as there have been cases of myxomas and fibroelastomas attached to the

tip of the coumadin ridge[7]. These abnormalities can be differentiated on imaging from the coumadin ridge by their different sizes, shapes, echogenic features, and mobility[7]. Although these cases are not common, careful attention needs to be given to rule out other pathology when the diagnosis is not immediately clear. Just like with any study, it is important to evaluate the findings from imaging in context with the patient's clinical evaluation.

As we continue to see more cases of coumadin ridge, we will likely arrive at a better understanding of the implications of this anatomic variant. One such example is its value in patients with atrial fibrillation, where coumadin ridge may serve as a site for catheterization[8]. There are also implications of using the coumadin ridge as a site to stabilize the catheter while ablating adjacent areas in the left atrium[9].

In conclusion, coumadin ridge is a normal variant of the left atrium. We presented a case in which a prominent ridge was found on two-dimensional transthoracic echocardiography. Awareness of its typical location and features on various image modalities are crucial to avoid unnecessary interventions which potentially put patients through unnecessary and risky treatments and surgeries.

COMMENTS

Case characteristics

A 58-year-old African American woman with hypertension, morbid obesity, and no remarkable history of heart disease, presented to general medicine clinic with complaints of worsening exertional dyspnea with abdominal and lower extremity swelling.

Clinical diagnosis

Lungs were clear to auscultation. Normal heart sounds, no S3 or S4, no murmurs, and no rubs. No hepatomegaly or extremity edema.

Imaging diagnosis

Transthoracic echocardiography showed prominent coumadin ridge in the left atrium.

Differential diagnosis

Coumadin ridge, left atrial pseudotumor.

Treatment

Coumadin ridge is a normal variant of the left atrium, which requires no additional intervention.

Related reports

Coumadin ridge may present as a linear or nodular mass, which can undulate with cardiac motion and can easily be mistaken for a tumor or a thrombus.

Experiences and lessons

Awareness of the location and imaging features of coumadin ridge will help prevent misdiagnosis and unnecessary workup.

Peer-review

It is a very interesting, well written paper.

Abstract

The end-stage renal disease population poses a challenge for obtaining venous access required for life-saving invasive cardiac procedures. In this case report, we describe an adult patient with end-stage renal disease in whom the hepatic vein was the only available access to implant a single-lead permanent cardiac pacemaker. A 63-year-old male with end-stage renal disease on maintenance hemodialysis and permanent atrial fibrillation/atrial flutter presented with symptomatic bradycardia. Imaging studies revealed all traditional central venous access sites to be occluded/non-accessible. With the assistance of vascular interventional radiology, a trans-hepatic venous catheter was placed. This was then used to place a right ventricular pacing lead with close attention to numerous technical aspects. The procedure was completed successfully with placement of a single-lead permanent cardiac pacemaker.

Key words: Trans-hepatic venous access; Permanent cardiac pacemaker; End-stage renal disease

Core tip: End-stage renal disease patients pose a great challenge to establish central venous access. In situations when life-saving cardiac procedures are required in such patients, the clinician must use non-traditional venous access sites to perform these procedures. In our case report, we illustrate the novel

use of the trans-hepatic venous access route to implant a single-lead permanent cardiac pacemaker in a patient with bradycardia and hypotension. Additionally, we describe the technical challenges associated with this procedure.

Transhepatic venous approach to permanent pacemaker placement in a patient with limited central venous access. *World J Clin Cases* 2015; 3(9): 835-837 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/835.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.835

INTRODUCTION

The end-stage renal disease population poses a challenge for obtaining venous access required for invasive cardiac procedures due to placement of multiple arteriovenous fistulas for hemodialysis access or venous thrombus formation. The left subclavian vein is the preferred venous access for implantation of a pacing lead, but in patients with limited access alternative approaches include the right subclavian vein[1] and iliac veins[2]. In this case report, we describe an adult patient with end-stage renal disease in whom the hepatic vein was the only available access to implant a single-lead permanent cardiac pacemaker.

CASE REPORT

A 63-year-old African American male with end-stage renal disease on maintenance hemodialysis for 10 years and permanent atrial fibrillation/atrial flutter presented with symptoms of bradycardia including lightheadedness and dizziness. Ventricular rate was between 30 to 40 beats per minute. Hypotension was noted during dialysis sessions with a lack of positive dromotropic response due to atrioventricular node dysfunction. Non-functioning arteriovenous fistulas were present in the left upper and left lower extremities. A right lower extremity arteriovenous fistula was being used for hemodialysis access. Contrast venography of the right chest revealed an occluded right innominate vein (Figure 1A). Vascular interventional radiology placed a 6 French/45 cm Berenstein catheter (Boston Scientific, Inc., Marlborough, MA, United States) *via* the right peripheral hepatic vein terminating in the right atrium (RA). In the cardiac electrophysiology lab this catheter was exchanged over a 0.81 mm wire with placement of a 7 French/25 cm peel away introducer sheath into the RA, Figure 1B. The right ventricular pacing electrode with a soft curved (hockey stick curve) stylet was advanced through the sheath into the right ventricular apex. The stylet was withdrawn and the lead was advanced to provide redundancy in the RA. Sensing and pacing threshold parameters were optimal. The suture sleeve was advanced and 2 sutures were applied around the suture sleeve incorporating the indwelling muscle tissue. A subcutaneous pocket was made at the insertion point of the pacing lead. The procedure was successfully completed with no complications. A final fluoroscopic image is shown in Figure 1C.

DISCUSSION

Our main challenge was to implant a pacing lead in a symptomatic patient with no central venous access in the right and left upper extremities or right and left lower extremities. The trans-hepatic approach has been used in a variety of clinical situations where traditional central access was not possible, such as exhausted hemodialysis options[3]. Current literature states complication rates are < 5% and include line sepsis, catheter migration, thrombosis, and bleeding[4]. However, as the patient population described is so unique, the incidence rate of patients with no central venous access requiring trans-hepatic access is unknown.

One limitation of this approach is the technical aspect of inserting the lead into the right ventricle *via* the inferior vena cava. Additionally, the pacing lead traverses the substance of the liver, and therefore is subject to respirophasic diaphragmatic excursions potentially leading to loss of redundancy and dislodgement. Consequently, it is important to provide more than the usual redundancy in the RA to minimize dislodgement of the lead (Figure 1D).

The trans-hepatic venous approach is feasible for a single-lead permanent pacemaker implantation when all other central venous access options are exhausted.

COMMENTS

Case characteristics

A 63-year-old African American male with a history of end-stage renal disease on renal replacement therapy and permanent atrial fibrillation/flutter.

Clinical diagnosis

Symptomatic bradycardia with hypotension.

Differential diagnosis

Lack of positive dromotropic response due to atrioventricular node dysfunction.

Imaging diagnosis

Contrast venography of the right chest revealed an occluded right innominate vein.

Treatment

A single-lead permanent cardiac pacemaker was placed into the right ventricle.

Related reports

The percentage of patients with end-stage renal disease with limited central venous access requiring trans-hepatic access is unknown.

Experiences and lessons

This case represents demonstrates the challenge of establishing central venous access *via* the trans-hepatic route in a patient with no other access sites. Additionally, the authors highlight the technical challenges associated with undertaking this procedure.

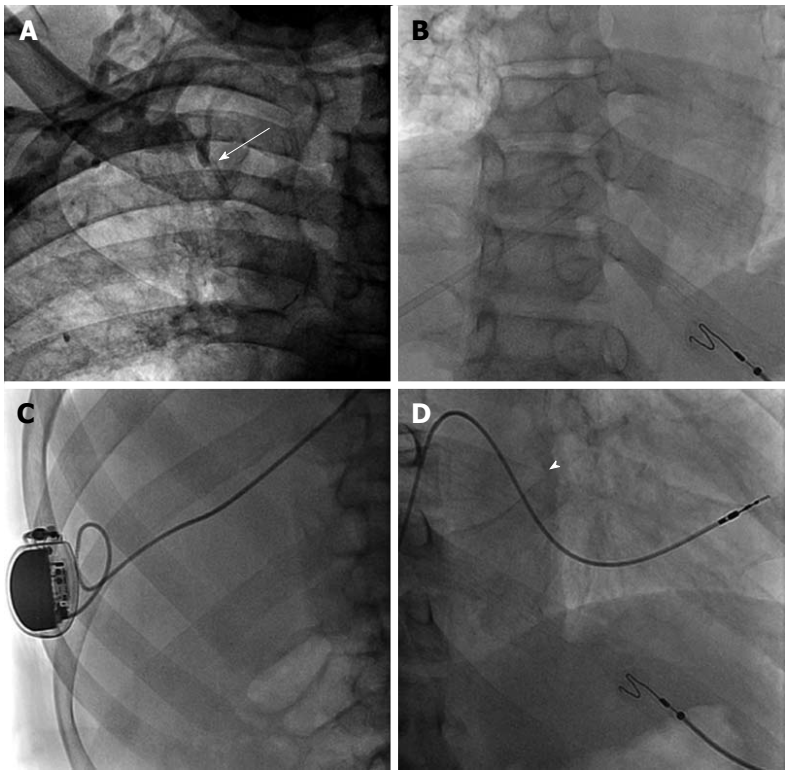

Figure 1 Transhepatic venous approach to single-lead permanent cardiac pacemaker in a 63-year-old male with bradycardia and hypotension. A: Right upper extremity venogram demonstrating total occlusion of the right innominate vein (arrow); B: Transhepatic catheter placement terminating in the right atrium; C: Placement of the pulse generator on the lateral aspect of the thoracic wall with attached right ventricular lead; D: Adequate redundancy provided to the right ventricular lead in the right atrium (arrowhead).

Peer-review

The authors have performed a good study, the manuscript is interesting.

Abstract

Patients with prosthetic cardiac valves are at high risk for thromboembolic complications and need life long anticoagulation with warfarin, which can be associated with variable dose requirements and fluctuating level of systemic anticoagulation and may predispose to thromboembolic and or hemorrhagic complications. Prosthetic cardiac valve thrombosis is associated with high morbidity and mortality. A high index of suspicion is essential for prompt diagnosis. Transthoracic echocardiography, and if required transesophageal echocardiography are the main diagnostic imaging modalities. Medically stable patients can be managed with thrombolytic therapy and anticoagulation, while some patients may require surgical thrombectomy or valve replacement. We present a case report of a patient with prosthetic mitral valve and an unusually large left atrial thrombus with both thromboembolic and hemorrhagic complications.

Key words: Thrombosis; Anticoagulation; Thrombolytic therapy; Transthoracic echocardiogram; Prosthetic valves; Transesophageal echocardiogram

Core tip: Patients with mechanical prosthetic cardiac valves require life long systemic anticoagulation. Maintaining therapeutic anticoagulation consistently is challenging, given the variable dose requirements with warfarin, especially with dietary changes and drug interactions. We present a case of a patient with fluctuating control of anticoagulation, which led to an unusually large horseshoe thrombus in her left atrium and subsequent cerebrovascular complications. We also provide a review of literature, diagnostic modalities and treatment options.

Horseshoe thrombus in a patient with mechanical prosthetic mitral valve: A case report and review of literature. *World J Clin Cases* 2015; 3(9): 838-842 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/838.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.838

INTRODUCTION

Patients with prosthetic cardiac valves are at high risk for thromboembolic complications and need life long anticoagulation with warfarin. Thrombosis of a mechanical prosthetic cardiac valve is a serious complication with high morbidity and mortality. Advancements in valve design and surgical techniques have improved prognosis but thrombo-embolism remains a source of complications in patients with mechanical prosthetic cardiac valves[1,2]. Warfarin is the only oral anticoagulant approved for systemic anticoagulation in patients with prosthetic cardiac valves. However, warfarin has been associated with variable dose requirements related to common genetic polymorphisms influencing their metabolism, varying amounts of dietary intake of vitamin K and interactions with other drugs being used concomitantly[3-5]. Fluctuating level of systemic anticoagulation may predispose to thromboembolic and or hemorrhagic complications. We present a case of a patient with a mechanical bi-leaflet mitral valve prosthesis who presented to our institution with an unusually shaped and large sized left atrial thrombus. The case exemplifies a recognized complication in this patient population and is followed by a review of literature including pathogenesis, clinical presentation and treatment options.

CASE REPORT

A 77-year-old female with medical history of severe rheumatic mitral stenosis treated with mitral valve replacement with 31 mm St. Jude mechanical bileaflet valve was brought to our emergency room with acute onset of right sided weakness and altered mental status by emergency medical services (EMS). Per a family member patient had complained of not feeling well and while EMS was being contacted, she became unresponsive. EMS intubated the patient for airway protection. Upon arrival to our hospital the patient was unresponsive, with heart rate of 127/min, irregular rhythm, blood pressure of 127/55 mmHg and temperature of 36.6 degrees centigrade. On chest auscultation heart sounds were soft with no clear audible valve click. Bilateral lung air entry was decreased with scattered crepitations. Neurological examination revealed pupils reactive to light but deviated to the left and right arm and leg paralysis. The patient was admitted to the medical intensive care unit. Review of her medical record showed that she had labile control of systemic anticoagulation with warfarin, with international normalized ratio (INR) fluctuating between 1.4 to 3.5 in the past six months; INR was 2.3 on admission. Initial laboratory investigations revealed leukocytosis, with white blood cells at 34.4 k/mL, hemoglobin 10.1 g/dL, platelets 845 k/mL, sodium 144 meq/L, blood urea nitrogen 23 meq/L and serum creatinine 0.7 meq/L. Electrocardiogram showed atrial fibrillation with ventricular rate of 113/min, with non-specific ST changes. Blood cultures were obtained and the patient was started on broad spectrum antibiotic coverage. Computed tomography (CT) scan of the head revealed no acute changes but old bilateral cerebellar lacunar infarcts and mild diffuse atrophy. An urgent transthoracic echocardiogram (Figure 1A) showed an oval shaped echo density (1.3 cm × 2.4 cm) attached to the atrial side of the mitral valve in a dilated left atrial cavity, likely representing a thrombus. Mean and peak pressure gradients across the mitral valve were 4 and 14 mmHg respectively (Figure 1B), which were similar to the gradients post-valve implantation. The left ventricular systolic function was mildly decreased with ejection fraction of 40%-45%.

Subsequently transesophageal echocardiogram was performed which revealed a horseshoe shaped, partially mobile, echo density, consistent with thrombus around the sewing ring of the mechanical valve on the left atrial side (Figure 2). Neurology team recommended anticoagulation with therapeutic intravenous heparin at 12 units/kg body weight per hour without initial bolus. Meanwhile patient deteriorated clinically with hypotension not responsive to fluid challenge and decreasing urine output and patient was started on pressor support. Repeat CT scan of the head showed interval development of extensive hypodensity in the left frontal, parietal, insular and temporal lobes and involving the left basal ganglia, with associated petechial hemorrhages. Heparin was subsequently discontinued due to intracerebral hemorrhage (ICH) seen on computed tomography of the head. The patient was initially anticoagulated with therapeutic intravenous heparin, which was subsequently discontinued due to ICH seen on computed tomography of the head. Thrombolytic therapy was contraindicated due to ICH. The patient passed away after withdrawal of life support per family's wishes.

DISCUSSION

According to a meta-analysis by Cannegieter *et al*[6], the incidence of valve thrombosis in prosthetic heart valve recipients was 1 per 100 patient-years in patients on warfarin therapy and around four times higher in patients on no anticoagulation therapy. The incidence of thrombosis was twice as likely for prosthetic valves in the mitral position as compared to the aortic position. Caged ball valves have a higher incidence of thrombosis compared to tilting disc and bileaflet valves[6]. Lengyel[7] reported the incidence of prosthetic cardiac valve thrombosis to be between 1%-4% despite adequate anticoagulation. Prosthetic mechanical valves in the mitral or tricuspid position, first generation Ball-cage and tilting-disc mitral valves have higher incidence of thrombosis. The pathogenesis of thrombosis is likely multifactorial, depending upon the thrombogenic effect of prosthetic material, left atrial geometry and function, presence of atrial fibrillation, inadequate anticoagulation, altered transprosthetic blood flow and any other cause for hypercoagulable state such as malignancy or

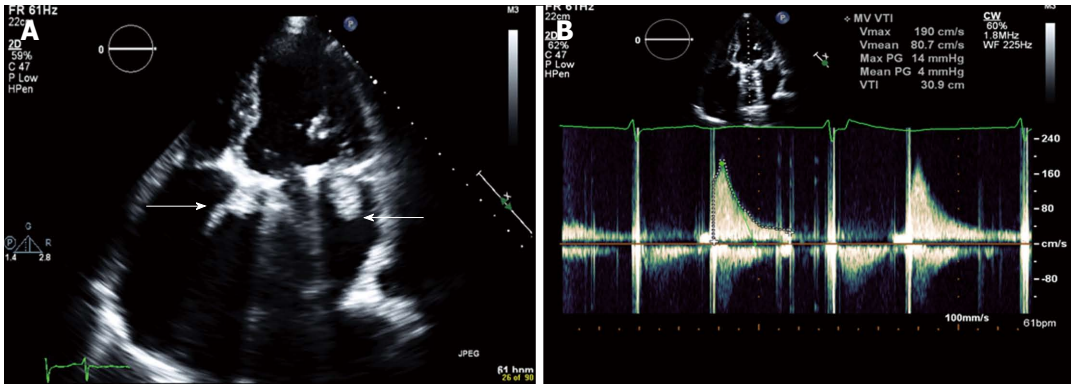

Figure 1 Prosthetic mitral valve thrombosis. A: Transthoracic two-dimensional echocardiogram in apical four-chamber view; B: Transthoracic continuous wave Doppler across mitral valve. Bi-leaflet prosthetic mitral valve seen with echo density, suggestive of thrombus, attached to the atrial side of the bi-leaflet prosthetic mitral valve. The maximum peak gradient across the prosthetic mitral valve is 14 mmHg and mean peak gradient 4 mmHg.

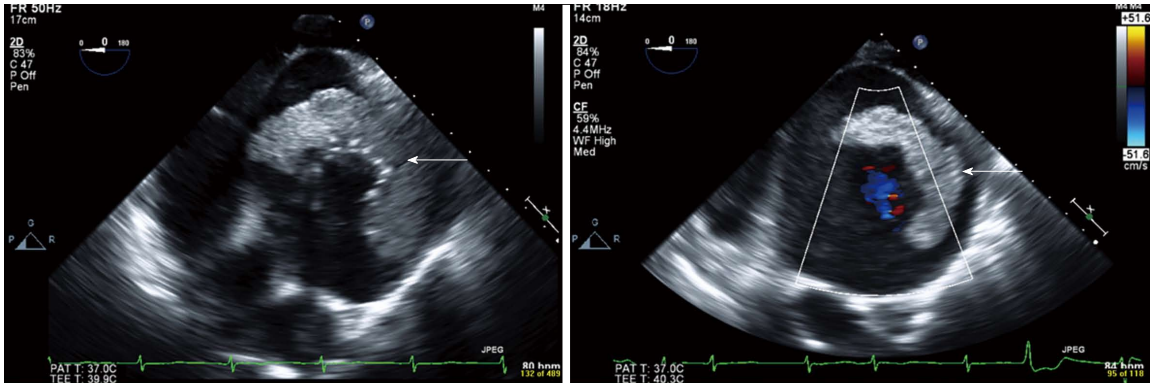

Figure 2 Transgastric views showing horseshoe shaped thrombus around the prosthetic mitral valve suture line.

drugs[8-11]. Inadequate anticoagulation could be a result of variable dose requirements of warfarin. Three new oral anticoagulants (NOACs) - dabigatran, rivaroxaban and apixaban are approved for systemic anticoagulation for patients in atrial fibrillation but not approved for patients with prosthetic cardiac valves. NOACs have several advantages over warfarin, including less dietary interference with their metabolism, fewer drug interactions and a more predictable anticoagulant effect that allows for administration of NOACs in fixed doses without the need for routine coagulation laboratory monitoring[12]. The RE-ALIGN study evaluated the use of dabigatran in patients with mechanical heart valves. The trial was terminated early because of excess of thromboembolic and bleeding events among patients in the dabigatran group[13]. Hence despite shortcomings, warfarin is the only oral anticoagulant approved for anticoagulation in patients with prosthetic cardiac valves for now.

Clinical features suggestive of cardio-embolic source include sudden onset of symptoms, loss of consciousness at onset, rapid regression of symptoms, simultaneous or sequential strokes in different arterial territories, or evidence of embolism to other organs. Presence of bi-hemispheric cerebrovascular, combined anterior and posterior circulation, or bilateral or multilevel posterior circulation infarcts on CT scan of the head are suggestive of cardioembolism[14]. In our patient's case the presentation was acute, with rapid deterioration in neurological status. Initially the head CT scan showed bilateral old infarcts, suggestive of cardioembolic source. However, the new infarcts on repeat imaging were extensive and confined to the left hemisphere.

Clinical presentation for patients with thromboembolic complications may vary from being asymptomatic to dyspnea, cardiogenic shock, cerebral or peripheral embolic episodes. Loss of prosthetic valve click on clinical examination may be suggestive of prosthetic valve thrombosis. Transthoracic echocardiogram is the initial diagnostic tool and provides information about valvular morphology and function. Transesophageal echocardiography is often required to provide more accurate images and to distinguish between pannus and thrombus. A thrombus has usually an echodensity similar to the myocardium while pannus appears more hyperechoic[15]. Fluoroscopy may also be useful for assessment of valve function by showing restriction of valve leaflet movements in case of prosthetic valve thrombosis[16].

Treatment options include thrombolytic therapy, surgical thrombectomy or surgical replacement of the valve. Depending on the clinical status of the patient,

surgical mortality can be as high as 69%. Thrombolytic therapy can also result in thromboembolic complications or hemorrhage[17]. Cáceres-Lóriga *et al*[2], have recommended that in all patients with confirmed right-sided prosthetic valve thrombosis initial treatment should be intravenous thrombolytic therapy, with serial echocardiograms. Thrombolytic therapy may be repeated if required and urgent surgical consultation for valve-replacement should be sought for failure of thrombus resolution. Medically stable patients can be managed with thrombolytic therapy and then continued anticoagulation.

Thrombosis of mechanical prosthetic cardiac valves is associated with high morbidity and mortality and treatment options available can also be associated with serious complications. This mandates the need for high clinical suspicion for thrombosis when a patient with a prosthetic cardiac valve presents with shortness of breath or with an embolic event.

ACKNOWLEDGMENTS

Rene Robinson-Armatta for providing assistance with acquiring echocardiographic images.

COMMENTS

Case characteristics

Acute onset of right sided weakness and altered mental status.

Clinical diagnosis

Unresponsive patient in atrial fibrillation with right arm and leg paralysis.

Differential diagnosis

Computed tomography (CT) scan of the head done to diagnose acute cerebrovascular accident and transthoracic echocardiogram done to evaluate for cardiac source of emboli.

Laboratory diagnosis

Laboratory tests showed elevated white cell count with mild anemia and subtherapeutic international normalized ratio (INR).

Imaging diagnosis

Initial CT scan of the head showed old bilateral infarcts and repeat CT head showed left frontal, parietal, insular and temporal lobes and involving the left basal ganglia, with associated petechial hemorrhages.

Treatment

Patient started on broad spectrum antibiotics for possible sepsis and initially started on intravenous heparin for subtherapeutic INR, but heparin discontinued due to subsequent intracerebral petechial hemorrhages.

Related reports

The authors have included references from the study by Cannegieter *et al* about thrombosis and bleeding complications in patients with mechanical cardiac valves. The authors have also reviewed and included in manuscript the manuscript by Barbetseas *et al* which explains how to differentiate thrombus from pannus.

Term explanation

Polymorphisms: Occurrence of more than one form; Thrombogenic: Promoting thrombosis.

Experiences and lessons

Maintaining therapeutic INR in patients with mechanical prosthetic cardiac valves is critical and high index of suspicion is required for early diagnosis of complications associated with prosthetic valves.

Peer-review

The authors present a clinical note of a 72-year-old female patient suffering from an ischemic stroke of embolic etiology secondary to thrombosis of mechanical prosthetic cardiac valve. This information is interesting from a clinical point of view.

Abstract

Pneumocystis pneumonia (PCP) is a life-threatening infection in immunocompromised patients. It is relatively uncommon in patients with lung cancer. We report a case of PCP in a 59-year-old man with a past medical history of chronic obstructive pulmonary disease treated with formoterol and a moderate daily dose of inhaled budesonide. He had also advanced stage non-small lung cancer treated with concurrent chemo-radiation with a cisplatin-etoposide containing regimen. The diagnosis of PCP was suspected based on the context of rapidly increasing dyspnea, lymphopenia and the imaging findings. Polymerase chain reaction testing on an induced sputum specimen was positive for *Pneumocystis jirovecii*. The patient was treated with oral trimethoprim-sulfamethoxazole and systemic corticotherapy and had showed clinical and radiological improvement. Six months after the PCP diagnosis, he developed a malignant pleural effusion and expired on hospice care. Through this case, we remind the importance of screening for PCP in lung cancer patients under chemotherapeutic regimens and with increasing dyspnea. In addition, we alert to the fact that long-term inhaled corticosteroids may be a risk factor for PCP in patients with lung cancer. Despite intensive treatment, the mortality of PCP remains high, hence the importance of chemoprophylaxis should be considered.

Core tip: *Pneumocystis* pneumonia (PCP) is relatively uncommon in patients with lung cancer. We report a case of PCP in a 59-year-old man with a past medical history of chronic obstructive pulmonary

disease treated with formoterol and a moderate daily dose of inhaled budesonide. He had also advanced stage non-small lung cancer treated with concurrent chemo-radiation. This report attempts to alert for the importance of PCP screening in lung cancer patients under chemotherapeutic regimens and with increasing dyspnea. It also alerts to the role of long-term inhaled corticosteroids as a risk factor for PCP in patients with lung cancer.

Msaad S, Yangui I, Bahloul N, Abid N, Koubaa M, Hentati Y, Ben Jemaa M, Kammoun S. Do inhaled corticosteroids increase the risk of *Pneumocystis* pneumonia in people with lung cancer? *World J Clin Cases* 2015; 3(9): 843-847 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/843.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.843

INTRODUCTION

Patients with hematological and oncological diseases are at increased risk for pneumonia caused by *Pneumocystis* pneumonia (PCP) because of their disease-related and therapy-induced immunosuppression[1]. However, PCP among lung cancer patients is probably an under-diagnosed complication whose incidence is still unknown and risk factors remain incompletely identified. We report here a case of PCP in a 59-year-old man with chronic obstructive pulmonary diseases (COPD) under long-term inhaled corticosteroid therapy and receiving a concomitant radio-chemotherapy for stage ⅢB non-small cell lung cancer.

CASE REPORT

We report the case of a 59-year-old man with a 50 pack-year smoking history. He had moderate COPD treated with formoterol and moderate doses of inhaled budesonide (800 μg/d). He was admitted to our hospital in March 2012 for hemoptysis and evaluation of a right upper lobe lung mass with invasion of the mediastinal pleura and ipsilateral mediastinal lymphadenopathy (Figure 1). Computed tomography (CT)-guided needle lung biopsies were positive for squamous cell carcinoma of the lungs. Additional work-up using abdominal and brain CT did not detect any extra-thoracic metastases. Thus, the disease was clinically classified as stage ⅢB (T3N2M0). From May to November 2012, he had undergone five cycles of etoposide 100 mg/m^2 and cisplatin 20 mg/m^2 chemotherapy given in combination with 32 rounds of radiotherapy at 74 Gray. Two months after the first chemotherapy cycle, the patient developed grade Ⅱ persistent lymphopenia (750-1000 cells/mm^3). A control CT scan performed in December 2012 showed partial remission.

Four months later, the patient came to the emergency department with a ten-day history of increasing breathlessness and fever without any other symptoms (in particular, there was neither chest pain nor hemoptysis). Upon examination, his temperature was 36.7 ℃, pulse was 120 bpm, respiratory rate was 33 breaths/min and blood pressure was 120/70 mmHg. His oxygen saturation was 99% on room air and his body mass index was 22 kg/m^2. Over the right lower lobe lung, decreased breath sounds and decreased tactile fremitus with dullness to percussion were noted. Results of the remainder of the examination were entirely normal. Chest X-ray showed a tumor in the right upper lobe. Nodular parenchymal infiltrates appeared in the left upper lobe lung. A little right pleural effusion was also noticed (Figure 2). An arterial blood gas obtained with the patient breathing room air showed pH = 7.41, pCO_2 = 40.6 mmHg, pO_2 = 68 mmHg, HCO_3^- = 27.2, and O_2Sat = 94.5%. Laboratory investigations showed a hemoglobin level of 12.7 g/dL, a leucocyte count of 8030/mm^3 with a differential of 81% polymorphonuclear leukocytes, 10% lymphocytes (lymphopenia at 803/mm^3), 7% monocytes, 1% eosinophiles and a platelet count of 329.000/mm^3. The patient's erythrocyte sedimentation rate was 86 mm/h, and C-reactive protein was 58 mg/dL. Protein level in the blood was 29 g/dL. Serum electrolytes, blood urea nitrogen, creatinine, serum glutamic oxaloacetic transaminase and serum glutamic pyruvic transaminase were all within normal limits. Purified protein derivative for a tuberculous skin test was non-reactive. Three acid fast bacilli smears and human immunodeficiency virus (HIV) testing were negative. The patient received 3 g of cefotaxim three times a day. On the fourth day in the hospital, his dyspnea was exacerbated and an arterial blood gas obtained on room air showed pH = 7.47, pCO_2 = 39.6 mmHg, pO_2 = 44.8 mmHg, HCO_3 = 21.9, and O_2Sat = 83.9%. A thoracic CT scan eliminated pulmonary embolism. However, it showed, in addition to the primitive tumor, widespread thin-walled cysts and nodules throughout the lungs but most prominent at the right lung. There were also a small right apical pneumothorax and a small bilateral pleural effusion (Figure 3). Pleural fluid was transudative and cultures were negative. The diagnosis of PCP was suspected based on the context of rapidly increasing dyspnea, lymphopenia following treatment with chemoradiation and the imaging findings. Bronchoscopy with bronchoalveolar lavage was indicated but could not be performed because of severe hypoxemia. Polymerase chain reaction (PCR) testing on an induced sputum specimen was positive for *Pneumocystis Jirovecii*.

Treatment for PCP was started with trimethoprim-sulfamethoxazole (TMP-SMX) given orally three times a day at a dose of 20 mg/kg per day with TMP and 100 mg/kg per day with SMX (12 tablets of co-trimoxazole daily). A short course of high-dose dexamethasone (120 mg/d) was also given intravenously for three consecutive days followed by 1 mg/kg per day of prednisone with gradual tapering.

The patient showed clinical and radiological improvement and was discharged after hospitalization for a

Figure 1 Thoracic computed tomography scan showed a mass in the upper lobe of the right lung with invasion of the mediastinal pleura and ipsilateral mediastinal lymphadenopathy.

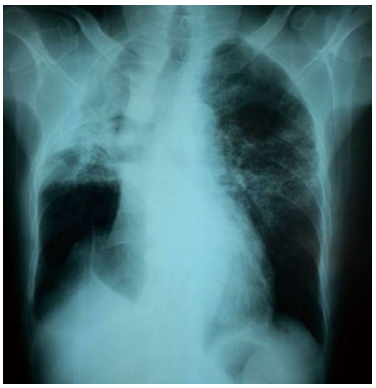

Figure 2 Chest X-ray performed at the second patient's admission showing the right upper lobe lung tumor, and nodular parenchymal infiltrates in the left upper lobe lung with a small right pleural effusion.

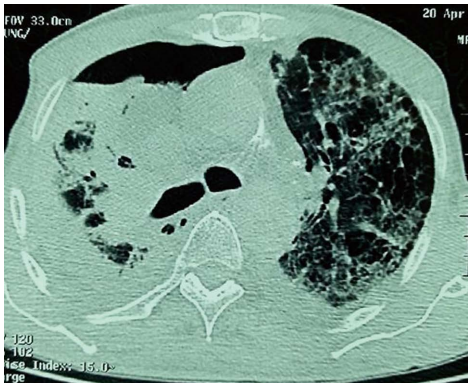

Figure 3 Thoracic computed tomography scan showing a primitive tumor with widespread thin-walled cysts and nodules throughout the lungs but most prominent at the left lung. There were also a small right apical pneumothorax and a small bilateral pleural effusion.

month with instructions to complete 21 d of treatment with TMP-SMX and one month of corticotherapy. Since then, he has been seen at our hospital once a month and he remained stable during two months. In July 2013, he was re-admitted for rapid deterioration of the general status. He reported also a shortness of breath that gradually worsened. A follow-up thoracic CT scan showed a large right pleural effusion. A needle pleural biopsy confirmed metastatic pleurisy. Therapeutic abstention was decided because of the deep deterioration of the general status, and the patient received just palliative care. He expired three months later. An autopsy was not performed.

DISCUSSION

PCP is an opportunistic life-threatening fungal infection caused by *Pneumocystis Jirovecii*. It is seen in immune-compromised individuals, primarily among HIV-infected patients[2]. However, the increasingly frequent use of immunosuppressive drugs had led to outbreak for PCP in patients not infected by HIV[1]. We report here a case of PCP in a patient with advanced stage non-small cell lung cancer treated by cisplatin/etoposide concurrent chemoradiation therapy. PCP is relatively uncommon in patients with lung cancer. Its incidence remains unknown. Recent evidence suggests that about 0.11% of the patients with solid malignancies developed PCP (30 cases of PCP among 26085 patients)[3]. In another retrospective investigation of 150 lung cancer patients receiving chemotherapy or radiotherapy during 1 year, authors found a low incidence of clinical PCP, less than 1%. However, there was a relatively higher (31%) percentage of PCP positivity in patients who developed pneumonia while being treated for lung cancer than in those being treated for other solid tumors[4]. The incidence of PCP in patients with solid tumors has recently increased, probably because of better overall survival and use of more aggressive chemotherapy[5]. The higher risk has been reported with vincristine and cyclophosphamide, but less communally with platinum-based regimens[2,5,6]. With these cytostatic agents, the risk of developing PCP depends on the severity and the duration of neutropenia[1]. Moreover, patients receiving their first cycle of chemotherapy are at a higher risk of infection than in following cycles[1]. In our case, the diagnosis of PCP was not initially suspected because of the long time from the completion of chemotherapy to the onset of pneumonitis and the absence of neutropenia. However, the patient should be regarded as a host risk for PCP due to additional factors such as the advanced stage of the underlying malignancy, associated comorbidities (COPD), the use of radiotherapy as well as inhaled corticosteroid therapy[1,7]. In fact, radiation to the thorax can increase the risk of developing PCP by producing significant lung parenchymal lesions or by causing lymphocyte-depleting as was observed in our case[7]. Paradoxically, it has been reported that PCP infiltrates may spare the area of the lung that is included in a radiation port either during the course of therapy or several months after[7,8]. In our patient, the pulmonary infiltrates were more prominent on the left lung compared to the previously irradiated right side. This presentation called "photographic negative of post-radiation pneumonia" is a distinct finding in PCP[9].

Most patients undergoing chemotherapy for solid

tumors received corticosteroids at the time of the PCP diagnosis[2,5]. In fact, it has been long known that systemic corticosteroid treatment is a major and a common factor for PCP, and accounts for 55% to 99% of published cases in non-HIV infected patients[10]. For instance, a dose of 30 mg of prednisone or the equivalent for 12 wk is considered a significant risk factor[6,8]. The mechanism could be a decrease of blood $CD4^+$ lymphocyte count[11]. Nevertheless, the impact of inhaled corticosteroid on the risk of infection is still unknown. On reviewing the medical literature, we only found one case of association between inhaled corticosteroid and PCP in a lung cancer patient with COPD[7]. Another case was also described in one asthmatic child[12]. These reports suggest that long term inhaled corticosteroid should be considered a risk factor for PCP especially in immune-compromised hosts such as COPD or lung cancer patients, even in the absence of marked leucopenia[7]. However, the magnitude of this risk, the effects of different preparations and doses, and the mechanisms of this effect remain unclear[13]. Of the inhaled corticosteroids studied, only fluticasone demonstrated a dose-related increase in risk of pneumonia in patients with COPD. This difference between fluticasone and budesonide may be explained by the longer retention of fluticasone in the airways, with potentially greater inhibition of type-1 innate immunity[14]. More studies are needed to understand the increased PCP risk with inhaled corticosteroids.

The outcome of PCP in patients without HIV infection is worse than that in HIV-positive patients[15] with a higher mortality (30%-60% *vs* 10%-20%)[16]. Despite its poor outcome, the need for primary PCP prophylaxis in patients with lung cancer is still considered less clear or even questioned by some authors. Several studies recommended that PCP prophylaxis should be performed if patients with lung cancer received prolonged systemic corticosteroids, prednisone or equivalent at least 20 mg for more than 4 wk[17]. Our patient did not receive any PCP prophylaxis because he was not under long-term steroid medication. He was just receiving long-term inhaled corticosteroids that might be, as already mentioned, a risk factor for PCP, even if it has not yet been clearly demonstrated[7]. This fact should lead to discussing prophylaxis in patients receiving inhaled corticosteroids, on a case-by-case basis, even without any specific recommendation.

Long-term inhaled corticosteroids may be linked with an increased risk of PCP in lung cancer patients with COPD, even in the absence of marked pneumonia. More studies are needed to clarify the magnitude of this risk, the effects of different preparations and doses, and the mechanisms of this effect. In lung cancer patients under long-term inhaled corticosteroids, chemoprophylaxis should be considered, although its indication and duration are still controversial.

COMMENTS

Case characteristics

A case of *Pneumocystis* pneumonia (PCP) in a 59-year-old man with chronic obstructive pulmonary diseases under long-term inhaled corticosteroid therapy and receiving a concomitant radio-chemotherapy for stage ⅢB non-small cell lung cancer.

Clinical diagnosis

Increasing breathlessness and fever.

Differential diagnosis

Bacterial pneumonia and pulmonary tuberculosis.

Laboratory diagnosis

Lymphocyte percentage was 10% (lymphopenia at 803/mm^3), erythrocyte sedimentation rate was 86 mm/h, C-reactive protein was 58 mg/dL, protein level in the blood was 29 g/dL, purified protein derivative for a tuberculosis skin test was non-reactive and three acid fast bacilli smears and human immunodeficiency virus (HIV) testing were negative.

Imaging diagnosis

Thoracic computed tomography scan showed a primitive tumor with widespread thin-walled cysts and nodules throughout the lungs, most prominent at the right lung, associated with a small right apical pneumothorax and a small bilateral pleural effusion.

Pathological diagnosis

Pneumocystis jirovecii pneumonia.

Treatment

Twenty-one days of treatment with trimethoprim-sulfamethoxazole and one month of systemic corticotherapy.

Related reports

The increasingly frequent use of corticosteroids, chemotherapy, and other immunosuppressive drugs had led to outbreak for PCP in patients not infected by HIV, in particular in oncological diseases such as lung cancer.

Term explanation

Pneumocystis jiroveci (formerly *Pneumocystis carinii*) is a fungal opportunistic pathogen found in immunocompromised patients. It has gained particular prominence since the onset of the acquired immune deficiency syndrome epidemic.

Experiences and lessons

PCP should be suspected in lung cancer patients with increasing dyspnea if they have risk factors such as chemotherapy and prolonged systemic corticosteroids or even long-term inhaled corticosteroids.

Peer-review

The subject is interesting.

Abstract

Tuberculosis (TB) is still a major health problem worldwide. We present a rare case of an immuno-competent patient with perianal TB. A 38-year-old man visited a clinic with pain, swelling, and redness in the perineum. He had been persistently coughing for the past 6 mo. The abscess had formed a fistula to the perianal region, indicating perianal abscess. *Mycobacterium tuberculosis* was found in sputum and perianal abscess. Surgical drainage was performed, and oral anti-tuberculous drugs were administered for 6 mo. The patient's clinical course was favorable. On review of the literature on 58 cases of perianal TB, we found that the duration of persistent perianal lesion was much longer in patients without active pulmonary TB (APTB) than in those with APTB (66.4 mo *vs* 8.3 mo; confidence interval, 0.0760-0.9620, P = 0.0380). Thus, in cases of non-healing or recurrent perianal lesions, TB should be considered.

INTRODUCTION

Tuberculosis (TB) is still a major health problem worldwide and is more prevalent in Asia. In Japan, in which TB prevalence is decreasing, estimated new TB cases per 100000 population per year is 10-19, which is in the same range with some European countries[1]. Extra-pulmonary TB occupied 3%-46% of all types of TB[2]. Perianal TB is an extremely rare type of extra-pulmonary TB (0.7%)[3]; however, its prevalence might be underestimated, as it can be misidentified as Crohn's disease or other granulomatous diseases[4]. Here, we report a rare case of perianal abscess caused by *Mycobacterium tuberculosis* (MTB).

CASE REPORT

A 38-year-old Japanese man visited a clinic with chief complaints of pain in the perineum, which had developed 4 d earlier. He also had been persistently coughing for the past 6 mo. Chest radiography revealed a cavity in the right upper lung field, and acid-fast bacilli (AFB) were detected in his sputum. These findings indicated pulmonary TB, and the patient was subsequently admitted to the hospital. His past history was unremarkable: He smoked 20 pieces/d. He installed Japanese pinball machines (pachinko) for a living. He had visited North Korea 20 years ago and South Korea 3 years ago. He had no family history of TB. His blood pressure was 126/76 mmHg, pulse rate was 100 beats/min, temperature was normal at 37.3 ℃, and with clear respiratory sounds. Redness, swelling, and tenderness were noted in the right perineum (Figure 1). Thoracic computed tomography confirmed the cavity in the right upper lung field and infiltration in the right upper and left middle lung fields (Figure 2). MTB DNA was amplified using polymerase chain reaction (PCR) (Kobasu TapMan® MTB, Switzerland), and sputum culture revealed MTB. A large amount of creamy white pus was drained from the incisional perianal abscess. The abscess had formed a fistula to the perianal region, indicating a perianal abscess. AFB were also detected in the wound pus and PCR and culture analysis confirmed MTB. Further, *Escherichia coli* was concomitantly isolated from the abscess. Oral administration of isoniazid, rifampicin, ethambutol, and pyrazinamide was initiated, and the clinical course was favorable. After completing the 6-mo oral administration of anti-TB drugs, the patient was operated upon for the anal fistula. His human immunodeficiency virus (HIV) test was negative. No apparent underlying disease was detected at the 3-mo follow-up examination.

We reviewed 58 cases of perianal TB (abscess, fistula, and ulceration) reported from 1970 to 2014 worldwide (Japan, 17 cases; Taiwan, 17 cases; South Korea, 4 cases; Hong Kong, 3 cases; United States, 3 cases; United Kingdom, 2 cases; Brazil, 2 cases; Spain, 2 cases; Turkey, 2 cases; Morocco, 1 case; Iran, 1 case; India, 1 case; France, 1 case; Bulgaria, 1 case), whereas 70.7% were from Asia[5-31]. The mean age (± SD) of the patients was 45.3 (± 10.6) years, and the male-to-female ratio [52 (89.7%) men and 6 (10.3%) women] was higher than that reported previously (4:1)[4,32]. Eighteen point six percent of the patients had underlying diseases related to immunodeficiency (respiratory diseases 3, diabetes mellitus 2, hepatitis 1, hepatitis + HIV 1, chronic kidney disease 1, malignancy 1, autoimmune disease 1, cardiovascular disease 1).

We researched duration of disease, that is the time from beginning of symptoms until diagnosed with perianal TB. Among 29 patients with complete data available on the duration of perianal lesion, the mean duration of disease was 34.6 mo. Of these, 15.3% of the patients had a surgical history of perianal lesions before the diagnosis of TB.

APTB was noted in 34 (57.6%) cases; history of TB, in 12 (20.3%) cases; and no history of pulmonary TB in 12 (20.3%) cases. The existence or non-existence of pulmonary TB was not reported in 1 (1.7%) case. We compared the characteristics of patients with APTB (n = 34) with those of patients without APTB (n = 24) (Table 1). The duration of disease in patients without APTB (66.4 mo) was significantly longer than that in patients with APTB (8.3 mo), as noted in a two-sample t-test (CI: 0.0760-0.9620; $P < 0.05$).

DISCUSSION

Gastrointestinal TB accounts for less than 1% of all TB cases, and perianal disease is exceedingly rare, comprising 1% of digestive tract incidence[5].

In our literature review, only 18.6% of the patients had underlying diseases related to immunodeficiency. Therefore, not only immuno-compromised but also immuno-competent patients should be carefully evaluated, because TB can also occur in immuno-competent individuals, as noted in our case.

The mean duration of perianal TB was 34.6 mo, and 15.3% of the patients had a surgical history of perianal lesions before the diagnosis of TB. Perianal TB may have gone un-diagnosed for a long period.

APTB was noted in 34 (57.6%) cases; Since in cases of perianal TB, APTB is often concomitant with, it is important to conduct chest radiography and a detailed interview, especially to record chronic cough, fever, night sweats, or weight loss, which suggest APTB, in order to diagnose perianal TB.

We compared the characteristics of patients with APTB (n = 34) with those of patients without APTB (n = 24). We found that the occurrence of intestinal TB and TB complications (miliary TB, peritoneal TB, and

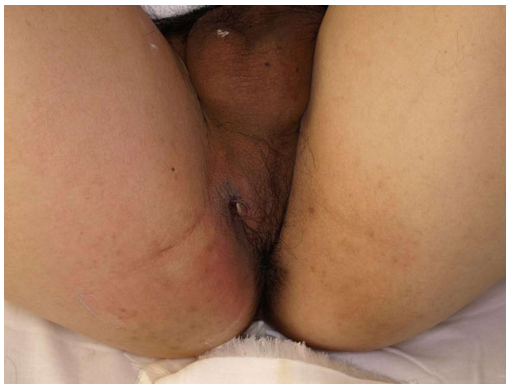

Figure 1 Redness, swelling, and tenderness is seen in the right perineum after the first drainage.

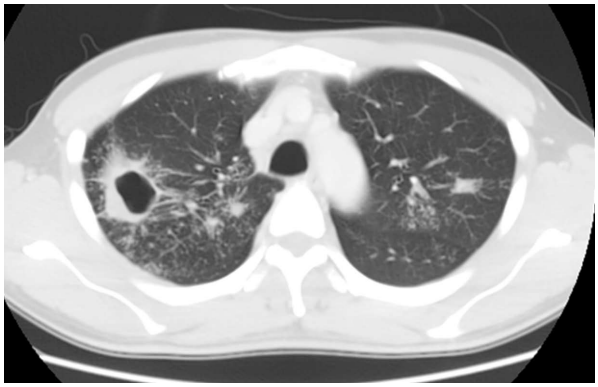

Figure 2 Thoracic computed tomography scan confirming a cavity in the right upper lung field and infiltration in the right upper and left middle lung fiel.

iliopsoas muscle abscess by TB) were similar in both patient groups. This raises a question regarding the infectious routes in patients without APTB, since TB rarely, if ever, occurs as a primary infection in a perianal region. Two possible explanations are as follows: first, hematogeneous spread after reactivation of latent lung TB could be responsible[7], and second, other foci may have not been sufficiently investigated, as seen in our cases wherein only 37 (62.7%) cases included data on intestinal examination.

The duration of disease in patients without APTB (66.4 mo) was significantly longer than that in patients with APTB (8.3 mo), as noted in a two-sample *t*-test (CI: 0.0760-0.9620; $P < 0.05$). Since perianal TB does not have any specific clinical characteristics[5,10], its occurrence without APTB may be underestimated. In cases of chronic or recurrent fistula, the diagnosis of TB should be considered, and culture for MTB and histologic examination should be performed.

The patient in our case installed Japanese pinball machines (pachinko) for a living. In Tokyo patients developed TB without any apparent contact with TB patients most frequently spent their time and maybe acquired the infection at pachinko parlors (24%) and amusement parks (24%), followed by saunas (16%)[33]. In the United States, residents and employees of congregate settings such as hospitals, correctional facilities, nursing homes, and homeless shelters are at a high risk for TB exposure[34-36]. Thus, an interview to collect information on the places that the patient stayed at or visited and employment situation often could be helpful in making a diagnosis of TB.

In conclusion, we report the case of an immunocompetent man with perianal TB and APTB. In cases of non-healing or recurrent perianal fistula, TB should be considered as a causative agent.

Table 1 Characteristics of perianal tuberculosis patients with active pulmonary tuberculosis and without active pulmonary tuberculosis *n* (%)

	Active pulmonary TB (*n* = 34)	Without APTB (*n* = 24)
Age (mean yr)	41.2	51.1
Sex (male)	30 (88.2)	22 (91.7)
Underling diseases	6 (17.6)	5 (20.8)
Previous anal surgery	4 (11.8)	5 (20.8)
TB complications	2 (5.9)	2 (8.3)
Intestinal TB	0	2 (8.3)
Anal carcinoma	2 (5.9)	1 (4.2)
Duration of anal lesion (mo)	6.8	66.5

TB complication: Miliary TB, peritoneal TB, and iliopsoas muscle abscess by TB. Underling disease: Respiratory diseases 3, diabetes mellitus 2, hepatitis 1, hepatitis + human immunodeficiency virus 1, chronic kidney disease 1, malignancy 1, autoimmune disease 1, cardiovascular disease 1. TB: Tuberculosis; APTB: Active pulmonary tuberculosis.

COMMENTS

Case characteristics

A 38-year-old male patient presented with pain in the perineum, which had developed 4 d earlier and persistently coughing for the past 6 mo.

Clinical diagnosis

The patient had redness, swelling, and tenderness in the right perineum.

Differential diagnosis

Testicular torsion, epididymitis, abscess, Fournier's gangrene, torsion of the appendix testis, trauma, testicular cancer, inguinal hernia, Henoch-Schönlein purpura (IgA vasculitis), mumps and Crohn's disease.

Laboratory diagnosis

Acid-fast bacilli were detected in the sputum and wound pus and PCR and culture analysis confirmed *Mycobacterium tuberculosis*.

Imaging diagnosis

Computed tomography scan showed a cavity in the right upper lung field.

Pathological diagnosis

Histological examination of the abscess showed epithelioid granulomas and Langhans' type multinucleated giant cells.

Treatment

Surgical drainage was performed, and oral anti-tuberculous drugs were administered for 6 mo.

Related reports

The authors reviewed 58 cases of perianal tuberculosis (TB) reported from

1970 to 2014 worldwide. And they found that the duration of persistent perianal lesion was much longer in patients without active pulmonary TB (APTB) than in those with APTB (66.4 mo *vs* 8.3 mo; CI: 0.0760-0.9620; *P* = 0.0380).

Experiences and lessons

This case report presents an immuno-competent patient with perianal TB and APTB. On literature on cases of perianal TB, the authors found that the duration of persistent perianal lesions was much longer in patients without APTB than in those with APTB. In cases of non-healing or recurrent perianal lesions, the diagnosis of TB should be considered.

Peer-review

The description of a case with perianal tuberculosis is per se of interest since this form of tuberculosis is very rare and diagnosis is delayed. The manuscript contains a complete and comprehensible description of clinical and microbiological finding.

Abstract

Primary adrenal myelolipoma is a rare, non-functioning adrenal benign tumor that is composed of mature adipose tissue and a variable amount of haemopoietic elements. Clinically, it is difficult to get diagnosed with adrenal myelolipoma because the patient usually doesn't have obvious symptoms and signs in early stage. In the present study, two cases of primary bilateral adrenal myelolipomas are reported. Clinical presentation, imaging diagnostic features, histopathological changes and surgical treatments of the two patients are discussed. Preoperative diagnostic imaging examinations (B-mode ultrasonography, computed tomography and magnetic resonance imaging sans) assisted getting a prediction diagnosis of bilateral adrenal myelolipomas. A two-stage surgery was used to successfully excise bilateral adrenal myelolipomas in the two patients. Conventional open adrenalectomy was applied to remove the adrenal myelolipomas greater than 6 cm, and laparoscopic adrenalectomy was performed to excise the adrenal tumors smaller than 6 cm. Bilateral adrenal myelolipomas of the two patients were finally confirmed by postoperative histopathological examinations. Understanding clinical, imaging diagnostic and histopathological features of bilateral adrenal myelolipomas will facilitate timely diagnosis and treatment of this condition. Surgical removal of bilateral adrenal myelolipomas is safe, curative and beneficial. The two-stage surgery appears to be the best treatment option for the patients with bilateral adrenal myelolipomas because it achieves optimal treatment effectiveness with minimized sequelae.

Key words: Bilateral adrenal myelolipomas; Magnetic resonance imaging scan; Imaging diagnosis; B-mode ultrasonography; Computed tomography scan; Two-stage surgery; Histopathological examination

Core tip: Adrenal myelolipoma is a rare adrenal benign

tumor. It is not easy to get diagnosed with the tumor due to lack of obvious clinical symptoms and signs in early stage. This report discusses clinical, imaging diagnostic and histopathological features in two patients with bilateral adrenal myelolipomas as well as a two-stage surgical strategy for removal of the adrenal tumors. Understanding clinical, imaging diagnostic and histopathological features of bilateral adrenal myelolipomas will facilitate timely diagnosis and treatment of this condition.

Yang Y, Ye LY, Yu B, Guo JX, Liu Q, Chen Y. Two case reports of bilateral adrenal myelolipomas. *World J Clin Cases* 2015; 3(9): 853-860 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/853.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.853

INTRODUCTION

Adrenal myelolipoma is a rare, benign, non-functional neoplasm of adrenal gland, which is composed of mature adipose tissue and a variable amount of haemopoietic elements. Myelolipoma is usually found to occur in unilateral adrenal gland, and rarely observed in bilateral adrenal glands[1-4]. Generally, bilateral adrenal myelolipomas are not easy to be diagnosed clinically because the patients have no obvious symptoms and don't feel pain or discomfort in the early stages of the disease. Over the last few decades, a definite diagnosis of adrenal myelolipoma could be made only with certainty at autopsy. Overall diagnosis rate of adrenal myelolipoma, which was made with autopsy, was merely 0.08%-0.2%[3,5]. In recent years, the diagnosis rate of adrenal myelolipoma has been significantly improved due to the development of modern imaging technologies [such as ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI)]. In the present study, two cases of bilateral adrenal myelolipomas that have been treated successfully in our hospital are reported. The clinical, diagnostic imaging and histopathohistological features of the two cases are retrospectively analyzed. A two-stage surgical strategy for removal of bilateral adrenal myelolipomas is discussed.

CASE REPORT

Case 1

History and physical examination: Patient A is a 40-year-old male, without family history of genetic diseases and smoking or drinking habits. His adrenal masses were found by B-mode ultrasound scanning while he had a regular health check-up in our hospital. He was admitted to the hospital after diagnosed with "left adrenal mass (tumor)". The patient had no other obvious symptoms. A thorough history and physical examination were indicated to rule out diabetes, hypertension, coronary heart disease, hepatitis and tuberculosis. Grade I hypertrophy of the prostate gland was found by prostate examination using rectal palpation technique. Patient's prostate gland was soft and spongy, but the central sulcus became shallow. Neither abnormal prostatic nodules nor rectal bleeding were found by prostate examination.

Diagnostic imaging: In order to establish a diagnosis, the patient was scanned with B-mode ultrasound, CT and MRI scans. The B-mode ultrasound scanning was done on the patient who was placed in the lateral or supine position using a Nemio 30 scanner with a 3.5- to 5-MHz curved linear transducer. A Picker PQ 6000 Spiral CT scanner with a slice thickness of 3-6 mm was used to scan the entire kidney of the patient. The patient's kidneys were also scanned using a Siemens Sensation 3.0T MRI scanner. Acquisitions included axial TSE/T2WI and FL/T1WI, and coronal TFI/T2WI sequences. The results of imaging scans (such as the density, signal strength, size, shape and location of a renal mass) were evaluated by two radiologists, respectively.

Both the left and right adrenal masses were simultaneously detected by diagnostic imaging examinations while the patient was hospitalized. Two hyper-echoic masses were observed by B-mode ultrasonography in the left and right adrenal glands. The sizes of the two hyperechoic masses were 9.7 cm × 9.5 cm in the left adrenal gland and 3.3 cm × 2.3 cm in the right adrenal gland, respectively. All masses had clear boundary and a regular shape. Color doppler flow imaging (CDFI) showed little scattered blood flow signals within the masses. CT showed a mixed density area of 9 cm × 10 cm with the absorption values ranging from 80-120 HU in the left adrenal gland, and a mixed density area of 3.5 cm × 5.5 cm with the absorption values ranging from 90-100 HU in the right adrenal gland, suggesting fat-density lesions in bilateral adrenal glands. MRI scan showed multiple round masses with unequal signals on both T1 and T2 in the left adrenal gland. The multiple round masses made the left kidney to shift downward. Among these masses, the biggest one was located in the posterior side of left adrenal gland and its size was about 8.69 cm × 7.82 cm. An enlargement of the medial limb of the right adrenal gland was also observed using MRI scan (Figure 1A-D).

After removal of the left adrenal myelolipoma, there were no obvious abnormalities found by B-mode ultrasonography in the left adrenal gland. However, B-mode ultrasonography showed a hyperechoic mass of 3.6 cm × 3.5 cm in the right adrenal gland. Both plain non-contrast and contrast-enhanced CT scans revealed that the multiple round masses had vanished from the left adrenal gland after surgery, but an irregular mass with clear boundary appeared in the right adrenal gland. The mass, which looked like a multilocular cystic lesion, had a mixed density area (mixed with fat-density and high-density shadows) with the average absorption values of 7-13 HU (Figure 1E and F).

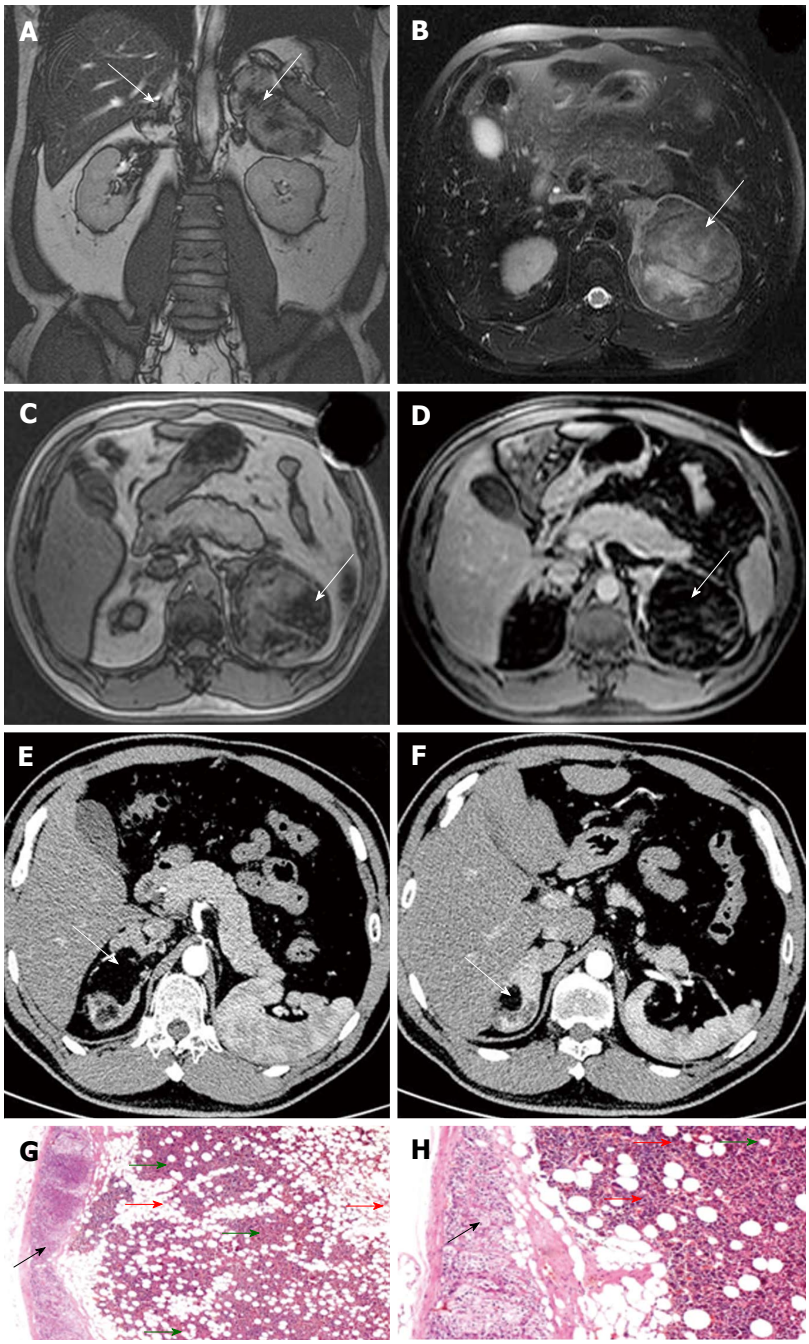

Figure 1 Diagnostic imaging and pathohistological examination results of patient A. A-D: Magnetic resonance imaging (MRI) results of bilateral adrenal myelolipomas before the first surgical procedure; A and B: 84 mm diameter circular mass (white arrow) with unequal signals on both T1 and T2 weighted MRI scans in the left adrenal gland (short T1 weighted mixed with longer T2). The mass has a clear boundary. An increased T2 signal can be seen within it; C: That an uneven T1 signal (which includes lipid signal) inside the mass reduces on anti-phase gradient echo T1WI in the left adrenal gland (white arrow). A reduced T1 signal intensity is seen on fat-suppressed image; D: There is no contrast enhancement in most part of the mass on dynamic contrast-enhanced MRI (white arrow). Separation of the lower composite signals shows the delayed linear enhancement pattern; E and F: Computed tomography scan results of the patient before the second surgical procedure. A circular mass (white arrow) with clear boundary has mixed low-density signals with the average absorption values of 7-13 Hu in the right adrenal gland. Separation of the lower composite signals shows no contrast enhancement in the mass; G and H: The adrenal myelolipomas observed on H and E stained sections. Tumor-like masses of extramedullary hematopoietic tissue is composed of adipose cells (red arrow) and hematopoietic cells (green arrow). Fat vacuoles can be seen in adipose tissue. Among adipose cells, there are medullary cells, megakaryocytes, erythrocytes and lymphoid cells with different maturity levels among fat cells. Normal adrenal gland tissue (black arrow) is surrounded by adrenal myelolipoma.

Surgery: A two-stage surgery was carried out in the patient to excise bilateral adrenal myelolipomas. Because the patient had a large myelolipoma in left adrenal gland and a small myelolipoma in right adrenal gland, a conventional open adrenalectomy was employed to remove the large myelolipoma in his left adrenal gland in first stage of surgery. During surgery, the patient was placed in supine position to make an abdominal incision after anesthesia. After excised the left adrenal myelolipoma, the resected myelolipoma

with a total volume of 11 cm × 8.5 cm × 6 cm was sent to the pathology laboratory for histopathological examination. The right adrenal myelolipoma was removed through laparoscopic adrenalectomy in second stage of surgery (10 mo later). The myelolipoma removed from right adrenal gland had an intact capsule and its total volume was 4.0 cm × 4.0 cm × 3.3 cm. A tumor tissue of 2.5 cm × 2.0 cm × 2.5 cm with the color mixing gray and red was observed inside the removed myelolipoma. Following the surgery, as a regular procedure, the indwelling urinary catheters and nasogastric tubes were kept in until the patients' urinary and gastrointestinal functions returned to normal. The patient was observed daily from the first postoperative day until discharge by the surgeon. Meanwhile, changes in the electrocardiogram (ECG), blood pressure, and blood oxygen saturation were continuously monitored. Anti-inflammatory drugs, symptomatic treatments and supportive care were provided to the patient.

Histopathology: All resection specimens of adrenal myelolipomas were examined by the pathologists using H and E staining (which was repeated twice on resection specimens). Tumor-like masses of extramedullary hematopoietic tissue were composed of adipose cells and hematopoietic cells. Fat vacuoles could be seen in adipose tissue. Among adipose cells, there were medullary cells, megakaryocytes, erythrocytes and lymphoid cells with different maturity levels among fat cells. The histopathological examination results confirmed the initial diagnosis of bilateral adrenal myelolipomas in this patient (Figure 1G and H).

Post-treatment follow-up: Follow-up data were unavailable because this patient did not schedule any post-hospital follow-up visits after he was discharged from the hospital.

Case 2

History and physical examination: Patient B is a 73-year-old male with diabetes for 14 years, but without family history of genetic diseases and smoking or drinking habits. A thorough history and physical examination were indicated to rule out hypertension, coronary heart disease, hepatitis and tuberculosis. He underwent transurethral resection of the prostate years earlier. The patient was diagnosed with bilateral renal cysts in 2009 but didn't receive further medical interventions after bilateral renal space-occupying lesions were observed during a routine physical examination. He was admitted to the hospital for further treatment after his bilateral renal space-occupying lesions were diagnosed again on B mode ultrasonography in 2011. The patients didn't have either obvious clinical symptoms or any discomfort when he was admitted to the hospital. Grade Ⅱ hypertrophy of his prostate gland was found by prostate examination using rectal palpation technique. Patient's prostate gland felt hard, but didn't have palpable nodules or shallow/disappeared central sulcus.

Diagnostic imaging: Patient B was examined with B-mode ultrasound, CT and MRI, respectively. The B-mode ultrasound scanning was done on using the Nemio 30 scanner with a 3.5- to 5-MHz curved linear transducer. The patient's kidneys were scanned by both the Picker PQ 6000 Spiral CT scanner with a slice thickness of 3-6 mm and the Siemens Sensation 3.0T MRI scanner. The medium-to-hyper echo complex masses were observed by B-mode ultrasonography in bilateral adrenal glands of the patient. The masses, which had clear boundary and regular shapes, were 8.8 cm × 7.5 cm on the left side and 9.0 cm × 8.8 cm on the right side, respectively. CDFI showed no obvious blood flow signals within the masses. CT scan found two fat-density shadows in bilateral adrenal glands, which sizes were 10.1 cm × 7.2 cm and 7.3 cm × 7.9 cm, respectively. Contrast-enhanced CT scanning made the two shadows become more inhomogeneous with a mild-to-moderate increasing density. MRI scan showed many masses in his bilateral adrenal glands. In the right adrenal gland, the largest volume of the masses was 8.7 cm × 9.97 cm × 4.92 cm and the smallest volume was 4.45 cm × 4.26 cm × 4.92 cm. In the left adrenal gland, the average volume of the masses was 7.74 cm × 7.52 cm × 4.58 cm. In MR images, the signals of these masses were non-uniform, which included a large number of signals generated by mature fat cells and intracellular lipid contents. After the right adrenal myelolipoma was removed in first stage, the MRI exam was performed again in this patient (Figure 2A-C). A round lesion with mixed signals on T1 and T2 (short T1 mixed with slightly longer T2) was found in the left adrenal gland. The lesion was characterized by decreased signal intensity in the antiphase (out-of-phase). Its size was about 7.46 cm × 7.82 cm. The upper pole region of the left kidney was found to be pressed by the lesion. The right adrenal gland still showed mixed signals on MRI (with both longer T1 and longer T2) and had unclear appearance of an anatomical structure. No lesion near the left retroperitoneal abdominal aorta was observed.

Surgery: The two-stage surgery was also carried out in patient B to excise his bilateral adrenal myelolipomas. Because the patient had large myelolipomas in both the left and right adrenal glands, a conventional open adrenalectomy was used to resect his bilateral myelolipomas. In contrast to patient A, the patients B's right adrenal myelolipoma was removed first, and his left adrenal myelolipoma was resected 3 mo later. In the first surgical procedure, an adrenal myelolipoma measuring 4.5 cm × 3.5 cm × 3.0 cm was removed from the right adrenal gland. Another adrenal myelolipoma measuring 9.0 cm × 7.0 cm × 4.5 cm was excised from the left adrenal gland in the second surgical procedure. After surgery, changes in the ECG, blood pressure, and blood oxygen saturation were continuously monitored in the patient. Anti-inflammatory drugs, symptomatic

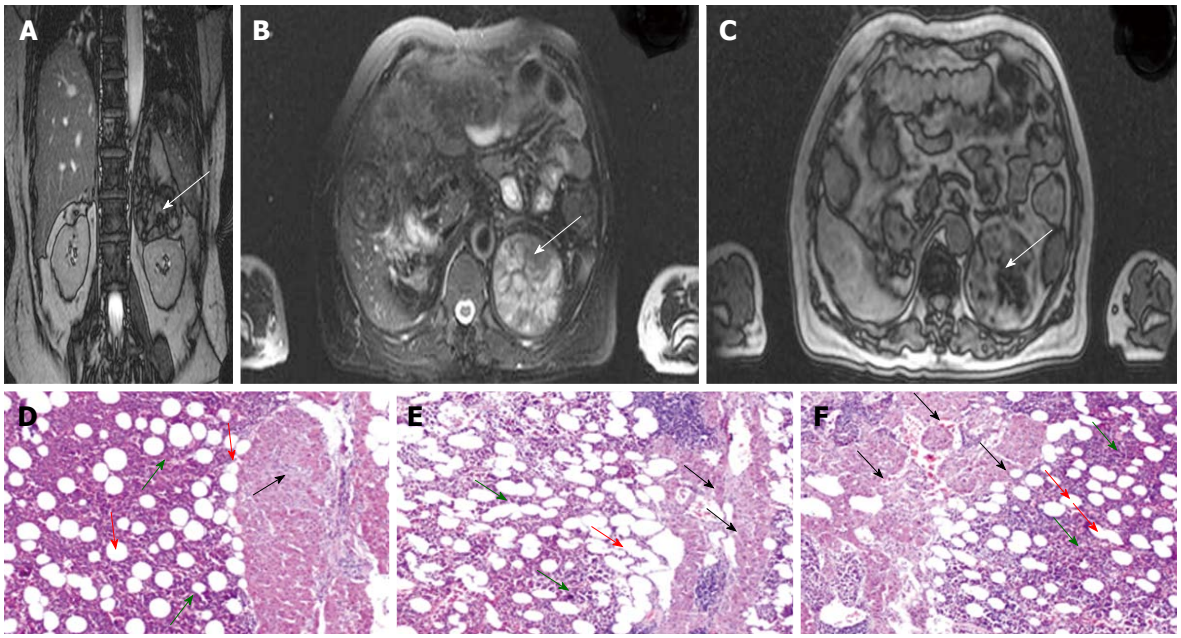

Figure 2 Diagnostic imaging and pathohistological examination results of patients B. A-C: Magnetic resonance imaging (MRI) results of adrenal myelolipomas (MRI scans were performed during the period between the first and the second surgical procedures). A 66 mm diameter circular mass (white arrow) with clear boundary shows mixed signals on T1 and T2 weighted MRI scans (short T1 mixed with slightly longer T2) in the left adrenal gland. The lesion is characterized by decreased T1WI signal intensity in the antiphase (out-of-phase); D: The histopathological features of the right adrenal myelolipoma that was excised in the first surgical procedure (stained with H and E); E and F: The histopathological features of the left adrenal myelolipoma that was removed in the second surgical procedure (stained with H and E). Tumor-like masses of extramedullary hematopoietic tissue is composed of adipose cells (red arrow) and hematopoietic cells (green arrow). Normal adrenal gland tissue (black arrow) is found to be surrounded by adrenal myelolipoma.

treatments and supportive care were also given to the patient. The patient had a good outcome after surgery.

Histopathology: All resection specimens of adrenal myelolipomas were examined by the pathologists using H and E staining (which was repeated twice on resection specimens). The histopathological examination of surgical excised specimens showed large amounts of tumor-like adipose tissue existed in bilateral adrenal medullas, in which extramedullary hematopoietic tissues were found to present. In addition, a thin layer of adrenal cortical tissues was found to surround the myelolipoma. These morphological changes corresponded to the typical histopathological features of adrenal myelolipoma, and confirmed the initial diagnosis of adrenal myelolipoma (Figure 2D-F).

Post-treatment follow-up: Follow-up data were unavailable because this patient did not schedule any post-hospital follow-up visits after he was discharged from the hospital.

DISCUSSION

Adrenal myelolipoma is a rare, benign and hormonally inactive neoplasm of adrenal gland. It occurs generally in unilateral adrenal gland, but the left and the right affected equally. As a benign tumor, myelolipoma does not spread to other body parts. Sometimes, a larger myelolipoma may cause localized tissue death and bleeding. The well-recognized complication of adrenal myelolipoma is spontaneous retroperitoneal haemorrhage[6]. Adrenal myelolipoma, which is composed of large amounts of fat and myeloid tissues, is shaped like or nearly like a round and has clear boundary. Based on its tissue components, adrenal myelolipoma can be categorized into three types: adipose tissue, myeloid tissue and a combination of both[7,8]. Primary bilateral adrenal myelolipoma is rarely observed in clinical practice[3,9,10]. In histopathology of bilateral adrenal myelolipoma, the tissue type of the left adrenal myelolipoma is usually the same as that of the right adrenal myelolipoma but it can't rule out the possibility that different tissue types of adrenal myelolipomas may exist in the left and right adrenal glands, respectively.

As early as 1905, Gierke *et al*[11] have begun to study adrenal myelolipoma. However, the etiology and pathogenesis of adrenal myelolipoma still remain unclear until now. Adrenal myelolipoma has been considered as a result of the differentiation of adrenal medullary or cortex cells into adipose tissue and extramedullary hematopoietic tissue in adrenal gland, which is caused by stimulation of some harmful factors such as stress, infection, ischemia, necrosis, *etc.*[12]. Some studies suggested that adrenal myelolipoma might result from ectopic proliferation of myeloid cells that started to occur during the embryonic period in adrenal gland[13,14]. Moreover, some researchers proposed that the tumor might be evolved from a nonfunctioning adrenal cortical adenoma[15]. As compared to unilateral adrenal myelolipoma, bilateral adrenal myelolipoma might involve more complicated pathogenic mechanism[16].

Generally, there are no specific clinical signs and symptoms observed in the patients with adrenal myelolipoma[3], and also no marked gender differences in the incidence rates of adrenal myelolipoma. It is difficult to predict the incidence of adrenal myelolipoma and to accurately identify the potential patients in the population, because so far there are not many cases to be reported worldwide. Currently, it is unavailable to obtain the authoritative statistical data about the incidence of adrenal myelolipoma. Adrenal myelolipoma is usually discovered by accident while a physical examination is performed in the patients who have suffered other types of diseases. These patients have almost no noticeable manifestations of adrenal gland disorders or endocrine disorders. A diagnosis of adrenal myelolipoma depends mainly on preoperative diagnostic imaging screening, localization and qualitative assessment[7,17,18].

B-mode ultrasonography can be employed to only screen adrenal myelolipoma, because it has limited application in the identification of the tumors that are smaller than 2 cm in diameter. CT scan, especially thin-section CT scan, could be a sensitive imaging technology to diagnose adrenal myelolipoma. However, CT signals of the adrenal masses may be doped with complicated and undesired signals from other biological components because fat tissue inside an adrenal mass is often mixed with other biological components such as calcified and hemorrhagic soft tissues. This may result in incorrect imaging information about the mass, thus leading to a wrong diagnosis.

As compared with CT scan, MRI scan is more sensitive and more accurate imaging diagnostic tool for adrenal tumors. MRI delineates soft tissue better than CT, promoting greater accuracy in preoperative assessment of adrenal myelolipoma. It can also help make a precise quantitative evaluation of adrenal masses through a comparison of unenhanced and contrast-enhanced scans. Under the unenhanced MRI scans, the masses with high proportion of fat tissue show high signal intensity on T1 and T2-weighted images. After contrast enhancement, the signal intensity of the adipose-rich masses will remain the same without any change on MRI. This will be most useful to distinguish adrenal myelolipoma from other adrenal lesions. In addition, MRI scan offers substantial advantages over CT scan for precisely locating a myelolipoma within the adrenal gland, because it uses a strong magnetic field to create high-resolution 3D images of the tumor.

Preoperative diagnostic imaging localization of an abdominal mass is most important in the differential diagnosis of adrenal myelolipoma. It will distinguish adrenal myelolipoma from renal angiomyolipoma, retroperitoneal liposarcoma and other types of abdominal masses. Therefore, MRI is very helpful to establish an accurate diagnosis of adrenal myelolipoma and to develop the surgical strategy for the treatment of this condition. Although diagnostic imaging examinations are generally effective in quantitative evaluation and diagnostic localization of adrenal myelolipoma, a final diagnosis can be made only after histopathological examinations reveal the existence of adrenal myelolipoma in the resection specimens.

Surgical removal of an adrenal myelolipoma is safe, curative and beneficial. However, surgical strategy may depend on the nature, grade, size and location of the myelolipoma[19,20]. When the patients have tumors larger than 3.5 cm in diameter or fast-growing tumors, surgical resection should be the best choice for treatment of adrenal myelolipoma. For an adrenal tumor smaller than 6 cm in diameter, laparoscopic adrenalectomy is generally recommended because this procedure provides patients with a faster recovery and less post-operative pain. However, if an adrenal tumor is greater than 6 cm in diameter or is very likely to grow quickly from its imaging characteristics, the appropriate surgical approach is a conventional open adrenalectomy.

Unlike that for unilateral adrenal myelolipoma, surgical strategy for bilateral adrenal myelolipoma needs to consider how to maximize both the preservation of the adrenal glands and the restoration of the adrenal function. If bilateral adrenal myelolipomas are removed at the same time, it will be inevitable that some of normal adrenal tissues are excised from both the left and right adrenal glands. This will cause bilateral adrenal insufficiency and serious postoperative complications. Therefore, the two-stage surgery should be the best treatment option for bilateral adrenal myelolipoma. Bilateral adrenal myelolipomas can be removed separately in two different stages of surgery at different times[19,21,22]. The reason for performing the two-stage surgery in the patients with bilateral adrenal myelolipoma is that the surgery can be done in a short time and causes less damage to the patients, thus reducing the risk of surgery and enhancing rapid surgical recovery. Most importantly, the two-stage surgical strategy can minimize the chance of adrenal crisis and postoperative complications.

In the present study, the two-stage surgery was successfully performed in the two patients with bilateral primary adrenal myelolipoma. Because patient A had both a large left adrenal myelolipoma and a small right adrenal myelolipoma, a conventional open adrenalectomy was employed to remove his left adrenal myelolipoma in first stage of surgery, and a laparoscopic adrenalectomy was used to excise his right adrenal myelolipoma in second stage of surgery (10 mo later). The conventional open adrenalectomy was employed to resect the patients B's myelolipomas in both left and right adrenal glands because this patient had large myelolipomas in both left and right sides. In contrast to patient A, the patients B's right adrenal myelolipoma was removed first, and his left adrenal myelolipoma was resected 3 mo later. There was no adrenal crisis or other complication to be observed in the patients after surgery. The two-stage surgical strategy has been proven to achieve optimal treatment effectiveness with minimized sequelae.

A combination of B-mode ultrasonography, CT and

MRI sans is the effective diagnostic approach to detect bilateral adrenal myelolipoma. However, before surgery, the quantitative evaluation and diagnostic localization of an adrenal myelolipoma may depend on not only the diagnostic imaging examinations, but also medical histories, clinical symptoms and signs, physical exams and laboratory tests. Surgical strategy for removal of bilateral adrenal myelolipoma should be created based on the nature, grade, size and location of the tumor. Two-stage surgical removal of bilateral adrenal myelolipoma could be the best treatment scheme to achieve optimal treatment effectiveness with minimized sequelae.

COMMENTS

Case characteristics

Rare bilateral adrenal masses were found in two patients.

Clinical diagnosis

Bilateral adrenal myelolipomas, without obvious clinical symptoms and signs.

Differential diagnosis

Retroperitoneal liposarcoma, renal angiomyolipoma, fat containing adrenocortical carcinoma and adrenal teratoma.

Laboratory diagnosis

Laboratory examinations revealed normal results.

Imaging diagnosis

B-mode ultrasonography, computed tomography and magnetic resonance imaging revealed the presence of bilateral adrenal myelolipomas.

Pathological diagnosis

Postoperative histopathological examinations confirmed finally the diagnosis of bilateral adrenal myelolipomas in the two patients.

Treatment

Bilateral adrenal myelolipomas were successfully resected using a two-stage surgical treatment scheme.

Related reports

Few cases of bilateral adrenal myelolipomas were reported with similar clinical presentation, imaging diagnostic features and surgical treatment.

Term explanation

A two-stage surgery is an operative procedure in which bilateral myelolipomas are resected separately from the left and right adrenal glands in two different stages of surgery at different times. One myelolipoma in unilateral (the left or right) adrenal gland is excised in first stage of surgery, and another myelolipoma in the contralateral adrenal gland will be removed in second stage of surgery (a couple of months later). It is a satisfying treatment scheme to achieve optimal treatment effectiveness with minimized sequelae.

Experiences and lessons

Understanding clinical, imaging diagnostic and histopathological features of bilateral adrenal myelolipomas will facilitate timely diagnosis and treatment of this condition. Two-stage surgical removal of bilateral adrenal myelolipomas appears to be the best treatment option for the patients.

Peer-review

At the outset, the authors are requested to rectify certain typographical errors which are present in the manuscript. The authors are requested to incorporate literature data concerning other reported cases of bilateral adrenal myelolipoma in respect to investigative and surgical methods. This will be helpful in determining the appropriate diagnostic and treatment modalities.

Abstract

Proliferative verrucous leukoplakia is an intriguing disease, which occurs particularly in women aged greater than 60 years, is not associated with tobacco and alcohol, and has a high risk of recurrence and malignant transformation. Although it is well known that the typical presentation is characterized by multifocal and verrucous white lesions, there is no description that its initial clinical presentation may simulate a lichenoid reaction.

Key words: Proliferative verrucous leukoplakia; Lichenoid reactions; Diagnosis

Core tip: Although uncommon, it is important for the clinician to recognize the main features of proliferative verrucous leukoplakia in order to provide the correct diagnosis and appropriate management.

PROLIFERATIVE VERRUCOUS LEUKOPLAKIA WITH LICHENOID ASPECT

Proliferative verrucous leukoplakia (PVL) was first described in 1985 as a rare form of oral leukoplakia with a distinct clinical presentation and outcome[1]. This condition more commonly affects non-smoking and non-drinking women, aged greater than 60 years. PVL clinically begins as flat homogenous leukoplakia, becomes multifocal and tends to develop exophytic, wart-like and verrucous areas. Besides this clinical progression, PVL also has a high tendency to recur after treatment and has a high risk of malignant

Figure 1 Lichenoid aspect on the right buccal mucosa (A), left buccal mucosa (B) and on the left lateral border of the tongue (C), leukoplakic lesions on the lateral border of the tongue (D).

transformation. According to several reports, malignant transformation rates vary between 33.3% and 100% and depend on many factors, particularly the number of patients and time of follow-up[2-4].

The characteristics reported above are well known and well accepted by the scientific community. However, there are many doubts and controversies particularly regarding etiology, diagnostic criteria and treatment[5]. The diagnosis of PVL is based on the retrospective association of clinical and histopathological features, which basically consist of observing progressive evolution of the lesions from a homogeneous and isolated area to a multifocal presentation with a verrucous appearance. As these manifestations take time, the diagnosis of PVL is often late.

In order to better recognize this condition, diagnostic criteria were recently proposed, which included 5 major and 4 minor criteria, as well as various combinations of these criteria[6]. In this proposal, one of the major criteria is "the presence of verrucous area". However, according to Aguirre-Urizar[7], the diagnosis of PVL may be delayed if verrucous appearance is considered a main diagnostic feature. In this author's opinion, the most important diagnostic criteria for this type of leukoplakia are the "proliferative" and the "multifocal" aspects. Thus, he proposed a new name for this entity: "Proliferative Multifocal Leukoplakia" with the aim of reducing under-diagnosis[7].

When attending patients with this disorder we observed that in some cases it was very clear and simple to establish the diagnosis of PVL as the patients had lesions with peculiar aspects. However, in other situations the lesions may have different clinical features such as erythroplakic changes[8], which may cause some difficulty in diagnosis. In this scenario, close follow-up is necessary and will permit observation of the development of more characteristic lesions such as in the patient presented below.

In May 2011, a non-smoking and non-drinking 64-year-old female patient was referred to our oral diagnosis service complaining of a painful area on the tongue. She reported the onset of a white lesion on the left lateral border of the tongue 3 years before attending our Clinic. At that time, she had been seen by another dental team and it was initially thought to be a fungal infection and she received treatment based on topical antifungals. As no improvement was observed, a lichenoid reaction was suspected and her dental metallic (gold) restorations were replaced and a partial fixed prosthesis was inserted. However, no improvement was observed. As the lesion persisted, an incisional biopsy was performed by an otorhinolaryngologist. Microscopically, the lesion showed moderate epithelial dysplasia and a chronic inflammatory infiltrate in the underlying connective tissue. The patient was then referred for our evaluation and the first visit to our service revealed white striations with atrophic areas on the buccal mucosa bilaterally. She also had similar alterations on the left lateral border of the tongue (Figure 1). An incisional biopsy was performed on the left lateral border of the tongue and another on the right buccal mucosa. Histopathological analysis of

both sites revealed hyperkeratosis and acanthosis with mild epithelial dysplasia. According to these clinical features and the patient's symptoms, she was treated with topical clobetasol 0.05% three times a day. After 3 wk, pain relief was observed. During the follow-up period, areas of leukoplakia were observed on the left lateral border of the tongue (Figure 1). Taking these findings into account, the diagnosis of possible PVL was suggested and the patient was advised about the need for close observation. The patient remained on regular follow-up without clinical modifications. However, after 15 mo the white lesion on the left lateral border of the tongue became more diffuse and another incisional biopsy was performed and the diagnosis of squamous cell carcinoma was established. The patient was then referred to a head and neck surgeon and a partial glossectomy was performed disclosing free surgical margins.

Recently, it was reported that the clinical presentation of oral lichen planus (OLP) has similarities to PVL based on the facts that most patients are females, without a history of tobacco or alcohol use and the presence of multifocal white lesions. In addition, as in OLP, the lesions have a predilection for the gingiva, tongue and buccal mucosa[9]. In addition to the above-mentioned similarities, we noted that some older female patients without tobacco or alcohol habits had lesions that were similar to lichenoid reactions, but the histopathological analysis proved to be hyperkeratosis and acanthosis with variable degrees of epithelial dysplasia. However, the diagnosis of lichen planus or lichenoid reaction was ruled out microscopically, and these patients later developed more leukoplakic lesions consistent with multifocal leukoplakia.

Therefore, we suggest that the initial clinical manifestation in some cases of PVL may mimic OLP or oral lichenoid reaction, and both biopsy and microscopic analysis are mandatory in order to avoid misdiagnosis, and consequently provide better patient management.

Abstract

Laparoscopic surgery (LS), also termed minimal access surgery, has brought a paradigm shift in the approach to modern surgical care. Early postoperative recovery, less pain, improved aesthesis and early return to work have led to its popularity both amongst surgeons and patients. Its application has progressed from cholecystectomies and appendectomies to various other fields including gastrointestinal surgery, urology, gynecology and oncosurgery. However, LS has its own package of complications. Port site infection (PSI), although infrequent, is one of the bothersome complications which undermine the benefits of minimal invasive surgery. Not only does it add to the morbidity of the patient but also spoils the reputation of the surgeon. Despite the advances in the field of antimicrobial agents, sterilization techniques, surgical techniques, operating room ventilation, PSIs still prevail. The emergence of rapid growing atypical mycobacteria with multidrug resistance, which are the causative organism in most of the cases, has further compounded the problem. PSIs are preventable if appropriate measures are taken preoperatively, intraoperatively and postoperatively. PSIs can often be treated non-surgically, with early identification and appropriate management. Macrolides, quinolones and aminoglycosides antibiotics do show promising activity against the atypical mycobacteria. This review article highlights the clinical burden, presentations and management of PSIs in LS as shared by various authors in the literature. We have given emphasis to atypical mycobacteria, which are emerging as a common etiological agent for PSIs in LS. Although the existing literature lacks consensus regarding PSI management, the complication can be best avoided by strictly abiding by the commandments of sterilization techniques of the laparoscopic instruments with appropriate sterilizing agent.

Key words: Laparoscopic surgery; Port site infection; Atypical mycobacteria; Sterilization; Surgical site infections

Core tip: Laparoscopic surgery has brought about a paradigm shift in the approach to various surgical diseases. Port site infection, although infrequent, is a complication which can undermine the benefits of the surgery. The complication is not life threatening, but definitely adds a lot to the morbidity, affects the postoperative quality of life, and spoils the aesthesis of the surgery. Leaving aside the bacterial causes, the rapidly emerging multidrug resistant atypical mycobacteria are a constant threat. By doing a thorough review of this topic, this paper aims to present the relevant literature regarding the diagnosis, currently available treatment options and commandments to prevent the occurrence of this somewhat preventable complication.

Sasmal PK, Mishra TS, Rath S, Meher S, Mohapatra D. Port site infection in laparoscopic surgery: A review of its management. *World J Clin Cases* 2015; 3(10): 864-871 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/864.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.864

INTRODUCTION

Rapid growths in health care technology have given the surgeon the power of not only treating diseases surgically but also limiting surgical invasiveness. The greatest example is minimal access surgery (MAS) also commonly termed laparoscopic surgery (LS) or keyhole surgery, which has caused a paradigm shift in the approach to modern surgery, by limiting the access related morbidities.

LS involves the use of reusable metallic or disposable plastic trocars inserted through small skin incisions or ports made on the skin away from the site of surgery. This ports form the portal of entry to perform the surgical procedure by means of specially devised instruments and telescope. It has gained popularity due to better aesthesis, lesser pain, early ambulation and discharge from the hospital with early return to work, minimizing the financial burden to the patient. Ever since Philips Mouret reported the first laparoscopic cholecystectomy in 1987, the approach has been adopted for many other surgical procedures including appendectomy, herniorrhaphy, colonic surgery, gastric surgery, urological and gynaecological surgery[1-5]. This is because of the combination of advancement in technology with the increasing acceptance of MAS by patients, which has led to the expansion of the horizon of LS.

LS, however, has its package of unique complications. One such complication, which is preventable although, is the port site infection (PSI). PSI soon erodes the advantages of LS, with the patient becoming worried with the indolent and nagging infection and losing confidence on the operating surgeon. There occurs a significant increase in the morbidity, hospital stay and financial loss to the patient. The whole purpose of MAS to achieve utmost cosmesis is turned into an unsightly wound, and the quality of life of patients is seriously affected.

In this article we review the current literature regarding the incidence, clinical presentation, etiopathogenesis, management and methods of prevention of PSI in LS. We emphasize on the management of PSI due to the emerging rapid growing atypical mycobacteria that do not respond to the standard anti-tubercular drugs.

Incidence of PSIs

No surgical wound is completely immune to infections. Despite the advances in the fields of antimicrobial agents, sterilization techniques, surgical techniques, and operating room ventilation, PSIs still prevail. Incidence of SSI after elective laparoscopic cholecystectomy is less than that after open elective cholecystectomy due to shorter length of incision[6]. The technique of primary port entry to the peritoneum does not show any difference in umbilical PSIs in patients undergoing laparoscopic cholecystectomy[7]. The umbilical PSI rate in LS has been reported to be 8% with 89% of the infections occurring after laparoscopic cholecystectomy, whereas 11% after laparoscopic appendectomy[8]. Francis *et al*[9] studied the factors predicting 30-d readmission after laparoscopic colorectal cancer surgery. Out of 268 patients in their study who underwent laparoscopic colorectal surgery, 48 (18%) were readmitted with surgical site infection (SSI)[9]. Several other authors have found that SSI rate is much higher in conventional surgical procedures than in MAS[10-12]. The immune functions are less affected in LS as compared to open surgery[13]. The incidences of PSI in laparoscopic cholecystectomy as per various studies[14-22] are illustrated in Table 1.

SSIs and PSIs

SSIs are infections consequent to the surgery that are present within a month of the operative procedure. Surveillance in surgeries, such as breast, cardiac, cranial, spinal and bone surgeries, with use of prosthetic material, extends to 90 d after surgery[23-25].

PSI is a type of SSI but limited to LS. The same criteria for SSIs are applicable to PSIs, but the infections are limited to superficial and deep surgical sites only as detailed below.

According to the definitions developed by the United States Centre for Disease Control (CDC), SSIs were categorized into[25]: (1) Superficial SSIs which involve skin and subcutaneous tissue; (2) Deep SSIs which involve fascia and muscle layers; and (3) Organ/Space SSIs.

Wounds are classified as (as per CDC criteria for SSI 2015)[25]: (1) Clean: A surgical wound that is neither exposed to any inflamed tissue nor has breached the gastrointestinal, respiratory, genital, or uninfected

NA: Not available.

urinary tract; (2) Clean-Contaminated: Surgical wounds where there is controlled entry into the gastrointestinal, respiratory, genital, or uninfected urinary tract with minimal contamination; (3) Contaminated: Fresh wounds related to trauma, surgical wounds with major breach in sterile technique or gross contamination from the gastrointestinal tract, and incisions through nonpurulent inflammatory tissues; and (4) Dirty or Infected: Old wounds following trauma having devitalized tissue and surgical procedure performed in the presence of active infection or visceral perforation.

Most of the surgical procedures done by laparoscopy belong to Classes 1 and 2 wounds. The human body hosts a variety of microbes which can cause infections. When the host systemic immunity is suppressed due to any disease, medications or disruptions of the integrity of the skin or mucous membranes secondary to surgical insult, patients' own commensal microbial flora may cause infection. The PSIs in LS manifest in the form of seropurulent discharge from the port sites with surrounding skin inflammation or symptoms related to the organ/space infection.

The active surveillance for PSIs in LS remains a challenge, due to the early discharge and day care setting[10,12]. In the absence of post-discharge surveillance, it is estimated that a third of all SSIs will be missed[26]. The reported incidence of SSIs varies in various regions of the world. The reported incidence of SSIs in a recent article from Turkey was higher than the CDC National Healthcare Safety Network (NHSN) rates[27]. Hence, the actual incidence of the PSIs may be much higher than revealed.

There is a higher incidence of superficial incisional SSIs as compared to that of deep incisional SSIs in LS[12]. The PSI after a LS should be promptly diagnosed and treated appropriately. Although it may not be possible to achieve zero percent PSI, every attempt should be made to prevent it. Insight into the pathophysiology of incision site infections, pathogens involved and knowledge of the appropriate antibiotic is essential for successful management of PSI in LS.

Risk factors for PSIs

A number of contributing factors are somewhat responsible for the emergence of postoperative PSIs. Antibiotics always may not be the answer to this problem. Thus, using them irrationally, as is often done will only result in the emergence of multidrug resistant microbes. The majority of the reports of postoperative wound infection are of SSIs. PSIs following LS have been less reported. The risk factors for SSIs, however, may be applicable to PSIs.

Preoperative stay in hospital: Lilani *et al*[10] reported a significant increase in the incidence of SSIs with preoperative stay of more than 2 d for open surgical procedures.

Duration of operation: The study by Lilani *et al*[10] reported a nil infection rate in surgeries of less than 30 min duration. There was a significant increase in SSIs for operations of prolonged duration for two hours or more.

Other factors: Obesity, prophylactic antibiotics, and drains have no effect on the rate of SSIs following laparoscopic cholecystectomy[28]. Factors like emergency/multi-procedure surgery and surgery in acutely inflamed organs adversely affect the rate of SSIs[20,22]. The risk of SSIs increases in patients with a history of nicotine or steroid usage, diabetes, malnutrition, long preoperative hospital stay, preoperative colonization of nares with *Staphylococcus aureus*, or perioperative blood transfusion[29,30].

PSIs are more common in the umbilical port[12]; the infection rate may depend upon the port through which the specimen is extracted. The infected specimen should be removed in an endobag in order to prevent wound infection and accidental spillage of contents or occult malignant cells. An improvised endobag can be prepared from a simple surgical glove which is easy to make, cheap, readily available and disposable[17].

Microbial flora causing PSIs in LS

PSIs occur due to exposure of surgical wound to microbes which may be from an endogenous or exogenous source. The source of endogenous flora usually is from the patient's skin, mucous membranes or any of the viscera. The exogenous flora may be from any contaminated sources present in the sterile surgical

field including surgeon and team, instruments, room air, *etc*[31].

The pathogenic organisms causing SSIs differ with the surgical procedure performed. Clean surgical wounds usually harbor *Staphylococcus aureus* which may have an exogenous origin or may be from the patient's native flora. Infections in clean-contaminated, contaminated and dirty surgical wounds are polymicrobial, resembling the endogenous flora of the target organ[32].

PSIs are of two broad varieties based on the timing when they are present. The more common type manifests early, within a week of the surgical procedure. Gram positive or negative bacteria are the usual offending organisms which are contracted from the native skin or infected surgical site. They usually respond well to the commonly used antimicrobial agents. The other variety is caused by rapid growing atypical mycobacterium species, which has an incubation period of 3 to 4 wk. They show a poor response to the usual antimicrobial agents[33].

Non-mycobacterial isolates: Kownhar *et al*[34] reported superficial SSIs as the most common in both MAS and open surgical procedures, with *Staphylococcus aureus* as the most common isolate. They studied the SSIs and found various common bacteria isolated as *Staphylococcus aureus* (37%) and *Pseudomonas aeruginosa* (37%), followed by *Klebsiella pneumonia* (8%), *Acinetobacter spp*. (3.2%), *Proteus spp*. (4.8%), *Escherichia coli* (4.8%), *Citrobacter freundii* (1.6%), *Edwardsiella tarda* (1.6%) and *Enterococcus faecalis* (1.6%). *Klebsiella sp.* is the most common offending organism in deep SSIs irrespective of the surgical approach[34]. Usually hospital acquired skin flora cause superficial SSIs. Organisms causing deep SSIs usually are endogenous in origin or may be the skin commensals which reach the fascia or muscle layers through surgical incision[23]. *Bacteroides sp.* was the predominant flora (60%) causing SSIs, in a study reported by Wolcott *et al*[35]. *Bacterioides fragilis* may originate from intraoperative visceral spillage. Mir *et al*[15] in their series found pseudomonas (42.2%) as the common offending organism in PSIs following laparoscopic cholecystectomy. They found that the organisms isolated were resistant to commonly used antibiotics in their hospital[15].

Mycobacterial isolates: Several reports have established the role of rapid growing mycobacteria (RGM), particularly *M. fortuitum* and *M. chelonae* which together have been termed as *M. fortuitum-chelonae complex* that is known to cause disease in humans as well as animals[36]. The endospores of this non-tuberculous mycobacterial (NTM) complex are usually considered saprophytes which colonize in sewage, soil and even tap water. This often cause localized skin infections 3-4 wk post-surgery[37,38]. The NTM complex can cause disseminated disease in immunosuppressive diseases. These atypical mycobacteria have a predilection to involve the skin and subcutaneous tissue. *M. chelonae* and *M. abscessus* have similar characteristics, and hence together were addressed as *M. chelonae/abscessus* group. Vijayaraghavan *et al*[39] reported an outbreak of laparoscopic PSIs due to *M. chelonae* at their center. They had 145 PSIs in 35 patients in a period of 6 wk. The contaminating source was found to be the water being used for washing instruments after chemical disinfection[39]. A series of eight cases of port site tuberculosis after laparoscopy was reported by Ramesh *et al*[40] from India, caused by *M. tuberculosis*.

A case of PSI following laparoscopic cholecystectomy caused by *M. flavescens* has been reported[41]. Duarte *et al*[42] reported an epidemic (74 cases) of postsurgical infections in Brazil, due to *M. massiliense*, after video assisted surgery, which had similar characteristics to *M. abscessus*. Recently, there have been reports of rapid growing mycobacterial infection following laparoscopic gastric banding in obesity[43,44]. Atypical mycobacteria infections following surgery, although rare, are known to occur when a prosthetic material has been used[45].

Clinical presentations of PSIs

Wound discharge and erythema around the port site are the most common presentation of non-mycobacterial infection usually occurring within a week of the surgery. They are usually limited to the skin and subcutaneous tissue[12,14]. There may be surrounding tissue inflammation with pain or tenderness and low grade fever[31].

The delayed type of presentation commonly caused by mycobacteria manifests nearly a month after surgery, in the form of persistent multiple discharging sinuses or lumps/nodules, not responding to antibiotics. There may be pigmentation and induration at the port site starting in a single port and spreading to others.

There are five clinical stages of atypical mycobacterial PSI[46].

First stage: A tender nodule appears in the vicinity of the port site, and its usual timing of appearance is around four weeks following the surgery.

Second stage: Increase in the size of the nodule, and increased tenderness of the site along with other signs of inflammation with eventual formation of a discharging sinus.

Third stage: Reduced pain sensation following discharge of the purulent material and necrosis of the skin surrounding the port site.

Fourth stage: Chronic sinus discharging white or serous fluid.

Fifth stage: Hyper-pigmentation of the skin surrounding the sinus and appearance of multiple nodules at different places.

Diagnosis of the etiological agent with early management

Early PSIs: Gram stains and culture sensitivity of the pus from port site wounds are to be taken. The swabs obtained are processed aerobically and anaerobically by standard methods to find the non-mycobacterial isolates. *Staphylococcus aureus* strains are usually isolated from clean wounds. Their status of β-lactamase production and methicillin resistance needs to be assessed[10]. Daily dressing, cleaning of the wound and a course of empirical antibiotic are started. Specific antibiotics as per the culture and sensitivity report are to be given subsequently. Drainage and debridement may sometimes be required for assisting in wound healing. There are reports of port site abscess presenting as discharging sinus months after surgery due to retained stone at the port site. Wound exploration and removal of the stone is necessary for the healing of such wound[47,48]. Samel *et al*[49] reported a case of gas gangrene of the abdominal wall due to *Clostridial* agents centering around right lateral port following laparoscopic cholecystectomy. There are also reports of life threatening necrotizing fasciitis of the abdominal wall following LS. Significant erythema and wound discharge around the port site along with fever are signs of necrotizing fasciitis[50,51]. A high grade of suspicion and aggressive management are necessary to deal with these life threatening bacterial infections.

Delayed PSIs: Chaudhuri *et al*[46] have shown a raised C-reactive protein level without leukocytosis and a normal differential count in patients with atypical mycobacterial infection[46,52]. Tissue or fluid obtained by biopsy or aspiration needs to be processed for baciloscopy, culture in Lowenstein-Jensen medium and BACTEC technique (Becton-Dickinson Diagnostic Instrument Systems, Sparks, Md). Isolation of the atypical mycobacteria by tissue culture is possible, although it takes time to grow. Moreover, maintaining the stringent environment for its culture is difficult. The most accurate method for rapid presumptive identification of *M. chelonae* is detecting resistance to polymyxin B disc (300 μg)[53]. The routine culture of pus does not grow any bacteria. The diagnosis is often based on the clinical signs and a high index of suspicion[52]. In case of growth of the organism, the isolate is to be confirmed by either biochemical reactions or the more recent nucleic acid amplification tests. Other investigations like tissue culture, real time-PCR, and serology for antitubercular antibody can support the diagnosis[53]. Even these reports are not full proof, as these tests could give a false positive result. The histopathological examination at times may reveal chronic granulomatous inflammation, comprising of epitheloid cells and lympho-plasmacytic infiltration[40].

Treatment of PSIs

Early PSIs, with bacterial isolates, are best managed with local wound care and antibiotics as per antibiogram. The study by Lilani *et al*[10] in clean and clean contaminated cases revealed *Staphylococcal sp.* as the most common isolate, which was resistant to penicillin. The isolates of *Pseudomonas aeruginosa* were totally resistant to gentamicin[10]. Mir *et al*[15] found most of the isolated strains of organisms causing SSI in elective laparoscopic cholecystectomy were resistant to antibiotics used in the hospital. They found the *Pseudomonas sp.* to be sensitive to imipenem in 89.47% of cases, but there was complete resistance to the combination of ampicillin and sulbactam and ceftrixone[15].

Management of PSIs with atypical mycobacteria lacks consensus. They respond poorly to first line anti-tubercular drug treatment. Second line anti-tubercular drugs including macrolides (clarithromycin), quinolones (ciprofloxacin), tetracyclines (doxycycline) and aminiglycosides (amikacin and tobramycin) in various combinations have been used with promising results[37,46,54]. Macrolides including clarithromycin are the only group of antimicrobials active against *M. chelonae* and *M. abscessus*[54]. *Mycobacterium fortuim-chelonae* complex has shown resistance to antibiotics because of mutation in the porin channels present in the bacterial wall, which is the site for entry of antibiotic molecules for antimicrobial activity[46,55]. Linezolid was found to be active against *M. chelonae* and has been successfully used for treatment, alone or as combination therapy[56]. The various antibiotics effectively used against the mycobacterial PSIs, as reported in various studies, are described in Table 2.

Prevention of PSIs

The million dollar question is why at all there occur PSIs in clean and clean contaminated wounds after LS. Is it because of the contamination from the endogenous source or through exogenous source? The endogenous source of infection cannot be avoided. But the incidence of PSIs after LS due to endogenous cause can be reduced by using sterile endobag for specimen retrieval.

The exogenous source of infection, however, is avoidable. Non-tuberculous mycobacteria may be present in water from various sources and soil which can contaminate hospital instruments. A breach in sterilization protocol of laparoscopic instruments is the most common cause of PSI with atypical mycobacteria[46]. The infection with atypical mycobacteria is usually limited to the laparoscopic procedure, as most of laparoscopic instruments are not autoclavable because of the heat sensitive outer insulation sheath. Moreover, as most of the laparoscopic instruments have multiple joints and crevices, where blood and tissue can collect. Frequent use of the instrument without optimal cleaning potentially results in contamination with organisms such as atypical mycobacteria. Endospores in the contaminated instrument get deposited in the subcutaneous tissue, which germinate in three to four

Table 2 Different antibiotics effectively used against *Mycobacterial sp.* in port site infections

Ref.	Type of study	Mycobacteria isolated	Treatment given
Ramesh *et al*[40]	Case series in 8 patients	*M. tuberculosis*	Standard first line antitubercular regimen Rifampicin, isoniazid, pyrazinamide and ethambutol for 2 mo followed by rifampicin and isoniazid for 9 mo
Chaudhuri *et al*[46]	Case series in 19 patients	Clinically suspected atypical mycobacterial infection. No isolates in culture	Clarithromycin and ciprofloxacin (500 mg each, twice daily) for 28 d to 3 mo For persistent local nodules, direct injection of amikacin injections into the nodules daily for 5 d (500 mg twice daily)
Verghese *et al*[37]	Case report	*M. chelonae*	Amikacin 750 mg/d and azithromycin 500 mg BD for 2 wk, followed by linezolid 500 mg BD and azithromycin 500 mg BD for 6 wk
Duarte *et al*[42]	Case series in 74 patients	*M. massiliense*	Sensitive to amikacin and clarithromycin, but resistant to ciprofloxacin, cefoxitine and doxycycline
Sethi *et al*[41]	Case report	*M. flavescens*	Ofloxacin and amikacin for 6 mo
Shah *et al*[61]	Case series in 7 patients	*M. fortuitum* *M. chelonae*	Clarithromycin and ciprofloxacin (500 mg each, twice daily) for 6-9 mo
Rajini *et al*[62]	Case report	*M. chelonae*	Clarithromycin 500 mg BD and doxycycline 100 mg OD for 4 wk

weeks to produce clinical signs and symptoms[42]. A study by Lorena *et al*[57] on *M. massiliense* BRA100 strain showed that it is resistant to even higher concentration of glutaraldehyde (GTA, 7%). Hence, they proved that GTA may not be effective for RGM. Other liquid sterilizing agents like orthophthaldehyde and per acetic acid may substitute GTA for high level disinfection with good efficacy[57].

Ten commandments for preventing PSI[58-61]: (1) Use of disposable trocars and instruments, and adequate availability of properly sterilised reusable trocars to cover all the surgical procedures in a day; (2) Use of autoclavable laparoscopic hand instruments; (3) Use of instruments with good ergonomics, limited joints and facility for proper cleaning of the debris collected in its crevices; (4) A proper cleaning of the instrument is best achieved by ultrasonic technology. Use of autoclaved water for cleaning the instruments after dismantling; (5) Proper guidelines should be followed regarding the concentration, contact time and cycles of use for instrument sterilization with liquid sterilizing agents; (6) Use of plasma sterilizer or ethylene oxide in between the consecutive surgery for instrument sterilization; (7) Avoiding inter-departmental sharing of instruments, such as using instruments used for gynecological or urological procedures; (8) Avoiding spillage of bile or gut content in the operative area or the port site; (9) Use of non-porous specimen retrieval bags for retrieving the specimen; and (10) Thorough irrigation and cleaning of the port site before wound closure.

CONCLUSION

PSI, although infrequent, can be a frustrating complication in MAS, both for the patient as well as the operating surgeon. Leaving aside the bacterial causes, the emerging rapid growing multidrug resistant non-tuberculous mycobacteria are a new threat to the surgical fraternity. Strictly abiding by the commandments of cleaning and sterilization of the laparoscopic instruments, with the appropriate sterilizing agent, the complication can be best avoided.

This review is likely to aid in understanding the relevant studies regarding the appropriate management of PSIs in LS. All the cases of PSI, especially of the atypical mycobacterium should be notified to know the exact incidence, etiology and the sensitivity pattern to various antibiotics. Macrolides, quinolones and aminoglycosides do show promising activity against the atypical mycobacterium. Further research is needed to find out appropriate guidelines for the diagnosis and treatment of this emerging problem.

Abstract

There is increasing awareness among the cardiology community regarding ictal bradyarrhythmias as a cause of loss of consciousness. A high degree of suspicion is necessary when diagnosing ictal bradyarrhythmias, and delay in diagnosing this condition may lead to morbidity associated with falls and trauma. Ictal bradyarrhythmias have also been suggested to be associated with sudden unexplained death in epilepsy, although evidence related to this association is limited. There is no guideline-directed therapy for symptomatic ictal bradyarrhythmias due to a lack of randomized, controlled trials. Cardiac pacemaker therapy is commonly used for these patients; however, currently, there is no universal agreement on the pacing indications for these patients. In this review, we focus on the pathophysiology and clinical presentation of ictal bradyarrhythmias and then discuss the pacing need based on the available literature data.

Key words: Arrhythmogenic epilepsy; Syncope; Ictal bradyarrhythmia; Pacemaker; Anticonvulsive therapy

Core tip: There is increasing awareness among the cardiology community regarding ictal bradyarrhythmias as a cause of loss of consciousness. Pacing is commonly used therapy for symptomatic ictal bradyarrhythmias. However, currently, there is no universal agreement on the pacing indications for these patients due to lack of randomized, controlled trials. In this review we will first focus on pathophysiology and clinical presentation of ictal bradyarrhythmias and then try to discuss the pacing need based on the available literature data.

INTRODUCTION

Epileptic seizures have been associated with a variety of systemic and autonomic manifestations.

Cardiovascular autonomic manifestations include alterations in heart rate and rhythm, blood pressure and electrocardiography (ECG)[1].

Sinus tachycardia is the most frequently observed arrhythmia in patients with epilepsy, with a reported a frequency of 60%-100%[1-3]. Heart rate acceleration has been shown to precede, follow or coincide with seizure[1]. Bradyarrhythmias are rarely observed, occurring in less than 5% of all seizures[1,4]. Sinus bradycardia, AV block and prolonged asystole have been reported in a variety of case reports and case studies[1]. Most episodes have been shown to occur in the ictal state by simultaneous electroencephalography (EEG) and ECG monitoring systems. Ictal asystole (IA) has been reported to be observed in 0.27%-0.4% of patients during prolonged video EEG telemetry[5,6]. Although rare, ictal bradyarrhythmias have substantial morbidity because they are related with sudden loss of consciousness (LOC), which may lead to falls and traumatic injuries. Ictal bradycardia (IB) and IA have also been suggested to be associated with sudden unexplained death in epilepsy (SUDEP), although evidence of association is limited[7-9].

This review will focus on the pathophysiology and clinical presentation of ictal bradyarrhythmias and discuss the pacing need based on the available literature.

PATHOPHYSIOLOGY

The pathophysiology of ictal bradyarrhythmias is not entirely clear, and complex pathways have been believed to be involved in the central nervous system. Most seizure-related bradyarrhythmias have been observed in individuals with temporal lobe epilepsy and appear to be less frequent in patients with seizures originating from the frontal lobes and other brain regions[8]. It has been hypothesized that seizure-related stimulation of certain brain regions, such as insular cortex, cingulate cortex, amygdala and hypothalamus, interferes with autonomic control of the heart *via* connections with autonomic nuclei of the brain stem and spinal cord[10]. Seizure-induced stimulation of the central nervous system has been suggested to directly affect postganglionic discharges on the heart[11]. A recent comprehensive review of literature data on seizure-related cardiac arrhythmias reported that ictal bradyarrhythmias have been observed during focal dyscognitive seizures and that they were mostly commonly observed in individuals with temporal lobe epilepsy[12]. Some studies have suggested lateralization of foci related to ictal arrhythmias; *i.e.*, seizures originating from the right hemisphere have been suggested to be more frequently associated with ictal tachycardia and seizures originating from left hemisphere with ictal bradyarrhythmias[5,13,14]. However, there are inconsistent data in the literature on this lateralization hypothesis[15,16].

CLINICAL PRESENTATION

Sudden LOC is the major manifestation of prolonged IA related to complex partial seizures. Clinical presentation with sudden LOC and related falls, as well as subsequent trauma, may be similar in clinical presentation to vasovagal syncope. Schuele *et al*[17] described similar heart rate patterns during asystolic events in patients with IA and vasovagal asystole, with a tendency for tachycardia preceding the asystolic event, which then evolved into progressive bradycardia and asystole. Based on these observations, the authors suggested that both IA and vasovagal asystole might be mediated through a similar mechanism, leading to increase in vagal tone. Cerebral hypoperfusion related to prolonged asystole appears to be responsible for sudden LOC in patients with IA rather than seizure-induced activation of cortical or subcortical regions. However, absence epilepsy should also be considered in patients with sudden impairments of consciousness. Absence epilepsy is primarily observed in children and adolescent patients and is characterized by sudden cessation of movement without convulsions, impairment of consciousness, fixation of gaze and sudden termination of the epileptic episode without postictal depression[18]. Absence seizures are typically accompanied by bilateral 3-4 Hz spike-wave discharges on EEG[18].

Arrhythmogenic epilepsy should be considered in the differential diagnosis of patients with syncope[10,19]. Ictal bradyarrhythmias should particularly be suspected in patients with epilepsy and syncopal episodes[10]. IA and symptomatic IB are commonly associated with complex partial seizures. Patients commonly present with seizure-related symptoms, such as staring, unresponsiveness, epigastric aura and oroalimentary and manual automatisms, preceding the syncope[20]. Thus, patients with atypical signs and symptoms before a syncopal episode should also be evaluated for the presence of arrhythmogenic epilepsy. IA or symptomatic IB may also be the first ictal manifestation of new onset epilepsy, and a high degree of suspicion is necessary for diagnosis. Recently, Giovannini *et al*[21] published a literature review on IA cases (31 patients from 21 articles) in the context of new-onset/newly diagnosed epilepsy. They reported that symptoms suggestive of partial seizures preceding syncope were absent for most patients. Only 7 patients have been reported to display symptoms such as visual illusion, hallucinations, jamais vu, fear, psychic aura and epigastric aura prior to syncope. Four patients have been reported to display seizure-related motor activities, such as tonic-clonic contractions and automatisms. Simultaneous long-term video EEG and ECG recording appears to be the key diagnostic modality for arrhythmogenic epilepsy[21]. Long-term subcutaneous implantable loop recorders have also been useful in selected cases[22,23].

LITERATURE DISCUSSION

There is no guideline-directed therapy for IA or symptomatic IB due to the lack of randomized controlled trials[24]. Therapeutic options for symptomatic ictal

bradyarrhythmias include anticonvulsive medications, epileptic surgery and/or cardiac pacemaker implantation. Currently, there is no universal agreement on the pacing indications for these patients. Some authors have suggested that IA is a benign phenomenon, and long-term data regarding the effectiveness of pacemaker therapy for IA are missing due to low recurrence rates[17]. Schuele *et al*[25] and Moseley *et al*[26] suggested that IA promotes seizure termination by causing cerebral ischemia/anoxia. However, case studies have indicated that pacemaker implantation may reduce seizure-related falls and injuries[24,27-29]. Giovannini *et al*[21] reported that most patients (21 of 31 patients) with IA in the context of new-onset/newly diagnosed epilepsy had undergone pacemaker implantation at the time of case report publications, although outcome data for these patients are unknown. Other studies have reported some discordant outcome findings after pacemaker implantation in patients with ictal bradyarrhythmias. Ghearing *et al*[27,28] reported outcome data for 7 patients with IA who had falls and LOC prior to pacemaker implantation. Only one patient experienced seizure-related falls after pacemaker implantation at a mean follow-up duration of 27 mo. Schuele *et al*[6] performed a database search for 6825 patients undergoing long-term video EEG monitoring for episodes of IA and found that IA was recorded in 10 patients (0.27% of all patients with epilepsy). Pacemaker implantation had been performed in 6 of these patients, and none of these patients reported recurrent IA or significant bradycardia leading to pacemaker activation. However, 4 patients had been reported to have recurrent and multiple seizures after pacemaker implantation. Moseley *et al*[29] reported the outcome data of seven patients with IA who had a pacemaker implanted in their institution between 1990 and 2004. The authors stated that the mean fall rate was significantly reduced from 3.28 to 0.005 falls/month after pacemaker implantation. Seizure-related fractures and motor vehicle accidents were also reduced following pacemaker implantation.

Strzelczyk *et al*[24] reviewed 16 patients with IA or IB from 4 epilepsy centers who had been evaluated between 2002 and 2009. They reported that pacemaker implantation had been performed in 7 of these patients (43.8%). Outcome data were available for 43 patient-years. Accordingly, 5 patients (31.3%) were seizure-free in the follow-up period; 2 of these patients had experienced epilepsy surgery, 2 had received anticonvulsive therapy, and 1 had received pacemaker implantation. Nine patients (56.3%) had persisting seizures but without seizure-associated falls; 3 of these patients had received anticonvulsive therapy, and 6 had received pacemaker implantation. Two patients (12.5%) who denied epileptic surgery and did not receive pacemaker implantation had persisting seizures and continuous falls. Based on these observations, the authors proposed a clinical algorithm for treating patients with symptomatic ictal bradyarrhythmias. They recommend that cardiac pacemaker should be considered for symptomatic patients after optimizing antiepileptic therapy and discontinuing any coexisting arrhythmogenic medications. Recently, Bestawros *et al*[30] reported outcome data of 8 patients with IA who received pacemaker therapy. The authors stated that all patients remained free of syncope during a follow-up of 72 ± 95 mo.

Although most patients continued to have seizures after pacemaker implantation in the above-mentioned studies, some papers have suggested decreases in the number of seizures and in seizure intensity after pacemaker implantation[31,32]. The mechanism of this unexpected finding is unclear; however, it has been suggested to be related to the effect of cardiac pacing on cardiac vagal afferents and their connections to the brain[29]. However, in our opinion, a placebo effect of cardiac pacemaker implantation cannot be excluded, similar to the suggestion for vasovagal syncope[33].

CONCLUSION

There is increasing awareness for ictal bradyarrhythmias as a cause of LOC in the cardiology community. A high degree of suspicion is necessary for diagnosing ictal bradyarrhythmias, and a delay in diagnosing this condition may lead to substantial morbidity for the patient. Based on the available data, a cardiac pacemaker might be related to decreased morbidity associated with falls and trauma. However, literature data also suggest that optimization of anticonvulsive therapy might be effective in preventing ictal bradyarrhythmias. In our opinion, pacemaker therapy should be reserved for patients who remain symptomatic after optimizing anticonvulsive therapy. Currently, no data are available related to any effect of cardiac pacemaker implantation on preventing SUDEP. Such evidence would be very useful for a potential indication of pacemaker therapy. The results of a randomized controlled study are urgently needed to clarify the pacemaker need in patients with ictal bradyarrhythmias.

Abstract

Pilonidal sinus disease has led to heated debates since it was first described in the medical literature. Although a consensus has been built on its etiology and pathogenesis, the same course has not progressed for treatment modality. This review is a short article about the process of pilonidal sinus disease from past to present. Some important points were mentioned between the years 1833, which is accepted as the milestone for the awareness of the disease, in which it was first reported until the year of 1880, in which it was given its name. Although its name has been the same for about two centuries, some other names such as "Jeep Disease" have also been used depending on the population affected by the disease. At present, it is indisputable that the disease is acquired. Large series were presented about the treatment in the last two decades. Some surgical methods were even named after the ones who first described them and they have many supporters. However, since the treatment modalities have some advantages and disadvantages and they do not have marked superiority over others, debates still continue. We hope that pilonidal sinus disease will not lose its significance and be underrated in parallel with the developments in technology and specialization in medicine.

Key words: Pilonidal sinus; History; Anorectal disease

Core tip: Pilonidal sinus disease has been a debate for about 2 centuries, about which many articles and reviews have been written until now. In this paper, some points that can be accepted as milestones were chronologically presented from the date in which it was first described until today. Since the debates still continue and there is no consensus on the treatment, we suggest that the debates will continue. For this reason and since this article shortly and clearly explains pilonidal sinus disease milestones, we think that it will contribute to the surgeons dealing with the issue.

INTRODUCTION

Science, medicine in particular, cannot be evaluated without writing. Unwritten things are unreadable. Therefore, unread science and interventions cannot be learned and cannot be known. The basic rules of knowledge of medical experiences and interventions are written. It should be published for people to reach, after it is written; so the information can be transferred to the new generations.

HISTORICAL OVERVIEW

Therefore, the beginning dates of many diseases as old as the history of humans is the date that they were written for the first time. This date is 1833 for pilonidal sinus disease. Herbert Mayo, British Physiologist, Anatomist and Surgeon (3rd April 1796-28th June 1852), described it as a sinus containing hair follicles located in the sacrococcygeal region in a woman, in 1833[1,2].

Afterwards, an article named "Hair Extracted from an Ulcer" published by Anderson[3] in "Boston Medical Surgical Journal" in 1847 was found. He reported a case of a 21-year-old male with a Scrophuloderma on his back, in his article written as a letter to the editor. He reported that he drained the cavity after 3 wk and a structure looking like a mesh made of multiple hairs of 2 inches long and after complete drainage and cleaning of the hair in the cavity, the wound healed quickly[3,4]. Seven years later, in 1854 Warren reported 3 similar cases and this study is the first case series known in the history of pilonidal sinus disease[5].

The disease was given many names until 1880. Widely used ones are; sacral, coccygeal or sacrococcygeal infundibulum, dermoid and dermoid fistula, congenital dermal sinus and sacrococcygeal ectodermal sinus[6].

Eventually, in 1880, Hodges[7] named the disease with the statement of "I venture to give the name of pilo-nidal (pilus, a hair, nidus, a nest) sinus to this rather singular lesion." He produced the word "pilonidal" by conjoining the word "pilus" which means hair in Latin and "nidus" which means nest[8].

ETIOLOGY AND PATHOGENESIS

Discussions about pilonidal sinus disease are still hot even though it was described 200 years ago. In the previous years, there were many fevered arguments and many theories to describe whether the disease is congenital or acquired.

80 years ago, Gage[9] reported that pilonidal cyst and sinuses are congenital and he was supported. According to the congenital disease theory, it might have originated from caudal remnants of the neural tube, dermal inclusions produced by sequestrated epithelial structures or dermal tractions that are produced during the involution of the tail during embryonic development[9-11].

The disease was a commonly seen problem among soldiers in World War Ⅱ, during which important explorations and developments were seen in medicine. It was detected to be particularly common among jeep drivers. It was emphasized that compression and irritation reaching the coccyx is important in the etiology and Buie[12] stated that the disease is acquired in his article named "The Jeep Disease".

In 1946, after the war, Patey and Scarff[13] demonstrated that it might be seen in other regions of the body. He wrote that a granulomatous reaction takes place following hair penetration of sub dermal tissue. In addition, he claimed that it is acquired, as it is also seen in the hands of barbers. Afterwards the idea of the disease being acquired became stronger with articles written by King[14,15] in 1947 and 1950.

Two important names that shook the last 20 years of modern surgery in pilonidal disease supported and explained acquired disease theory as the discussions go on. Bascom[16-19] says: "Only the bones get up when people stand up. Sacrum has to stick on to and pull up skin, fat and muscles to move the buttocks. This pulling process produces a vacuum effect all over the gluteal region. Hair enters the pit in case of a minor folliculitis as a result of the vacuum produced by the movement of the gluteal region".

Karydakis[20], who published the largest pilonidal sinus case series in 1992, developed the most logical theory about the etiology and etiopathogenesis of the disease. He reported as a result of his 35 years of work on pilonidal sinus that the etiology is acquired. Especially minor local trauma is the most important predisposing factor of the disease. Hair penetration process is the basis of pilonidal sinus according to Karydakis[21]. Three main factors play a role in embedding of hair: Invaders formed by free hair (H-hair), the force that provides hair embedding the (F-force), and the vulnerability of the skin that lets the embedding of the hair deeper in the gluteal region (V-vulnerability). Pilonidal sinus disease develops in cases in which these three factors are present together and the disease development possibility could be calculated with HxFxV formula[20,21]. As a result, recently most of surgeons are in the opinion that the disease is acquired.

TREATMENT

What about the treatment besides the discussions about the name and etiology? No consensus is obtained about the treatment even though tens of treatment options are written and discussed.

One might think who cares about the treatment of a pilonidal sinus as there are many life threatening diseases in the field of general surgery. However tens of surgical and non-surgical treatment options are described. Discussions continue as the treatment options have advantages and disadvantages, and no option is preferable to the other ones significantly. Different surgical procedure descriptions and modification of surgeons' different procedures, lead to increase the numbers of surgical techniques[22].

The ideal treatment for pilonidal disease should be simple, with short hospitalization, less pain, local anesthesia if possible, low cost, the patient should go back to daily activities in a short time and recurrence rates should be low after treatment. Combination of all these measures is not possible for all treatment options. Therefore, treatment procedures must be planned according to the patient.

Conservation or a surgical method should be chosen when the treatment is planned according to the patient. Unnecessary surgical operations should be avoided for patients that could be treated conservatively and also time and workforce waste should be avoided for a patient that requires surgical treatment by trying a conservative treatment.

Many surgical techniques are present from simple surgical treatment methods such as incision, drainage, unroofing, curettage, and secondary healing, to the described and modified techniques such as excision flap, Karydakis, Bascom, MacFee[16-23]. In addition, conservative methods such as phenol solution, crystalized phenol technique, cauterization, and alcohol injection have also been used[24-27]. No consensus was obtained as all authors advocate their own method. Treatment has to be planned according to the disease and the patient. Natural evaluation, recurrence reasons of the disease must be known very well and the state of the sacrococcygeal region should be evaluated carefully.

Pilonidal sinus caused interest in many aspects. Many materials such as the effect on quality of life and relationship with hormones were investigated and found place in the literature[25,28]. Besides all these processes there is consensus about the symptoms and clinical presentation of the disease. Patients present with 4 different forms as symptomatic, acute pilonidal abscess, chronic fistulizing form or complex pilonidal sinus disease. Chronic fistulizant form is the most common clinical presentation[26].

Where and how does the pilonidal sinus disease stand in general surgery? General surgeons used to take care of orthopedic emergencies, plastic, cardiovascular and thoracic surgery in 1950s. However, increased number of specializations emerged with the development of technology. Today, especially after the millennium a big portion of general surgeons in academic field are interested in specific fields of general surgery. Pilonidal sinus became a part of colorectal surgery as many diseases are addressed to specific fields. For example surgeons and centres interested in hepatobiliary surgery, peripheric vascular surgery or transplantation surgery are distant to the subject.

I hope, surgeons working outside of big centres with specialization in specific surgical fields and colorectal surgeons will continue to pay adequate attention and each of us will take his/her part.

In surgery, there is no such thing as major or minor. Therefore, pilonidal sinus disease should not be underestimated. Sometimes treatment might disappoint both the surgeon and the patient. At a point that you think everything is going very well, you are face to face with repeating surgeries, insecurity and dissatisfaction of the patient, and fear of surgical failure.

With the hope that pilonidal sinus is never underestimated nor forgotten…

Author contributions: Papanikolaou IS, Polymeros D, Dimitriadis GD and Triantafyllou K conceived the idea and designed the study; Papanikolaou IS and Magdalinos N performed the research; Beintaris I, Lazaridis LD and Malli C collected the data; Triantafyllou K analyzed the data; Papanikolaou IS, Sioulas AD and Triantafyllou K drafted the manuscript; all authors read and approved the final manuscript.

Institutional review board statement: IRBS was considered to be non-obligatory given that patients received the standard-of-care treatment in both endoscopic departments. Additionally, our retrospective research project involves use of existing information collected from human participants, but there are not any identifiers linking individuals to the data.

Informed consent statement: Patients were not required to give informed consent to the study because the analysis used anonymous clinical data that were obtained after each patient agreed to treatment by written consent.

Conflict-of-interest statement: None to declare.

Data sharing statement: There is no additional data available.

Abstract

AIM: To retrospectively compare previous-day *vs* split-dose preparation in terms of bowel cleanliness and polyp detection in patients referred for polypectomy.

METHODS: Fifty patients underwent two colonoscopies: one diagnostic in a private clinic and a second for polypectomy in a University Hospital. The latter procedures were performed within 12 wk of the index ones. Examinations were accomplished by two experienced endoscopists, different in each facility. Twenty-seven patients underwent screening/surveillance colonoscopy, while the rest were symptomatic. Previous day bowel preparation was utilized initially and split-dose for polypectomy. Colon cleansing was evaluated using the Aronchick scale. We measured the number of detected polyps, and the polyp miss rates per-polyp.

RESULTS: Excellent/good preparation was reported in 38 cases with previous-day preparation (76%) *vs* 46 with split-dose (92%), respectively (P = 0.03). One

hundred and twenty-six polyps were detected initially and 169 subsequently ($P < 0.0001$); 88 *vs* 126 polyps were diminutive ($P < 0.0001$), 25 *vs* 29 small ($P = 0.048$) and 13 *vs* 14 equal or larger than 10 mm. The miss rates for total, diminutive, small and large polyps were 25.4%, 30.1%, 13.7% and 6.6%, respectively. Multivariate analysis revealed that split-dose preparation was significantly associated (OR, *P*) with increased number of polyps detected overall (0.869, $P < 0.001$), in the right (0.418, $P = 0.008$) and in the left colon (0.452, $P = 0.02$).

CONCLUSION: Split-dose preparation improved colon cleansing, enhanced polyp detection and unmasked significant polyp miss rates.

Key words: Colonoscopy; Bowel preparation; Polyp miss rate; Polyp detection; Colorectal cancer

Core tip: Colonoscopy and polypectomy are currently considered as the gold standard to prevent colorectal cancer. However, a significant proportion of precancerous lesions are missed during the procedure, limiting its efficacy and giving rise to interval cancers. Adequate bowel cleanliness represents a major factor with regards to colonoscopy quality. This study demonstrates that split-dose bowel preparation results to significantly better mucosal cleansing compared to previous-day preparation. Moreover, we showed that preparation with the split-dose regimen significantly enhanced polyp detection, especially of the diminutive ones. Finally, better inspection of the colonic epithelium unmasked a notable polyp miss rate.

Papanikolaou IS, Sioulas AD, Magdalinos N, Beintaris I, Lazaridis LD, Polymeros D, Malli C, Dimitriadis GD, Triantafyllou K. Improved bowel preparation increases polyp detection and unmasks significant polyp miss rate. *World J Clin Cases* 2015; 3(10): 880-886 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/880.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.880

INTRODUCTION

Colonoscopy is currently regarded as the modality of choice, in order to reduce the incidence of colorectal cancer (CRC) and its associated mortality[1]. The rationale behind this is its ability to detect and remove polyps that represent precancerous lesions[2,3]. However, interval CRC, namely cases that are diagnosed between screening and post-screening surveillance examinations, do exist[4,5]. The majority of them are thought to originate from missed polyps during colonoscopy. Polyp and adenoma miss rates reach 28% and 24%, respectively, in several studies reducing colonoscopy preventive efficacy against CRC[6,7].

Numerous technical-, patient- and endoscopist-related factors influence the detection of polyps during colonoscopy[8-11]. In this setting, international associations of endoscopy include adenoma detection rate (ADR) among principal colonoscopy quality indicators[12,13]. Poor bowel preparation is regarded as an impediment to the detection of both small and large polyps[14]. Therefore, multiple interventions have been proposed to improve bowel cleansing and thus increase the quality of colonoscopy[15-17].

Using a tandem colonoscopic evaluation we investigated the impact of different timing of purgative administration in colon cleansing and polyp detection. Polyp miss rates, as well as variables affecting polyp detection were also assessed.

MATERIALS AND METHODS

Study population

This retrospective study was performed on a consecutive series of patients from January to December 2012. All patients were diagnosed with colon polyps during colonoscopy in a small private clinic on an island near Athens and were referred for polypectomy in the Endoscopy Unit of "Attikon" University General Hospital. Exclusion criteria included: (1) age less than 18 or more than 80 years; (2) history of bowel resection; (3) history of inflammatory bowel diseases; (4) suspicion of polyposis syndrome; (5) incomplete colonoscopy (in one of the two examinations); (6) poor bowel preparation as assessed with the Aronchick scale; and (7) ongoing anticoagulation treatment.

Bowel preparation

Prior to the index colonoscopies, patients received the full dose of a 4-L polyethylene glycol (PEG) regimen (Fortrans, Ipsen, Athens, Greece) in the previous day. On the other hand, split dosing (3 L on the previous and 1 L on the same day) was preferred for the subsequent colonoscopies. In all cases patients were advised to maintain a low-fiber diet during the day preceding the examinations.

The quality of bowel cleansing was evaluated by the performing endoscopists using the Aronchick scale. This assesses the preparation quality of the entire colon as excellent (a small volume of clear liquid or greater than 95% of the surface seen), good (a large volume of clear liquid covering 5% to 25% of the surface but greater than 90% of the surface was seen), fair (some semisolid stool that could be suctioned or washed away, but greater than 90% of the surface was seen), poor (semisolid stool that could not be suctioned or washed away and less than 90% of the surface was seen), or inadequate (repeat preparation and colonoscopy was needed)[18]. The evaluations of bowel cleanliness were further summarized as adequate (excellent/good) and inadequate (fair/poor).

Colonoscopy procedure

Two equally experienced endoscopists with experience of more than 5000 colonoscopies each did all the examinations. Specifically, one endoscopist conducted the diagnostic examinations using uniquely previous-day preparation and the other performed the second series with split-dose preparation. The endoscopist who performed the polypectomies was not aware of the number, size and location of polyps detected during the first colonoscopies and had no data regarding the quality of bowel preparation during index colonoscopies. Procedures were done using olympus CF-Q145L standard-definition white-light colonoscopes (Olympus Corporation, Tokyo, Japan). Polypectomies were accomplished by means of forceps, snares or endoscopic mucosal resection, as needed.

All patients signed a standard informed consent form prior to the exam. Institutional ethics committee approval for our study was not needed, since all patients received the standard-of-care without reference to any study.

During the examinations, pulse rate, arterial blood pressure, oxygen saturation and consciousness level were monitored. Supplemental oxygen was routinely delivered *via* nasal catheters at 2 L/min. Intravenous conscious sedation and analgesia including midazolam (Dormicum, Roche Hellas, Athens, Greece) and pethidine hydrochloride (Petidina cloridrato, Molteni Farmaceutici Cilteni, Scandicci, Firenze, Italy) was administered depending on patient's willingness along with comorbidities and baseline vital signs assessment. Reversal agents including flumazenil (Anexate, Roche Hellas, Athens, Greece) and naloxone (Naloxon, B. Brown Melsungen AG, Melsungen, Germany) were available in case of sedation-related complications. No antispasmodics were administered.

In the first colonoscopies, the colonoscopes were advanced to the cecum and polyps were identified during both insertion and withdrawal, counted, but not removed. In the second examinations, all detected polyps were resected and sent for histologic evaluation. Adenomas larger than 1 cm and/or with high-grade dysplasia or a villous component more than 25% were defined as advanced adenomas. To note, numerous tiny hyperplastic polyps in the rectosigmoid area were not subject to assessment.

For each procedure eligible for analysis, the following data were collected: (1) patients' characteristics (age, gender, American Society of Anesthesiologists-ASA grade); (2) indication for colonoscopy; (3) sedation and oxygen administration; (4) bowel preparation quality; (5) polyp features (size, location, shape); and (6) other findings. According to their size, polyps were categorized as diminutive ($\leqslant$ 5 mm), small (6-9 mm) and large ($\geqslant$ 10 mm). Polyp size was determined by comparison with opened biopsy forceps. All colonoscopies were performed between 8:00 a.m. and 2:00 p.m.

Statistical analysis

Polyps per patient were calculated as number of detected polyps/number of patients. Polyp miss rates were calculated as: number of missed polyps/total number of missed polyps + total number of polyps on initial examination and presented as percentages. Both parameters were calculated overall and within strata of polyp size and location. Ideally, a third gold-standard preparation methodology against which comparisons regarding polyp miss rates were applied should be available. Since that was not the case in our retrospective trial we decided to use as reference the type of bowel preparation that showed better results regarding colon cleanliness. Therefore, no OR (95%CI) were calculated in the univariate analysis.

Continuous variables were presented as means or medians and standard deviations, while categorical ones were expressed as absolute values and percentages. Differences in the number of detected colon polyps (overall, right- and left-sided) between the two endoscopic procedures were examined using non-parametric related samples (Wilcoxon Signed Rank Test) tests.

A multivariate linear regression analysis model was constructed to examine variables associated with the number of polyps (overall, right- and left-sided) detected at colonoscopies (dependent variable). Independent variables include: patients' age; sex (male *vs* female), ASA grade (1 *vs* 2), indication for colonoscopy (screening/surveillance *vs* symptoms evaluation) and the quality of bowel preparation (adequate *vs* inadequate). The OR (95%CI) and the level of significance were calculated. A P value of less than 0.05 indicated statistical significance.

Statistical analysis of data was carried out by international business machines corporation (IBM) SPSS Statistics Client for Trial 32. bit 22.0 Microsoft Windows Multilingual (IBM, New York, USA).

RESULTS

Clinical characteristics

A total of 50 patients (28 male) completed both examinations; 4 patients were excluded. Reasons for exclusion were poor bowel preparation (n = 3) and failure to complete the second colonoscopy secondary to sedation-related hypoxemia (n = 1). Mean age was 58.4 ± 11.1 years. Indication for the index colonoscopies were: screening (n = 22), blood in stool (n = 7), abdominal pain (n = 12), family history of CRC (n = 2), altered bowel habits (n = 4) and post-polypectomy surveillance (n = 3). Median interval period between the two exams was 6 wk (range: 1-12).

Bowel preparation quality

Bowel preparation according to the Aronchick scale in the 2 series of colonoscopies was described as excellent in 17 (34%) *vs* 24 (48%) patients, good in 21 (42%)

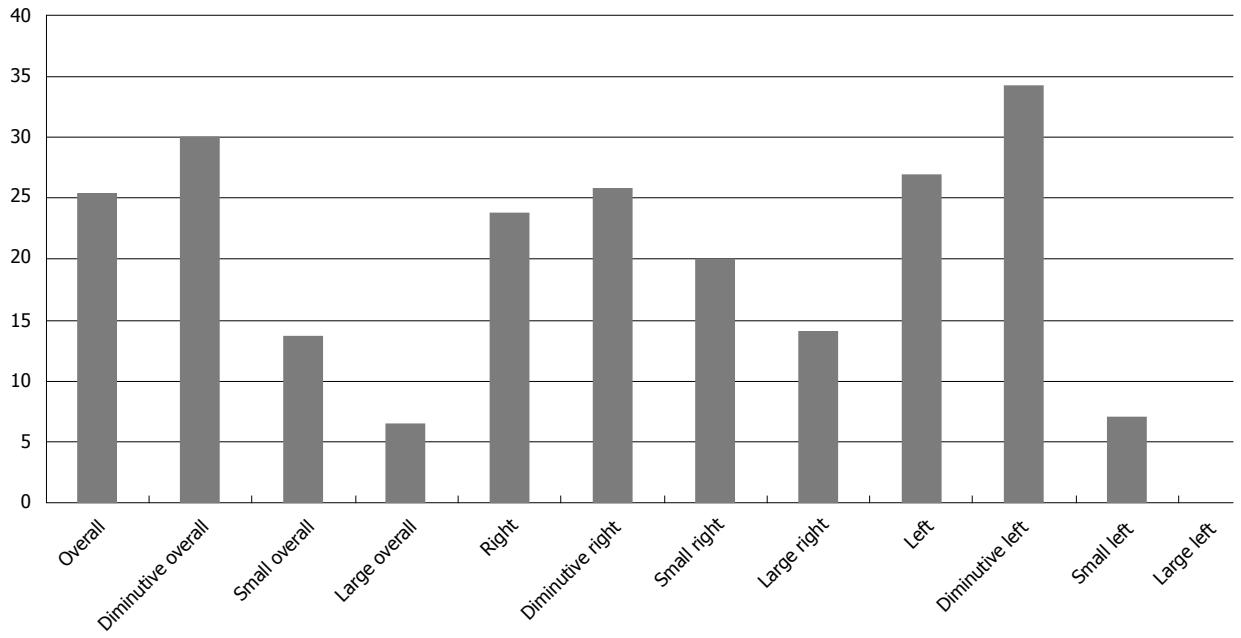

Figure 1 Polyp miss rates (as % percentages).

Table 1 Differences in number of detected polyps between the 2 colonoscopies

	Previous day	Split-dose	*P* value
Overall	126	169	< 0.001
Diminutive overall	88	126	< 0.001
Small overall	25	29	0.046
Large overall	13	14	0.317
Right	64	84	< 0.001
Diminutive right	46	62	< 0.001
Small right	12	15	0.083
Large right	6	7	0.317
Left	62	85	< 0.001
Diminutive left	42	64	< 0.001
Small left	13	14	0.317
Large left	7	7	1.000

vs 22 (44%) patients and fair in 12 (24%) *vs* 4 (8%) patients, respectively. When the evaluations of bowel cleanliness were classified as adequate (excellent/good) and inadequate (fair/poor), the second group of colonoscopies showed a significant increased rate of adequate preparations (92% *vs* 76%, $P = 0.03$).

Polyp detection and polyp miss rates

One hundred and twenty-six polyps were detected during the first examinations. Of those, 88 were diminutive, 25 small and 13 large; 43 additional polyps were identified during the tandem colonoscopies divided in 38 diminutive, 4 small and 1 large. Importantly, better colonic cleansing with the split-dose preparation contributed to significantly increased numbers of identified overall, right- and left-sided polyps ($P < 0.0001$). Significantly more diminutive polyps were detected throughout the colon ($P < 0.001$), while a marginal increase in the number of small polyps was also revealed (Table 1).

The calculated miss rates regarding overall, diminutive, small and large polyps were 25.4%, 30.1%, 13.7% and 6.6%, respectively. The overall miss rates for polyps located in the right colon (cecum, ascending and transverse colon) was 23.8% compared with 27% in the left colon (distal to splenic flexure). Based on size, the miss rates for right-sided diminutive, small and large polyps were 25.8%, 20% and 14.2%, respectively, in comparison to 34.3%, 7.1% and 0%, respectively, for left-sided ones (Figure 1).

Linear regression analysis revealed that increased patients' age and split-dose bowel preparation were the only variables associated with the number of polyps detected overall. Split-dose bowel preparation entered the model first [OR = 0.869 (95%CI: 0.456-1.283); $P < 0.001$], followed by increased age [OR = 0.054 (95%CI: 0.017-0.092); $P = 0.005$]. The same variables were also associated with the number of polyps detected in the right colon. Split-dose bowel preparation entered the model first [OR = 0.418 (95%CI: 0.111-0.724); $P = 0.008$], followed by increased age [OR = 0.032 (95%CI: 0.004-0.060); $P = 0.024$]. Split-dose bowel preparation was the only variable associated with the number of polyps detected in the left colon [OR = 0.452 (95%CI: 0.076-0.828); $P = 0.02$].

Polyp histology

A total of 169 polyps were found and resected in 50 patients during the second series of colonoscopies. Histologic examination of resected polyps revealed tubular adenomas ($n = 110$), advanced adenomas ($n = 18$), serrated lesions ($n = 7$), hyperplastic polyps ($n = 51$) and adenocarcinoma ($n = 1$). Of note, 9 advanced adenomas and 4 serrated lesions were detected in the

right colon, while 9 and 3 respectively, similar lesions, were located in the left colon.

DISCUSSION

This study demonstrates that split-dose bowel preparation results to significantly better mucosal cleansing compared to previous-day preparation. Moreover, we showed that better preparation with the split-dose regimen significantly enhanced overall, right- and left-sided polyp detection, especially referring to diminutive ones. Furthermore, improved view of the colonic epithelium unmasked a noteworthy polyp miss rate, inversely linked to their size.

Colonoscopy is currently considered as the gold standard for the detection of colonic neoplasia. However, emerging data demonstrate that a significant proportion of precancerous lesions are missed during the procedure, limiting its efficacy and leading to interval cancers[19].

It is established that variations in colonoscopy quality reflect differences in numerous patient-, procedure- and endoscopist-related parameters. Taking that into consideration, a great body of interventions has been conducted aiming to decrease colonoscopy's native imperfections, including internal audits and feedback to individual endoscopists, education in quality indicators, implementation of mandatory withdrawal times, bowel preparation modifications, discussion with poor-performers, introduction to emerging technologies, routine sedation administration, repeat attempts for cecal intubation and report card utilization[20-22].

In terms of pre-colonoscopy bowel preparation, numerous interventions have been suggested. These include dietary modifications and various purgatives alone or combined with adjunctive agents (*e.g.*, prokinetics, enemas, simethicone). Timing of bowel preparation administration has been tested in several randomized controlled trials focusing on bowel cleanliness and lesion detection. Recently, the European Society of Gastrointestinal Endoscopy adopted the results of a meta-analysis recommending split dose preparation for morning colonoscopies[10,23,24]. In line with this, our study highlights the significantly better colon cleansing achieved with split-dose preparation, as well as its contribution to increase polyp detection. However, our splitting of PEG dose was 3:1, in contrast to the recommended 2:2. Additionally, we did not collected data with respect to patients' satisfaction, impact on daily activities and willingness to repeat the same bowel preparation in the future, if indicated.

Our data supports the importance of better bowel preparation in the detection of additional polyps. This finding is in line with the results of Gurudu *et al*[21] demonstrating improved polyp detection rates (PDR) and ADR with split-dosing. Unfortunately, we cannot provide information for possible differences in adenoma detection in the present study, as the index series of colonoscopies was diagnostic. However, PDR and ADR seem to correlate well, at least in segments proximal to the splenic flexure[25].

Miss rates for total, diminutive, small and large polyps were 25.4%, 30.1%, 13.7% and 6.6% respectively. These results indicate that the smaller the polyp size, the higher the polyp miss rate, which is in accordance to findings of previous studies[6,26]. Location did not affect the polyp miss rates similarly to a recent study conducted by Ahn *et al*[27]. Interestingly, other data suggests that the risk of missing a polyp is related to left colon location[28]. However, it should be clearly stated that no gold-standard bowel preparation method against which our studied alternatives (*i.e.*, previous-day *vs* split-dose preparation) were compared in terms of polyp miss rates was available. Therefore, we favored split-dose preparation's findings to serve as comparator given that it yielded significantly better results as regards colon cleanliness. This reflects the current knowledge that the risk of missing polyps and adenomas during colonoscopy is affected by bowel preparation quality[29]. Nevertheless, our assumption encompasses a disadvantage of this study and weakens its conclusions.

As obvious, this study bears several limitations. First, we enrolled a small number of patients, which limits the power of our results. Second, we used as as reference methodology the results of the split-dose examination to calculate miss rates, as presented above. Third, we did not assess the inter-observer agreement considering bowel preparation status evaluation. Our results could have been affected by a possible significant discrepancy between the two examiners in rating preparation quality. Fourth, we could not provide data regarding histological features of polyps identified in the first series of colonoscopies (as they were not removed). Fifth, no reports of patients' preference in terms of timing of purgatives administration and comfort during the examinations were collected (the majority of patients had received sedation). Sixth, we did not captured data regarding withdrawal times which seem to influence ADRs. Additionally, we did not utilize validated scales such as Boston or Ottawa scales to assess the quality of cleansing in each bowel segment, as the Aronchick scale is closer to what an endoscopy unit uses in its "normal" -outside a study-practice, which was what we actually wanted to assess. Finally, we are not aware of the true polyp miss rate, since we considered the second colonoscopy as the gold standard.

In conclusion, our results support that split-dose bowel preparation improves the quality of colonoscopy in terms of mucosal cleanliness and polyp detection. However, future efforts to identify barriers and develop interventions aiming to further enhance colonoscopy effectiveness in the prevention of CRC are also necessary, as there are many factors that contribute to a high-quality examination.

COMMENTS

Background

Several factors influence colonoscopy quality and affect its potential to decrease

colorectal cancer incidence. Quality of bowel preparation represents one of the most studied ones. In this setting, numerous regimens, combinations and administration timings have been tested. Apart from rating bowel cleanliness achieved, polyp and adenoma detection seems to improve in parallel to the quality of preparation. This retrospective study assesses two different schedules of preparation regimen administration in terms of bowel cleansing and polyp detection.

Research frontiers

In this study it is suggested that splitting preparation regimen results in better quality of colon cleanliness than that achieved by previous-day dosing and leads to improved polyp detection.

Innovations and breakthroughs

The authors' 3:1 splitting of polyethylene glycol (PEG) regimen is shown to significantly improve the adequacy of bowel preparation and increase the number of detected polyps in both entire and colon segments. A remarkable polyp miss rate is substantially unmasked.

Applications

The results of this study serve as additional evidence aiming to improve colon cleanliness and polyp detection rates in every day clinical practice.

Terminology

Polyps per patient: number of detected polyps/number of patients. Polyp miss rates: number of missed polyps/total number of missed polyps + total number of polyps on initial examination. PEG is an osmotic laxative containing PEG, water and added electrolytes that is used in bowel preparation prior to colonoscopy and surgery.

Peer-review

The manuscript "Improved bowel preparation increases polyp detection and unmasks significant polyp miss rate" is clear and well-written. The manuscript reports on the comparison of two methodologies, full dose *vs* spilt dose, in colonoscopy and concludes with the report, that split-dose regimen enhanced polyp detection and reduced polyp miss rate.

Abstract

AIM: To examine the usefulness of a new tapered metallic stent (MS) in patients with unresectable malignant hilar bile duct obstruction.

METHODS: This new tapered MS was placed in 11 patients with Bismuth Ⅱ or severer unresectable malignant hilar bile duct obstruction, as a prospective study. The subjects were six patients with bile duct carcinoma, three with gallbladder cancer, and two with metastatic bile duct obstruction. Stenosis morphology was Bismuth Ⅱ: 7, Ⅲa: 3, and Ⅳ: 1. UMIN Clinical Trial Registry (UMIN000004758).

RESULTS: MS placement was 100% (11/11) successful. There were no procedural accidents. The mean patency period was 208.401 d, the median survival period was 142.000 d, and the mean survival period was 193.273 d. Occlusion rate was 36.4% (4/11); the causes of occlusion were ingrowth and overgrowth in 2 patients each, 18.2%, respectively. Patients with occlusion underwent endoscopic treatment one more time and all

were treatable.

CONCLUSION: The tapered MS proved useful in patients with unresectable malignant hilar bile duct obstruction because it provided a long patency period, enabled re-treatment by re-intervention, and no procedural accidents occurred.

Key words: Malignant hilar bile duct obstruction; Metallic stent; Tapered metallic stent

Core tip: Placement of a tapered metallic stent in patients with unresectable malignant hilar bile duct obstruction proved useful because it allowed a longer patency period without procedural accidents.

New tapered metallic stent for unresectable malignant hilar bile duct obstruction. *World J Clin Cases* 2015; 3(10): 887-893 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/887.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.887

INTRODUCTION

The guidelines for biliary cancer diagnosis recommend drainage as frequent as possible in patients with unresectable malignant hilar bile duct obstruction for improvement of patient's quality of life or when performing chemotherapy[1]. As an approach route for hilar bile duct occlusion, there are surgical, percutaneous, and transpapillary routes; and the region where drainage can be carried out differs depending on the location of the tumor, thus it is very difficult to establish treatment strategies. An endoscopic approach is recommended as the drainage route because of the low invasiveness and high success rate of internal drainage[1]. Metallic stents (MSs) are considered useful for internal drainage in terms of patency period[1]. Even past randomized controlled trials reported that MSs are associated with a longer patency period and lower occlusion rate than plastic stents (PSs)[2,3]. Under such considerations, it may be necessary to set the strategies to use MSs in patients with unresectable malignant hilar bile duct obstruction. In this study we examine the usefulness of a new tapered MS developed for exclusive use in patients with unresectable malignant hilar bile duct obstruction.

MATERIALS AND METHODS

The patients with unresectable malignant hilar bile duct obstruction and showed a remarkable increase of hepatobiliary enzymes, had Bismuth Ⅱ or higher degree stenosis according to Bismuth classification[4] and had been treated between July 2011 to December 2012 were included in this study (Table 1). There were 11 patients (7 men and 4 women) aged 72.273 ± 10.771 (59-85) years. The diagnosis was established based on a combination of images plus pathological findings. The cause of obstruction was bile duct carcinoma in 6, gallbladder cancer in 3, and metastatic bile duct obstruction in 2 patients. We evaluated the intrahepatic bile duct with a little contrast media. Stenosis morphology was Bismuth Ⅱ in 7, Ⅲa in 3, and Ⅳ in 1 patient. The stenosis was 22.727 ± 8.545 (10-35) mm long. Remarkable increase of hepatobiliary enzymes was defined as a value double or more the normal value of ALT (IU/L), ALP (IU/L), or T-Bil (mg/dL), or a combination of them. ALT (IU/L) was 114.055 ± 96.915, ALP (IU/L) was 1157.09 ± 420.250, and T-Bil (mg/dL) was 5.427 ± 4.4365 prior to drainage. Inclusion criteria were: (1) Patients with unresectable malignant hilar bile duct obstruction; (2) No criteria on underlying disease, age or sex; and (3) Patients who give gave their informed consent. Exclusion criteria were: (1) Patients in whom the endoscopic approach was difficult; (2) Patients with a bleeding tendency; (3) Patients who had suffered serious procedural accidents; (4) Patients who did not provide their informed consent; and (5) Patients who were determined not to be appropriate by the physician in charge. The MS was placed in all the patients *via* the endoscopic retrograde cholangiopancreatography (ERCP) route. Magnetic resonance cholangiopancreatography was performed in all of them before drainage. There was no case of cholangitis. Chemotherapy was performed in 6 patients and 5 received the best supportive care. The patients were followed up from MS placement to their death, and if patients were alive by March 2014 they were evaluated. Before ERCP, all patients were given the standard premedication consisting of intravenous administration of midazolam (3 to 10 mg), and the dose depended on age and tolerance. Scopolamine butylbromide or glucagon was used for duodenal relaxation. During ERCP, arterial oxygen saturation was continuously monitored using a pulse oximeter. Patients were kept fasting after the procedure for at least 24 h with drip infusion of 2000 mL and stayed in the hospital for at least 72 h. They received 8-h infusion of a protease inhibitor (nafamostat mesilate, 20 mg/d) and were prescribed antibiotics (SBT/CPZ, 2 g/d) for 2 d. For cannulation, catheters PR-104Q, R110Q-1 and PR233Q were used. Wire-guided cannulation was not performed. A 0.025-inch or 0.035-inch guidewire (Jagwire: Microvasive, Boston Scientific Corp., Natick, MA, Revo Wave: PIOLAX, or VisiGlide: Olympus Corp., Tokyo, Japan) was used. The endoscopes used were JF240, JF260V, TJF260V (Olympus Corp.), backward side-viewing endoscopes. After cholangiography, a guidewire was placed in the bile duct to conduct endoscopic sphincterotomy (EST). Clever-Cut3V

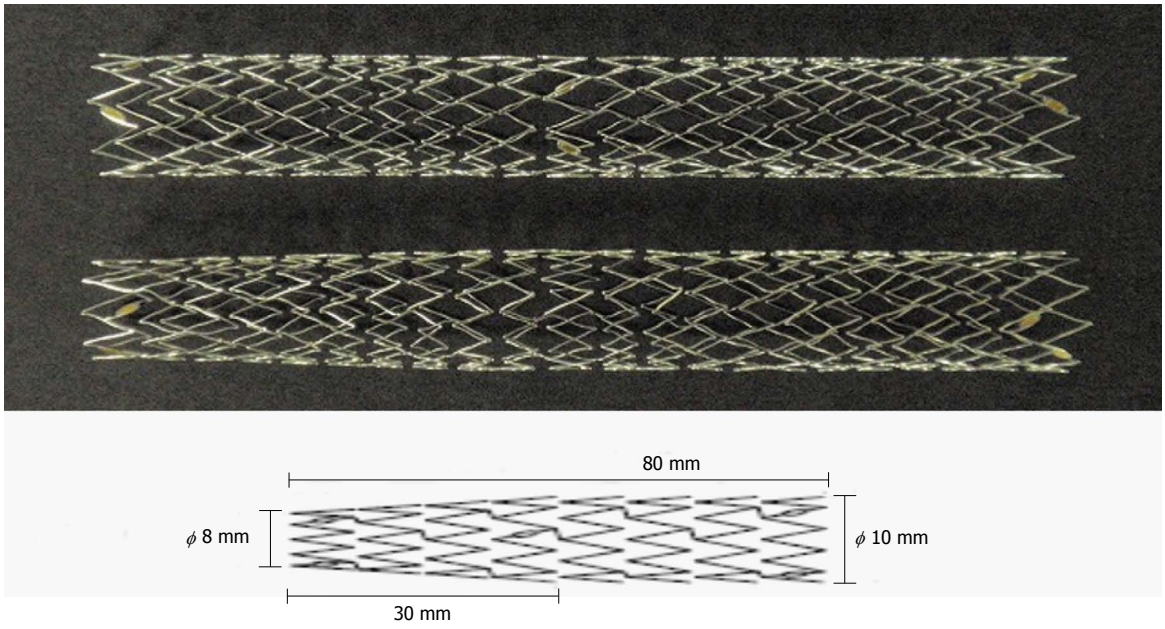

Figure 1 The metallic stent at the top is the ordinary laser-cut uncovered metallic stent. The one at the bottom is the laser-cut uncovered metallic stent (PIOLAX: Japan) created for exclusive use in the liver. This metallic stent is 8 cm in full size with a 3-cm tapered tip and a mesh space of 6-8 mm in the center of the stent; its internal diameter is 10 mm in the papillary side and 8 mm in the hepatic side.

(Olympus Corp.) was used as the knife for EST. EST was conducted using a single electrosurgical current generator (PSD-20, Olympus Corp.) at a power of 25 watts. EST was carried out in all the patients. The effect of drainage was determined by placing an endoscopic nasobiliary drainage (ENBD), or a PS in either the right or left bile duct. The effect of drainage was evaluated 7 d after drainage placement, and it was determined effective if the T-Bil was normal or 2/3 or less; then a tapered MS was placed. In patients without effective drainage, ENBD or PS was placed in the bile duct in the side where the drainage is not placed. An ENBD tube of 7 Fr. was used (FLEXIMA: Boston Scientific Corp., Natick, MA, or SD9: SILUX Straight type). Tube stents of 7 Fr., 8.5 Fr. and 10 Fr. were used (FLEXIMA: Boston Scientific Corp., or SD9: SILUX Straight type). And if the drainage was effective, the new tapered MS was placed in the region. As for tapered MSs, the delivery system is a laser-cut MS created for use exclusively in the liver. These MSs are 7 Fr in size, with a full length of 8 cm and a 3-cm tapered tip. The mesh space is 6-8 mm at the center of the stent, and its internal diameter in the papillary side is 10 mm, while in the hepatic side it is 8 mm (PIOLAX: Japan) (Figure 1). In patients for whom two tapered MSs were required, stenting was performed in the partial stent-in-stent manner[5-7]. The axial force and radial force of this MS were evaluated as follows. Axial force is the unbending force of the MS from the curved part. To measure the axial force, a portion of the stent was pushed perpendicularly by a force gauge (model DPX-5TR, Imada, Tokyo) until the angle became 60 degrees, and the force necessary to keep it in place was recorded. The measurement was made in an oven at 37 ℃ for 3 points distant 20, 40, and 60 mm from the bending point. Radial force is the dilating force of the MS. Radial force was measured using a radial force

measurement machine (RX 500, Machine Solutions, Flagstaff, Ariz) in an oven at 37 ℃. An MS sample in a fully expanded state was placed in the cylindric space of the machine, and the cylinder was contracted to shrink the MS to its minimum size of 2 mm. Then the force on the cylinder was reserved by an expansion force of the MS until it achieved its fully expanded state of 10 mm in diameter. The placement success rate, patency period, occlusion rate, and success rate of re-intervention of this MS were examined. Procedural accidents during ERCP-related procedures were evaluated according to Cotton's classification[8]. When the jaundice level was T-Bil 3 mg/dL less, we started chemotherapy. This study was conducted under approval of our ethical committee, and was registered as prospective clinical trial. UMIN Clinical Trial Registry (UMIN000004758).

Statistical analysis

Fisher's exact probability test, student's *t*-test, and the Mann-Whitney *U*-test were used for statistical analyses to compare the blood test findings prior to drainage insertion and post MS insertion. A *P* value < 0.05 was regarded as significant. Cumulative stent patency and survival were estimated using the Kaplan-Meier estimator. Data were analyzed using SPSS software version 17 (SPSS, Chicago, IL).

MS: Metallic stent.

RESULTS

Initial drainage was successful in 6 (54.5%) of the eleven patients, and the remaining 5 (45.5%) had poor drainage thus drainage in the right and left bile ducts was performed. In the end, drainage was successful in all the patients. Since drainage was effective, MS was placed in all of them. In the six patients who underwent unilateral bile duct drainage one MS was placed, while in the five patients who underwent right and left bile duct drainage, two MS were placed; stenting was successful in all the patients. The mean number of MSs used was 1.545 ± 0.522 (1-2). All the parameters assessed at one week after stenting showed significant improvement compared with those before drainage insertion: ALT 33.00 ± 13.892 (IU/L), ALP 566.91 ± 365.157 (IU/L), and T-Bil 1.373 ± 0.8833 (mg/dL) (Tables 2-4). There were no procedural accidents due to stenting. The axial force of this MS was 0.156 ± 0.017 N when evaluated at bending point 20 mm, and radial force was 4.76 ± 0.18 N when evaluated at a dilated diameter of 4 mm. The patency of MS is shown in Table 5. The mean patency period was 208.401 d, the median survival period was 142.000 d (mean 193.273 d). The occlusion rate was 36.4% (4/11), and the occlusion causes were ingrowth in 2 (18.2%) patients and overgrowth in another 2 (18.2%). Patients with occlusion underwent endoscopic treatment one more time and in all of them it was 100% (4/4) successful. In patients who developed overgrowth in the contralateral hepatic side, an MS was placed in the partial stent-in-stent manner. In patients with an MS in each bile duct who developed overgrowth, an MS was additionally placed. In two patients with two MSs in the right and

left bile duct who developed ingrowth, two PSs were placed in the right and left bile duct in the stent-in-stent manner. Re-treatment was successful in all the occlusion patients. The accidental occurrence symptom about the ERCP related procedures did not accept it.

DISCUSSION

In this study we evaluated a new tapered MS for unresectable malignant hilar bile duct obstruction. The MS used in this study was the laser-cut MS that enables precise stenting because shortening is structurally less[5]. Although evaluation may be partially difficult due to the small sample size, we experienced no procedural accidents during insertion, the patency period was long, and re-intervention was successful in all the patients; thus we consider this is a useful stent. This MS has moderate radial force at low axial force[9]. With regard to procedural accidents, this MS has low axial force, which enables stenting along the bile duct and may prevent kinking. When an MS is placed, usually procedural accidents such as acute pancreatitis or acute cholecystitis do not occur, however, abdominal pain may occur[10]. There may be various causes for this, including stress on the bile duct due to high axial force or strong radial force of the MS, or to a mismatch of the bile duct and MS regarding diameter, especially if the MS is of a diameter larger than that of the hepatic bile duct. The MS used in this study has a low axial force and a moderate radial force as shown in past reports; thus it is useful to treat stenosis and carry out stenting while applying low pressure on the bile duct. Furthermore, the tip is tapered, enabling good positioning of the stent (Figure 2). This may reduce the risk of abdominal pain due to stenting and of procedural complications such as hepatic abscess because the Glisson's sheath is not compressed. In this study no procedural accidents occurred; still if pancreatography is performed frequently during the procedure or it is difficult to catheterize the bile duct, pancreatitis might occur after ERCP[11,12].

As for the patency period, the sample size was small and thus evaluation is difficult. However, the patency period was in the same range as that found in a previous report of similar sample size, and which was considered as satisfactory[13]. The nature of the tumor, effect of chemotherapy, and characteristics of the MS itself may influence the patency period; yet, these should be evaluated in a study involving a large number of patients in the future.

Re-treatment was 100% (4/4) successful. Recent advancement of endoscopes and medical devices has enabled re-treatment in a comparatively easy

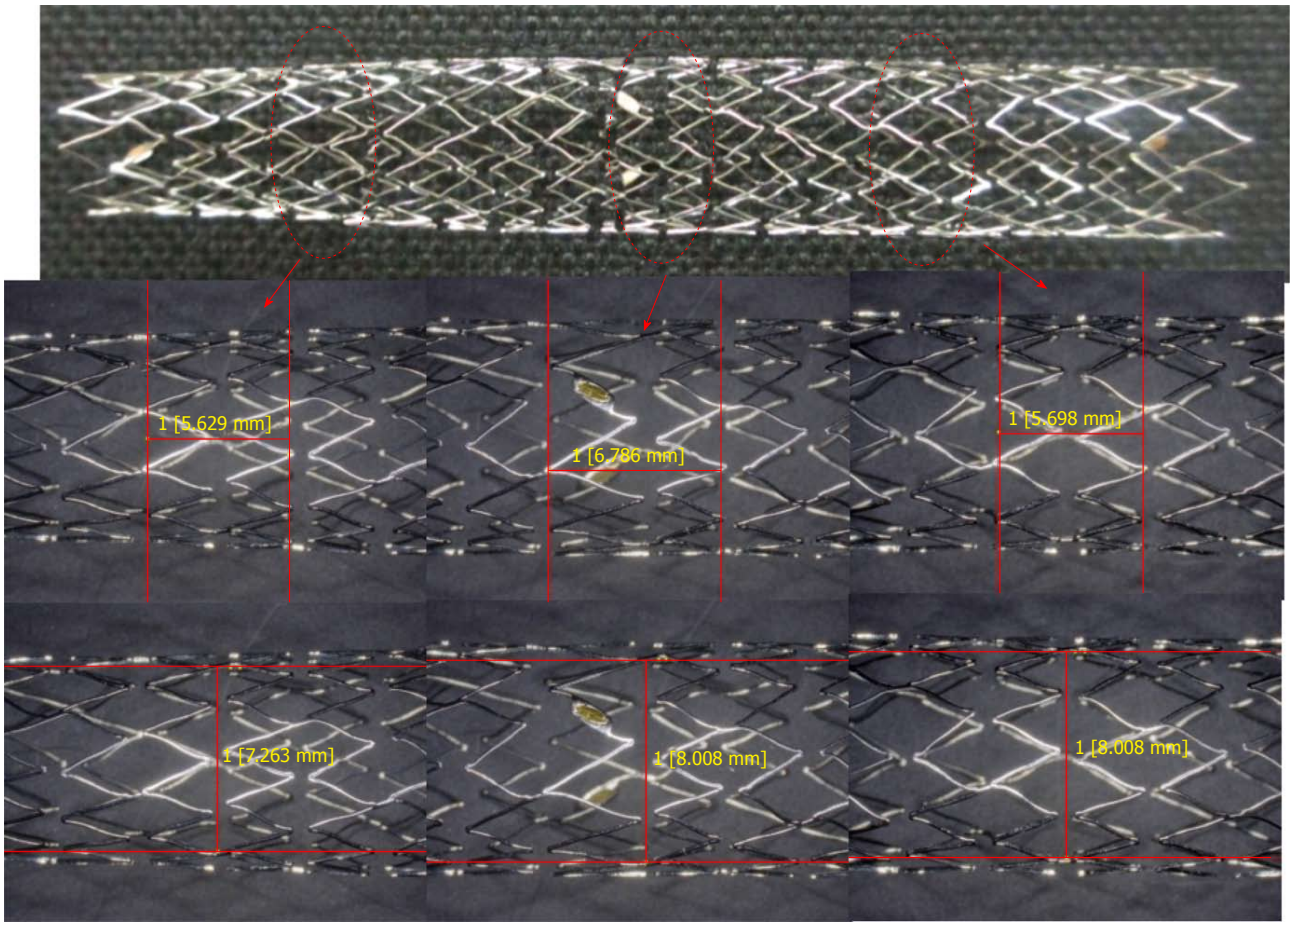

Figure 3 Laser-cut metallic stent with a comparatively large mesh space of about 6.8 mm × 8.0 mm in the center.

way. This MS has a large mesh space that facilitates re-intervention. Indeed, Mukai *et al*[14] reported that in the liver MSs with a large mesh space were an excellent choice because it was easier to re-intervene. Furthermore, other authors have also reported on the usefulness of MSs with a large mesh space that were created for exclusive use in the liver in patients with unresectable malignant hilar bile duct obstruction[13,15]. The MSs used in these reports were of the braided type with a mesh space of 7 mm; that is, a space similar to that of the mesh space of the laser-cut tapered MS used in this study (Figure 3). The laser-cut tapered MS used in this study has a large mesh space, which facilitates manipulation through the mesh and re-intervention. From such results and reports, it is currently considered that MSs with a large mesh space may be an excellent choice for use in the liver. Compared with the braided MS, the laser-cut MS used in this study hardly suffered shortening and enabled precise placement. However, in the future it may be necessary a randomized clinical trial to assess which one is best regarding placement success rate and patency period.

Our results suggested that the new tapered MS was useful for patients with unresectable malignant hilar bile duct obstruction because the patency period was long, re-treatment was possible, and there were no procedural accidents during their insertion.

COMMENTS

Background

Even past randomized controlled trials reported that metallic stents (MSs) are associated with a longer patency period and lower occlusion rate than plastic stents. Under such considerations, it may be necessary to set the strategies to use MSs in patients with unresectable malignant hilar bile duct obstruction.

Research frontiers

In this study, the authors examine the usefulness of a new tapered MS developed for exclusive use in patients with unresectable malignant hilar bile duct obstruction.

Innovations and breakthroughs

It may be necessary to set the strategies to use MSs in patients with unresectable malignant hilar bile duct obstruction.

Applications

A new tapered MS developed for exclusive use in patients with unresectable malignant hilar bile duct obstruction.

Terminology

The results suggested that the new tapered MS was useful for patients with unresectable malignant hilar bile duct obstruction because the patency period was long, re-treatment was possible, and there were no procedural accidents during their insertion.

Peer-review

This study prospectively estimated the efficacy of an uncovered metal stent with slightly tapered shape in its distal end for the patients with malignant biliary obstruction at the liver hilum.

Abstract

Primary splenic lesions are rare entities among which littoral cell angioma (LCA) is a recently described, uncommon vascular lesion that is unique to the spleen. It has heretofore been described primarily in pathologic series and has been found mostly to behave as a benign entity. A few reports of malignant variants have been reported. We present a case report of a solitary LCA discovered after splenectomy for an incidentally discovered splenic lesion, along with a literature review.

Key words: Littoral cell angioma; Splenic tumor

Core tip: Littoral cell angioma (LCA) is a rare benign vascular lesion of the spleen. LCA can range from no symptoms to a vague set of symptoms such as: abdominal pain, splenomegaly, thrombocytopenia, anemia, fever, chills, weakness and fatigue. Diagnosis is made by histopathology after splenectomy.

Bailey A, Vos J, Cardinal J. Littoral cell angioma: A case report. *World J Clin Cases* 2015; 3(10): 894-899 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/894.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.894

INTRODUCTION

Primary splenic tumors are uncommon and are classified as lymphoid tumors, non-lymphoid tumors, and tumor like lesions[1-12] (Table 1). Among non-lymphoid tumors, vascular neoplasms are the most common and arise from the vascular elements that compose the splenic red pulp. Conversely, the lymphatic tissue containing splenic white pulp is from where lymphoid neoplasms arise. In regards to vascular tumors of the spleen, the biologic behavior can be both benign and malignant.

Littoral cell angioma (LCA) of the spleen is a rare vascular tumor that was first described in 1991 by Bhatt *et al*[13]. Initially thought to be benign, the biologic

Table 1 Classification of splenic tumors with associated clinical, pathological and radiological factors[1-12]

Category	Type	Clinical	Pathological	Radiological
Lymphoid	Non Hodgkin lymphoma	Fevers, sweats, change in weight are common symptoms	Derived from B or T cells, lympho-proliferative	CT: Hypodense nodules, diffuse or military distribution MRI: Isotense on precontrast images, hypotense on postcontrast images
	Hodgkins lymphoma	Spleen is a rare primary site	Nodular sclerosis subtype, Reed-Sternberg cells	CT: Hypodense nodules with nodular sclerosis
	Inflammatory pseudotumor	Secondary to inflammatory response to infection or injury Benign	Spindle cells, lymphocytes in fibroblastic stroma	CT: Well circumscribed +/- calcifications, hypoattenuating MRI: Hypo- or isointense on T1 images. Variable signaling on T2 images
	Plasmacytoma	Rare diagnosis	Diffuse infiltration of plasma cells	Not well categorized findings
	Histocytic lymphoma	Non specific symptoms, elevated ESR	Nodules with central necrosis	US: Cystic appearance CT: Sharply demarcated with central necrosis
	Hemangioma	Benign, slow growth, asymptomatic	Sinusoidal epithelium, proliferation of vascular channels	Solid to cystic components US: Echogenic solid to complex mass CT: Iso- to hypoattenuation associated with calcification MRI: Hypo- to isointense on T1 images, hyperintense on T2 images
	Hamartoma	Benign, asymptomatic. Associated with tuberous sclerosis and Wiskott Aldrich	Solid nodules, well circumscribed, well defined gross appearance. Unorganized vascular channels with fibrotic cords	US: More sensitive than CT, solid mass +/- calcification CT: Isoattenuating MRI: Isointense on T1 images, hyperintense
	Lymphangioma	Asymptomatic, benign, mostly in children	Multiple solitary nodules, Flattened endothelium with proteinaceous material in a capillary, cavernous or cystic presentation	US: Splenic cysts hypoechoic septations CT: Thin walled low attenuation masses, subcapsular location MRI: Hypointense on T1 images, hyperintense on T2 images
Vascular	Littoral cell angioma	Asymptomatic, benign with malignant potential	Well delineated nodules of anastomosing vascular channels with endothelial cells	US: Hypoechoic to hyperechoic CT: Iso to hypoattenuating with contrast enhancement MRI: Low intensity lesions
	Angiosarcoma	Older patients, malignant, nonspecific symptoms	Diffuse involvement of spleen arises from sinus endothelial cells, high mitotic rate	US: Complex mass, heterogenous, necrotic degeneration CT: Ill-defined mass with heterogenous enhancement, punctate calcification MRI: Mixed signal intensity on T1 and T2
	Hemangioendothelioma	Nonspecific symptoms, young adults	Variable morphologic appearance	US: Hypoechoic mass CT: Low attenuated mass with enhancement of solid portions MRI: Heterogenous solid mass. Hypointense on T1 and T2 images
	Fibrosarcoma	Asymptomatic	Well differentiated, spindle shaped, fibroblasts, collagen is commonly present	Non specific imaging findings
Non-lymphoid	Lipoma	Asymptomatic	Adipose tissue, no atypia, cytoplasmic vacuoles	CT: Well defined fat density mass
	Kaposi sarcoma	Associated with HIV/AIDS +/- skin lesions	Spindle cell proliferation, spongelike vascular channels	CT: Ill-defined nodules, homogeneous US: Hyperechoic nodules
	Peliosis	Associated with anabolic steroid, TB, AIDS, cancer. Asymptomatic	Cyst like blood filled cavities within splenic parenchyma	US: Echogenic mass CT: Hypoattenuating, multiloculated with septa
Tumor like	Nonparasitic cysts	Congenital or neoplastic in origin. Benign.	Varies according to type of cyst including dermoid cyst	US: Cystic lesions with solid components CT: Hypoattenuating lesions, well defined
	Granulomas	Associated with chronic granulomatous disease and sarcoidosis	Granulomas non-necrotizing or necrotizing	CT: Hypodense nodules MRI: Hypointense T1 and T2

ESR: Erythrocyte sedimentation rate; CT: Computed tomography; MRI: Magnetic resonance imaging; US: Ultrasound; HIV: Human immunodeficiency virus; AIDS: Acquired immunodeficiency syndrome; TB: Tuberculosis.

behavior of LCA has not been firmly established, as there have been several reports of LCA with malignant features[14,15]. LCA may occur at any age and has no gender predilection. To date, a total of 110 cases have been reported in the literature with 4 published pathologic series and 3 published case series[13,16-32].

LCA is discovered as a splenic lesion in patients who are undergoing a workup for laboratory evidence

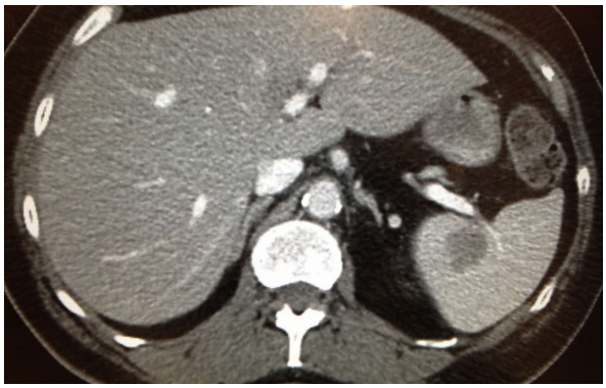

Figure 1 Computed tomography abdomen and pelvis, axial view of hypodense splenic lesion.

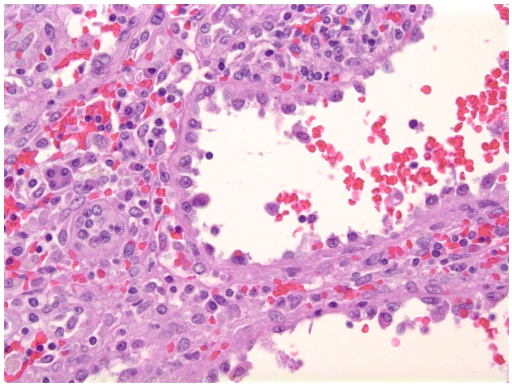

Figure 2 High power view of the tumor demonstrates tall columnar endothelial cells that line the cyst-like spaces. These cells show no cytologic, nuclear atypia or mitotic figures (H and E stain, × 400).

of anemia or thrombocytopenia[33-36]. Imaging findings of LCA are nonspecific and splenomegaly, to a varying degree, is a common finding. Due to the nonspecific findings that often result from the diagnostic workup, splenectomy is often performed for both diagnostic and therapeutic purposes. In the present report, a case of an incidentally discovered LCA is described.

CASE REPORT

A 65-year-old female presented to the outpatient oncology surgery clinic for surgical evaluation of a 2.2 cm splenic lesion. The lesion was discovered incidentally on a computed tomography (CT) abdomen/pelvis study to evaluate recurrent urinary tract infections (Figure 1). Also, the CT scan revealed a second incidental finding of a 1.1 cm right adrenal nodule. The patient was asymptomatic without abdominal pain, persistent fever, chills, weight loss, or other constitutional symptoms. Her past medical history included hypertension, diabetes mellitus, gout and peripheral neuropathy. Physical examination was unremarkable except for abdominal wall scars from prior open hysterectomy, cholecystectomy and left nephrectomy, the latter of which which was performed at a young age for a nonfunctioning

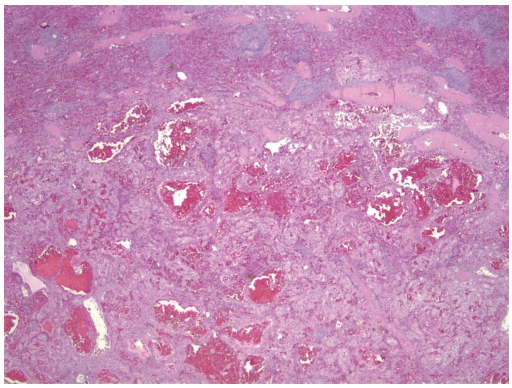

Figure 3 Low power view of the well-demarcated tumor with uninvolved spleen. The tumor has anastomosing vascular channels and cyst-like hemorrhagic spaces.

left kidney secondary to congenital ureteropelvic junction obstruction. A biochemical workup to exclude a functioning adrenal tumor was performed and included serum renin and aldosterone levels as well as 24 h urinary fractionated metanephrine and cortisol levels, all of which were within the limits of normal. Of note, she was not leukopenic, anemic or thrombocytopenic.

Given the size of her incidentally discovered splenic lesion, she was offered operative resection for diagnostic purposes. Based on her extensive prior surgical history, an open approach to the splenectomy was planned. The patient received preoperative pneumococcal, meningococcal and haemophilus B vaccinations. The operation and recovery were uneventful and the patient was discharged to home on postoperative day four.

Grossly, the spleen weighed 270 g and measured 23.3 cm × 18.1 cm × 7.2 cm. The splenic lesion measured 2 cm × 2 cm × 2 cm. Histopathologically, the tumor was found to have anastomosing vascular channels with large cyst formations which were lined predominately by tall, histiocytoid cells which projected into the vascular spaces along with interspersed flat endothelial cells (Figures 2 and 3). Immunohistochemically, the cells compromising the tumor stained positive for CD68 and lysozyme (Figures 4A and B). The specimen also showed variable expression of S100. CD34 and CD31 stains were positive on the endothelial cells, however negative on the histiocytoid cells (Figures 4C and D). Final pathologic diagnosis was littoral cell angioma.

DISCUSSION

LCA is a rare vascular neoplasm of the spleen. It has been found to affect both men and women in an equal distribution. Given the relative lack of symptom specificity, LCA is most often found incidentally as a splenic mass on abdominal imaging; however, two cases of LCA presenting with splenic rupture and hemoperitoneum have been reported[37,38]. The sonographic appearance of LCA is variable, and ranges from a hypoechoic to a hyperechoic mass with a mottled texture[14]. On contrast

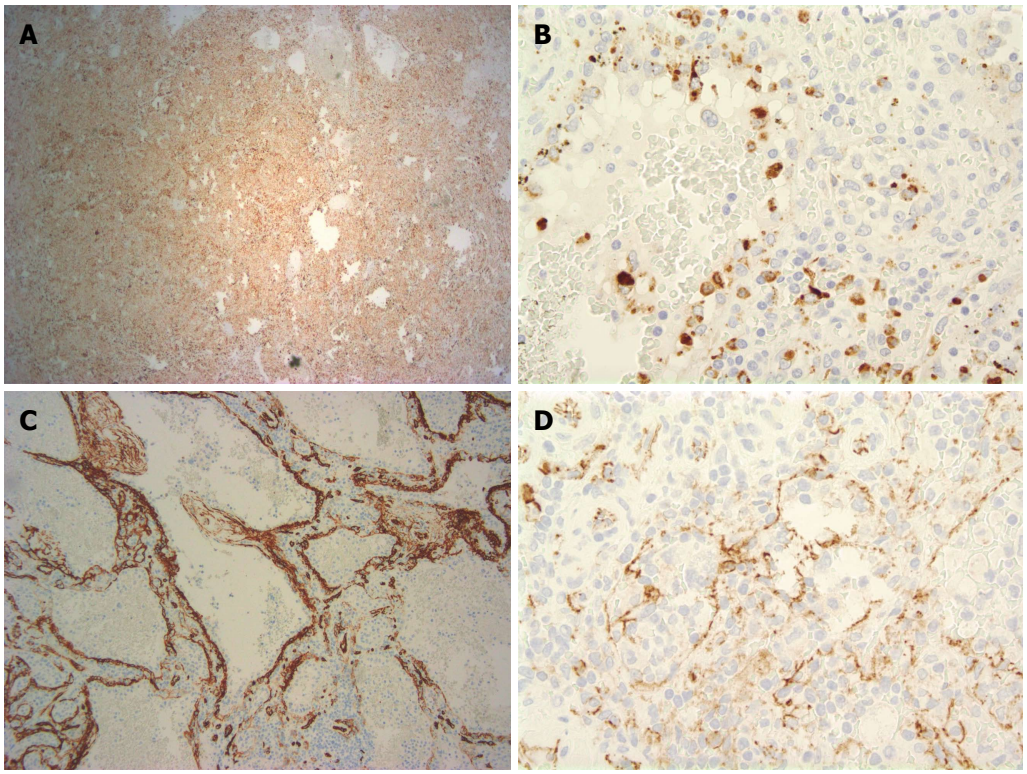

Figure 4 Endothelial cells lining the cyst-like spaces are immunoreactive. A: CD68 (CD68 stain, × 100); B: Histiocytic marker lysozyme (lysozyme stain, × 400); C: Endothelial marker CD34 and the histocytoid cells are negative for CD34 (CD34 stain, × 400); D: Endothelial marker CD31 (CD31 stain, × 400).

enhanced CT, LCA is isodense to slightly hypodense as related to the surrounding splenic parenchyma in both the arterial and early portal venous phase[39,40]. Magnetic resonance imaging characteristically shows a T1 and T2 hypointense mass. LCA is often multifocal and lesions can be variable in size[14]. The differential diagnosis of lesions that can mimic LCA on imaging includes lymphangioma, hamartoma, lymphoma, Kaposi' s sarcoma, and hemangioma. Therefore, a definitive diagnosis can only be obtained pathologically[41].

Pathologically, LCA is a vascular tumor of the spleen that represents a tumoral counterpart of the normally present littoral cells that line the splenic sinus channels of the red pulp[30]. First described by Falk *et al*[33] in 1991 in a pathologic series of 17 cases, this new entity was described histologically as consisting of anastomosing vascular channels with cyst like spaces and papillary projections. The endothelial cells lining the channels are tall and plump compared to the flat endothelial cells lining the channels in a normal spleen. Immunohistochemically, LCA is characteristically CD 34 negative, CD 68 positive, CD 21 positive and CD 8 negative[22]. Additionally, the epithelial cells in LCA do occasionally express S-100 protein[16]. High expression of formin homology domain protein 1 (FHOD1) distinguished littoral cells from LCA. FHOD1 protein is expressed by normal littoral cells, not by LCA[42]. Further research has been done evaluating molecular markers and LCA to help aide in the accurate diagnosis of LCA tumors. O'Malley *et al*[43], looked at splenic lesions and the activity of the Ets Related Gene (*ERG*) and the Wilms Tumor-1 gene (*WT-1*). They found that LCA splenic lesions had a pattern of ERG positive and WT-1 negative[43]. Of the other types of splenic lesions evaluated cavernous hemangiomas were found to have the same pattern, therefore these markers are not specific enough alone to make the diagnosis of LCA.

LCA has most commonly been described as a benign process. However, observations of malignant behavior have been described[41]. In one case, metastatic lesions were found in the liver and retroperitoneum four years after splenectomy for LCA[44]. This case initially had symptoms of ureteral obstruction and renal failure. In comparison, our patient did not have ureteral obstruction however did have recurrent UTI's and a history of congenital ureteropelvic junction obstruction. Kranzfelder *et al*[45], showed a case of familial individuals with LCA and primary splenic angiosarcoma, raising the question of possible malignant transformation. There were no similar signs and symptoms between their case and the presented case. Harmon *et al*[17], published a case report of a patient with transitional cell carcinoma of the bladder with suspected splenic metastasis. The pathology revealed LCA and not splenic metastasis. Ben-Izhak *et al*[14], showed a case of malignant littoral cell tumor naming it littoral cell hemangioendothelioma. This case report featured a symptomatic patient with liver metastasis eight years after splenectomy. In reviewing all of these cases, the immunohistochemical pattern was similar giving the diagnosis of LCA.

LCA has been shown to be rarely associated with visceral malignancies including colorectal adenocarcinoma, pancreatic cystadenocarcinoma, pancreatic neuroendocrine tumor, renal cell cancer, hepatocellular carcinoma, non-small cell lung cancer, seminoma, ovarian cystadenocarcinoma, papillary thyroid cancer and transitional cell carcinoma of the bladder[17]. Furthermore, there have been a few reports describing an association of LCA with immunological disorders, such as, ankylosing spondylitis, myelodysplastic syndrome, non-Hodgkin lymphoma, Crohn's disease, Wiskott Aldrich syndrome, chronic glomerulonephritis, aplastic anemia and Gaucher's disease[17,22,46]. Given the association of LCA with other malignancies as well as the few reported cases of malignant behavior, patients should undergo close follow up after splenectomy; however, no established postoperative surveillance guidelines exist.

Littoral cell angioma is a rare vascular tumor of the splenic red pulp, and is typically an incidental finding on abdominal imaging. The splenic lesion can only truly be differentiated from other splenic masses by histologic examination. Splenectomy is the appropriate treatment, as LCA has a variable behavior pattern of which malignant tendencies are worrisome. Furthermore, longitudinal surveillance in the postoperative phase is recommended.

COMMENTS

Case characteristics

Littoral cell angioma (LCA) can range from no symptoms to a vague set of symptoms such as: abdominal pain, splenomegaly, thrombocytopenia, anemia, fever, chills, weakness and fatigue.

Clinical diagnosis

The main clinical finding is a splenic lesion.

Differential diagnosis

The differential diagnosis of a splenic lesion is lymphoid, vascular, non lymphoid and tumor like which can be distinguished by pathology.

Imaging diagnosis

Ultrasound, computed tomography and magnetic resonance imaging are all acceptable modalities for imaging and diagnosing a splenic tumor; all of which are non-specific for LCA.

Pathological diagnosis

The splenic specimen is analyzed for abnormal littoral cells along with immunohistochemical stains to provide definitive diagnosis of LCA.

Treatment

Treatment is surgical resection with close surveillance as a malignant variant is possible.

Related reports

Over a hundred cases of LCA have been reported since 1991, research continues into the realm of pathological markers and surveillance is new territory with cases of malignant variants being reported.

Term explanation

Hemangioendothelioma is a term to describe a vascular neoplasm that may be considered benign as well as malignant.

Experiences and lessons

This case teaches that there is malignant potential for LCA lesions of the spleen.

Peer-review

This is the well-written case report of LCA.

Abstract

Acute hepatitis is a very rare, but potentially fatal, adverse effect of intravenous amiodarone. We present a case of an 88-year-old man with history of ischemic dilated cardiomyopathy and severely depressed left ventricular function that was admitted to our coronary care unit with diagnosis of decompensated heart failure and non-sustained ventricular tachycardia. A few hours after the beginning of intravenous amiodarone he developed an acute hepatitis. There was a completely recovery within the next days after amiodarone withdrawn and other causes of acute hepatitis have been ruled out. This case highlights the need for close monitoring of hepatic function during amiodarone infusion in order to identify any potential hepatotoxicity and prevent a fatal outcome. Oral amiodarone is, apparently, a safe option in these patients.

Key words: Polysorbate 80; Hepatitis; Hepatotoxicity; Idiosyncratic reactions; Amiodarone

Core tip: We report a rare case of acute hepatitis induced by intravenous amiodarone in a patient with non-sustained ventricular tachycardia. The physiopathology of this adverse effect is still unclear. Close monitoring of hepatic function during amiodarone infusion is essential to avoid any potential hepatotoxicity.

INTRODUCTION

Long-term oral amiodarone therapy is associated with many extracardiac adverse effects, such as thyroid dysfunction, photosensitivity, corneal microdeposits and pulmonary and hepatic toxicities. The frequency

of most adverse effects is related to the total drug exposure. Hepatic toxicity in these patients ranges from an asymptomatic elevation of serum aminotransferases (in approximately 25%) that is usually transient and resolves after dose reduction or withdrawal, to severe liver disease (1%-3%)[1]. Acute hepatic toxicity during intravenous amiodarone has been rarely described[2-6].

CASE REPORT

An 88-year-old man with history of ischemic dilated cardiomyopathy and severely depressed left ventricular function presented at Emergency Department due to progressive worsening of dyspnea, orthopnea and peripheral edema during the previous week. He was on long-term treatment with aspirin, ramipril, furosemide, transdermal nitroglycerin, sinvastatine and pantoprazole. He had no history of alcohol abuse or chronic acetaminophen intake.

On physical examination, blood pressure was 110/60 mmHg and percutaneous peripheral oxygen saturation was 87% on air. He had bilateral basilar rales on pulmonary auscultation and moderate lower leg edema. Arterial gasometry confirmed type 1 respiratory failure and blood tests were unremarkable, including liver function. Electrocardiogram monitoring revealed periods of non-sustained ventricular tachycardia (NSVT).

He was admitted to our coronary care unit with the diagnosis of acute decompensated heart failure and NSVT. He was started on intravenous amiodarone with a bolus dose of 300 mg followed by a continuous infusion of 900 mg over 24 h. Control blood tests performed 18 h after starting amiodarone showed an abrupt elevation of aminotransferases (aspartate aminotransferase 3398 U/L, alanine aminotransferase 1964 U/L), lactate dehydrogenase (2127 U/L), direct bilirubin (2.47 mg/dL) and international normalized ratio (2.79). Gamma-GT and alkaline phosphatase were normal. Despite hemodynamic and ventricular electric stability, he evolved with worsening of hepatic function associated with thrombocytopenia, metabolic acidosis and acute kidney injury. Abdominal ultrasonography showed a liver with normal appearance and excluded hepatic artery and vein thrombosis and any bile duct abnormalities. Viral hepatitis serologies (hepatitis B and C, cytomegalovirus, Epstein-Barr and herpes zoster viruses) and autoimmune markers (antinuclear antibody, anti-smooth muscle antibody, anti-liver/kidney microsomal antibody type 1) were negative.

Drug-induced liver injury secondary to amiodarone was the main diagnostic hypothesis and amiodarone was withdrawn about 40 h after its beginning (total dose of 1800 mg). Since then, he improved gradually with progressive normalization of renal and hepatic function (Figures 1 and 2). At day 4, he restarted amiodarone in oral form, at loading doses of 200 mg three times daily, without any additional liver injury. There was no recurrence of VT and he was discharged on day 12 with nearly normal hepatic tests.

DISCUSSION

This report describes a severe acute hepatitis induced by intravenous amiodarone. Among the few cases reported in literature of idiosyncratic reactions to intravenous amiodarone, some had a fatal outcome[4-6].

American College of Gastroenterology guidelines recommends that the causality assessment in patients with drug-induced hepatic injury should rely primarily on consensus expert opinion following a thorough evaluation for competing etiologies[7]. The causal relationship between intravenous amiodarone exposure and acute hepatitis has been established based on the following principles: (1) Sudden hepatic tests abnormalities within 24 h after starting amiodarone administration; (2) Presence of a pattern of hepatocellular injury with peak aminotransferases levels of more than 50 times the upper limit of normal; (3) Rapid improvement after amiodarone withdrawal; and (4) Exclusion of other causes.

It's often difficult to distinguish between this entity and acute hepatic ischemia since many of these patients on intravenous amiodarone present hemodynamic instability. In this case, the patient was under invasive monitoring and maintained mean arterial pressure superior to 75 mmHg, which makes the diagnosis of ischemic hepatitis unlikely. He also didn't have a severe congestive heart failure that could possibly explain a congestive hepatopathy. Thrombocytopenia and acute kidney injury were assumed to be secondary to acute hepatic injury. Because of his favorable evolution, we did not perform a hepatic biopsy.

According to the Council for International Organizations of Medical Sciences/Roussel Uclaf Causality Assessment Method scale[8] this case fulfilled the criteria of a highly probable amiodarone adverse effect.

The physiopathology of this adverse effect is still unclear. Different potential mechanisms have been proposed, including an immunologically mediated mechanism[9,10], a free radical mechanism, in which formation of free radicals leads to peroxidative injury of membrane lipids and necrosis[11,12] and a mechanism based in increased expression of the *PPAR-*α gene secondary to disrupted hepatic lipid homeostasis[13]. The mechanism of oral amiodarone induced hepatotoxicity seems to be different from that induced by intravenous amiodarone. Some reports, including our own, showed that introduction of oral amiodarone in these patients did not result in any additional liver injury. Based on this observation, Rhodes *et al*[14] proposed that polysorbate 80, the solvent of intravenous formulation of amiodarone, could be involved in this adverse effect since it is present in the intravenous but not in the oral form of amiodarone. Polysorbate 80 has been implicated in the E-ferol syndrome, which has been described in infants after intravenous administration of E vitamin with this component[15]. The E-ferol syndrome shows significant similarities to the cases of liver toxicity due to amiodarone[14]. In addition, polysorbate 80 has a short

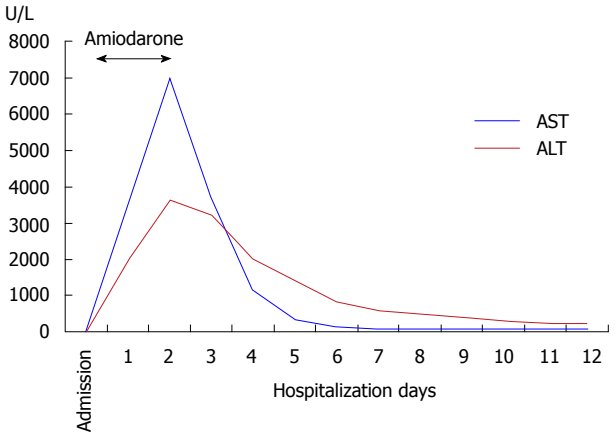

Figure 1 Evolution of aminotransferases levels during hospitalization. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

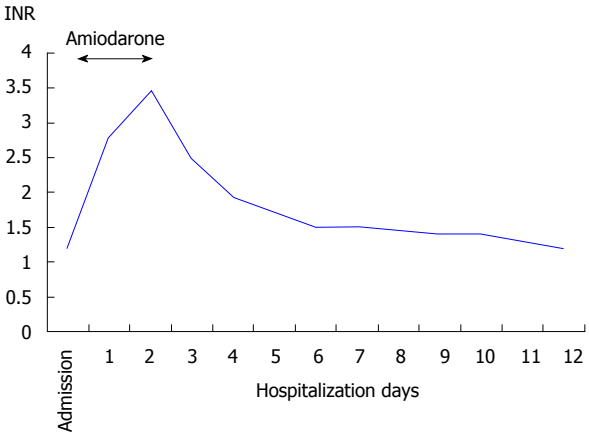

Figure 2 Evolution of international normalized ratio levels during hospitalization. INR: International normalized ratio.

plasma half life, which could justify the rapid recover of hepatic failure after discontinuation of intravenous amiodarone. In 2008 Food and Drug Administration approved a polysorbate-free formulation of amiodarone (Nexterone, Baxter Healthcare Corporation, Deerfield, IL), however it's still not available in several hospitals.

In conclusion, acute hepatotoxicity is a rare, but potentially fatal, adverse effect of intravenous amiodarone. This case highlights the need for close monitoring of hepatic function during amiodarone infusion in order to identify any potential hepatotoxicity and prevent a fatal outcome. If available, it should be considered the use of polysorbate-free formulation of intravenous amiodarone. Oral amiodarone is, apparently, a safe option in these patients.

COMMENTS

Case characteristics

An 88-year-old man admitted with acute decompensated heart failure and non-sustained ventricular tachycardia underwent intravenous amiodarone.

Clinical diagnosis

The patient developed severe acute hepatitis induced by intravenous amiodarone.

Differential diagnosis

Acute viral hepatitis, autoimmune hepatitis, ischemic liver injury, congestive hepatopathy.

Laboratory diagnosis

Aspartate aminotransferase 3398 U/L, alanine aminotransferase 1964 U/L, lactate dehydrogenase 2127 U/L, direct bilirubin 2.47 mg/dL and international normalized ratio 2.79; viral hepatitis serologies and autoimmune markers were negative.

Imaging diagnosis

Abdominal ultrasonography showed a liver with normal appearance and excluded hepatic artery and vein thrombosis and any bile duct abnormalities.

Pathological diagnosis

Hepatic biopsy was not performed due to favorable evolution after amiodarone withdrawal.

Treatment

The treatment was mainly supportive after amiodarone withdrawal.

Related reports

Few cases of acute hepatic injury after intravenous amiodarone have been reported in literature. Some of them had a fatal outcome.

Term explanation

Idiosyncratic reactions are unpredictable adverse drug reactions that do not occur in most patients, but can be life-threatening.

Experiences and lessons

This case highlights the need for close monitoring of hepatic function during amiodarone infusion in order to identify any potential hepatotoxicity and prevent a fatal outcome. Oral amiodarone is, apparently, a safe option in these patients.

Peer-review

This is a well written case report on a serious complication following *iv* amiodarone administration.

Abstract

Congenital hepatic fibrosis is part of many different malformation syndromes, of which oculo-encephalo-hepato-renal syndrome is the most common. These syndromes largely overlap, and so accurate classification of individual patients may be difficult. We present herein three syndromic siblings who were products of a consanguineous marriage. We investigated in detail at least six organ systems in these patients, namely the liver, brain, eye, kidneys, skeleton, and gonads. The common features observed in these three cases were congenital hepatic fibrosis, retinitis pigmentosa, truncal obesity, rotatory nystagmus, mental retardation, advanced myopia, and high-arched palate. The clinical dysmorphology in these patients was distinct and lacked the major features of the known syndromes associated with congenital hepatic fibrosis. Although some features of these presented cases are similar to those found in Bardet-Biedl syndrome (BBS), the absence of some major criteria of BBS (polydactyly, renal abnormality, and hypogonadism) suggests that this may be a new syndrome. All three patients remain under follow-up in the departments of Gastroenterology, Ophthalmology, and Neurology at Hacettepe University.

Key words: Congenital hepatic fibrosis; Nystagmus; Mental retardation; Retinitis pigmentosa; High-arched palate

Core tip: Congenital hepatic fibrosis is an inherited disorder that may also accompany other congenital syndromes. Here, we present three siblings with a new variant syndrome characterized by congenital hepatic fibrosis, retinitis pigmentosa, mental retardation, nystagmus, high-arched palate, truncal obesity, and advanced myopia.

INTRODUCTION

Congenital hepatic fibrosis (CHF) is an autosomal recessive inherited malformation defined pathologically by a variable degree of periportal fibrosis and irregularly-shaped proliferating bile ducts[1,2]. The exact incidence and prevalence of CHF are not known, but it is a rare disease. By 1981, only 200 patients with CHF had been reported in the literature[3]. The first manifestations of the disease in most patients are signs or symptoms related to portal hypertension, especially splenomegaly and varices, often with gastrointestinal bleeding[4]. The clinical manifestations of CHF are non-specific, making the diagnosis of this disorder difficult. Although the onset of symptoms and signs is highly variable (ranging from early childhood to the 6th decade of life), CHF is most frequently diagnosed during adolescence or young adulthood[4]. The late appearance of symptoms and their clinical evolution suggest that CHF is a dynamic and progressive condition.

CHF occurs in association with a range of both inherited and non-inherited disorders. Described herein are three siblings from consanguineous parents, all of whom had CHF in conjunction with retinitis pigmentosa, truncal obesity, rotatory nystagmus, mental retardation, advanced myopia, and high-arched palate. The aim of this report was to evaluate the clinical findings of these three cases and to compare these findings with relevant syndromes; Joubert, Bardet-Biedl, cerebellar vermis hypoplasia, oligophrenia, ataxia, coloboma, hepatic fibrosis (COACH), Arima, and Meckel, among others.

CASE REPORT

Patient 1

The eldest child of the family is a 34-year-old female patient who presented with nystagmus, truncal obesity [body mass index (BMI): 29, waist circumference: 97 cm], and blurred vision. The family history was unremarkable, with the exception that her parents were first cousins. She reported that her liver disease and splenomegaly were discovered when she presented to the hospital for pneumonia at the age of seven, whereupon she underwent splenectomy and then cholecystectomy.

Laboratory studies revealed the following: hemoglobin 13.4 g/dL, white blood cell count 9200/mm^3, platelet count 246000/mm^3, international normalized ratio 1.09, partial thromboplastin time 28.3 s, aspartate aminotransferase (AST) 27 U/L, alanine aminotransferase (ALT) 25 U/L, gamma glutamyl transpeptidase (GGT) 32 U/L, total bilirubin 0.59 mg/dL, and albumin 3.4 g/dL. Serum electrolytes, renal function, and urinary examination were normal. The real time and Doppler ultrasonographic examination revealed portal vein cavernous transformation, a heterogeneous liver, and normal kidneys. A needle biopsy of the liver showed an increased number of irregularly-shaped bile ducts, with nodularity of the liver parenchyma accentuated by fibrous septa typical of CHF (Figure 1).

Her neurological examination demonstrated mild mental retardation, normal motor examination aside from hypoactive deep tendon reflexes (+1), and normal cerebellar tests. She had a high-arched palate, dystonia in her hands, and pes planus. Her vibration and position senses were decreased. Brain magnetic resonance imaging (MRI) revealed bilateral substance deposition in the globus pallidus, suggesting the presence of chronic liver disease.

She had exhibited signs of blurred vision in infancy/childhood, but her family was not concerned until she attended primary school. She had significant myopia and rotatory nystagmus with normal facial expression (Figures 2 and 3). Fundus examination revealed a pale optic disc, abundant bone spicules involving even the macula, and advanced arterial sclerosis. She also had myopia and rotatory nystagmus. Her bilateral visual acuity was restricted to hand movements only. Electroretinography yielded findings of retinitis pigmentosa (Figure 4). Examination of other cranial nerves yielded normal findings. No respiratory or cardiac abnormalities were found, and she had normal secondary sex characteristics.

Patient 2

The second patient, a 31-year-old female and the sister of the first patient, also presented with blurred vision, nystagmus, and truncal obesity (BMI: 33, waist circumference: 107 cm).

Laboratory tests revealed the following: hemoglobin 13.4 g/dL, white blood cell count 6600/mm^3, platelet count 223000/mm^3, ALT 19 U/L, AST 23 U/L, GGT 64 U/L, alkaline phosphatase 70 U/L, total bilirubin 0.72 mg/dL, blood urea nitrogen (BUN) 8 mg/dL, creatinine 0.69 mg/dL, and albumin 4.2 g/dL. Urinary examination was normal. Findings of a liver biopsy of this patient were also consistent with CHF (Figure 5).

Her neurological examination showed mental retardation, normal motor examination aside from hypoactive deep tendon reflexes, normal cerebellar tests, and a

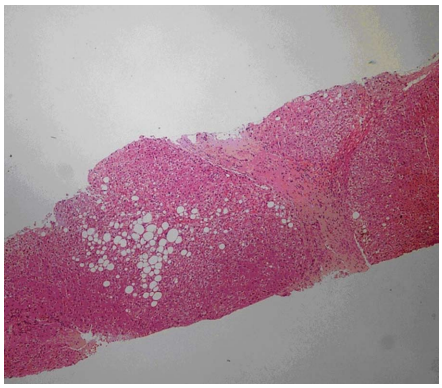

Figure 1 Liver biopsy showing an increased number of abnormal bile ducts, with nodularity of liver parenchyma accentuated by fibrous septa.

negative Romberg test. Her sensation of vibration and position was decreased. Her brain MRI yielded normal findings. She had a high-arched palate.

The patient's blurred vision was noticed while in primary school. Although decreased, her visual acuity was better than her elder sister; 2/20 with significant myopia bilaterally. Fundus examination revealed a pale optic disc, abundant bone spicules involving even the macula, and advanced arterial sclerosis. She also had rotatory nystagmus. Electroretinography yielded findings of retinitis pigmentosa. Examination of other cranial nerves yielded normal findings. No respiratory, cardiac, or renal abnormalities were found, and she had normal secondary sex characteristics with regular menses.

Patient 3

The third patient, a 30-year-old male and the brother of the first two patients, also presented with blurred vision, nystagmus, and truncal obesity (BMI: 28, waist circumference: 97 cm). Laboratory tests revealed the following: hemoglobin 15.3 g/dL, white blood cell count 5900/mm^3, platelet count 92000/mm^3, ALT 67 U/L, AST 46 U/L, GGT 122 U/L, alkaline phosphatase 107 U/L, total bilirubin 1 mg/dL, BUN 14 mg/dL, creatinine 0.85 mg/dL, and albumin 4.6 g/dL. Urinary examination was normal. Liver biopsy of this patient was also consistent with CHF (Figure 6).

Patient 3 also had mental retardation, although less pronounced than his sisters. He did not have any motor deficit, aside from hypoactive deep tendon reflexes (+2). His cerebellar tests were normal and Romberg test was negative. His brain MRI revealed normal findings.

The patient's blurred vision and night blindness were noticed while in primary school. He managed to finish primary school in a special facility for mentally retarded children. His visual acuity was 1/20 bilaterally, with significant myopia. Fundus examination revealed a pale optic disc, abundant bone spicules involving even the macula, and advanced arterial sclerosis. He also had rotatory nystagmus. Electroretinography yielded findings of retinitis pigmentosa. Examination of other cranial nerves yielded normal findings. No respiratory, cardiac, or renal abnormalities were found. He had normal secondary sex characteristics, was married, and had one child.

DISCUSSION

CHF has been described frequently in combination with other abnormalities, such as renal disease, cerebellar malformations, and mental retardation[5,6]. The term oculo-encephalo-hepato-renal syndrome is currently employed to report this association. This syndrome is not a single entity, but rather a group of disorders including COACH[7], Meckel[5], Joubert[8], and Arima syndromes[9] (Table 1). These syndromes largely overlap, and so accurate classification of individual patients may be difficult. It has been suggested that the basic defect in COACH, Joubert syndromes, and other similar conditions might be a disturbance in normal epithelial-mesenchymal interactions due to different genetic mutations[8].

A special subgroup of CHF is COACH syndrome, which is characterized by hypoplasia of the cerebellar vermis, oligophrenia, congenital ataxia, coloboma, and hepatic fibrosis[7]. The abnormalities observed in this syndrome appear to be variable. Numerous congenital anomalies were reported to accompany this syndrome, including slender long bones, postaxial polydactyly, pulmonary stenosis, and atrial septal defect. We found no anomalies involving the kidneys, lungs, or heart in any of our patients, and they did not have ataxia. Furthermore, the absence of the primary features of COACH syndrome (*i.e.*, oligophrenia and ocular coloboma, polydactyly, ataxia, and cerebellar vermis hypoplasia) in our patients excludes that diagnosis.

Another member of this group of disorders, Arima syndrome, is characterized by cerebellar vermis hypoplasia, psychomotor retardation, ocular abnormalities including nystagmus, and polycystic kidneys. Of those, only mental retardation and nystagmus was evident in our patients. Moreover, death in infancy is common in this syndrome, usually due to respiratory failure, and survivors usually have severe mental retardation[10].

Joubert syndrome is an autosomal recessive condition distinguished by hypoplasia of the cerebellar vermis, hypotonia, retinal dystrophy characterized by abnormal eye movements, and impaired psychomotor development together with an abnormal respiratory pattern[11]. This syndrome is genetically heterogeneous with mutations in two genes (*AHI-1* and *CEP290*) identified to date[12]. Although not a constant feature, CHF has also been reported to co-exist with Joubert syndrome. Molar tooth sign (MRI appearance of hypoplasia of the cerebellar vermis and accompanying brainstem abnormalities in an axial plane through the junction of the midbrain and pons) is nearly a pathognomonic finding for this syndrome. In our previous study, we reported two sisters with Joubert syndrome and CHF

Table 1 Comparison of our cases with other related syndromes

who presented with abnormal eye movements, speech disorder, and mental motor retardation. Their MRIs were suggestive of Joubert syndrome[6]. However, none of the current three patients had molar tooth sign on MRI, essentially excluding Joubert syndrome. The overlapping features of our patients with Joubert syndrome included poor vision, nystagmus, retinitis pigmentosa, and CHF. These are not constant findings for Joubert syndrome, but have been reported in the literature as co-existent.

Cohen's syndrome is one of the rare autosomal recessive disorders that are over-represented in the Finnish population[13]. The phenotype in Finnish patients is highly homogenous, consisting of non-progressive mild to severe psychomotor retardation, motor clumsiness, microcephaly, characteristic facial features, childhood hypotonia and joint laxity, progressive retinochoroidal dystrophy, myopia, intermittent isolated neutropenia,

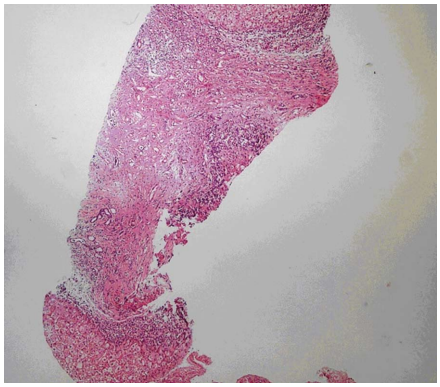

Figure 6 Liver showing nodular appearance due to fibrous bands in which bile ducts are elongated and periportal ductular proliferation is seen.

and a cheerful disposition. The characteristic facial features include high-arched or wave-shaped eyelids, a short philtrum, thick hair, and low hairline. Truncal obesity appearing during or after mid-childhood can be seen in a minority of individuals with the syndrome[14]. Our cases share some features of Cohen's syndrome, such as retinitis pigmentosa, myopia, mental retardation, and obesity, but facial dysmorphism and the other aforementioned features which are highly typical for Cohen's syndrome were absent in our cases.

Retinitis pigmentosa is the term given to a set of hereditary retinal diseases that feature degeneration of rod and cone photoreceptors[15]. A major form of syndromic retinitis pigmentosa, Bardet-Biedl syndrome (BBS), is variably associated with obesity, cognitive impairment, polydactyly, hypogenitalism, and renal disease[16]. BBS has also been found to be associated with CHF. Three families with BBS mapped to the BBS2, BBS3, and BBS4 loci of 2q31 were recruited in one study for a comprehensive eye exam and, in selected cases, electroretinography testing. The results of that study suggested that BBS3 and BBS4 mutations may play a role in the development of myopia[17]. Our patients share primary (truncal obesity and retinitis pigmentosa) and secondary (high-arched palate and CHF) features of BBS. Truncal obesity was defined in our patients according to the International Diabetes Federation 2005 criteria[18]. However, the primary features of BBS, such as postaxial polydactyly, hypogonadism, and renal abnormalities, were absent in the presented cases. Different mutations in unknown genes could possibly be responsible for the advanced myopia in our patients, similar to the situation in BBS. Although myopia has been rarely reported in BBS, advanced myopia was noted in our cases.

In forming the diagnostic criteria for each syndrome, it is important to consider anatomical malformations in conjunction with the clinical signs and symptoms. We investigated six organs in detail, namely the liver, brain, eye, kidneys, skeleton, and gonads. There are major anatomical malformations of the kidney, hands (polydactyly), and gonads in BBS, and of the brain in Joubert, Arima, COACH, and Meckel syndromes. As shown in Table 1, our cases, who presented with CHF, advanced myopia, rotatory nystagmus, truncal obesity, retinitis pigmentosa, mental retardation, and high-arched palate, did not have all or even at least three major components of any listed syndrome. The authors

entertain the possibility that our cases may represent a new syndrome. As shown in Table 1, the presented cases most closely resemble BBS. Beales *et al*[16] reviewed the diagnostic criteria of BBS after evaluating 112 cases based on their clinical findings and they added new criteria; however, liver fibrosis was not included as part of BBS. The predominance of liver fibrosis and the absence of polydactyly, renal abnormality, and hypogonadism in our cases distinguish them from BBS. These clinical findings suggest that our patients might represent a new syndrome.

Our report may contribute to a better delineation of the variable clinical expression of cases within the spectrum of oculo-encephalo-hepato-renal syndromes.

COMMENTS

Case characteristics

Three patients presented with blurred vision and truncal obesity.

Clinical diagnosis

Abnormal signs on physical examination were mental retardation, high-arched palate, pes planus, myopia, rotatory nystagmus, and retinitis pigmentosa on electroretinography.

Differential diagnosis

Cerebellar vermis hypoplasia, oligophrenia, ataxia, coloboma, hepatic fibrosis (COACH), Meckel, Joubert, Arima, Cohen, Bardet-Biedl syndromes.

Laboratory diagnosis

Laboratory test results were essentially within normal limits, with the exception of mildly-elevated alanine aminotransferase in two patients and mild thrombocytopenia in one patient.

Imaging diagnosis

Doppler examination in one patient revealed portal cavernous transformation, while magnetic resonance imaging of the brain was within normal limits in all patients.

Pathological diagnosis

Liver biopsy revealed an increased number of irregularly-shaped bile ducts, with nodularity of the liver parenchyma accentuated by fibrous septa typical of congenital hepatic fibrosis (CHF) in all patients.

Treatment

The patients did not require immediate treatment, but were treated for their ophthalmological disturbances.

Related reports

The co-existence of CHF, retinitis pigmentosa, mental retardation, nystagmus, high-arched palate, truncal obesity, and advanced myopia in the patients may indicate a new variant syndrome different from the known oculo-encephalo-hepato-renal syndromes (*i.e.*, COACH, Meckel and Joubert).

Term explanation

CHF has been described frequently in combination with other abnormalities, such as renal diseases, cerebellar malformations, and mental retardation. The term oculo-encephalo-hepato-renal syndrome is currently employed to report this association.

Experiences and lessons

CHF may present as part of a syndrome affecting the central nervous system and eyes.

Peer-review

The authors have described three cases of CHF associated with ophthalmological and neurological findings which could represent a new syndrome.

Abstract

Dapsone (DDS-diamino diphenyl sulphone) is a sulfone antibiotic being used for a variety of clinical conditions. Poisoning in children by DDS is rarely reported. Poisoning in acute cases will be frequently unrecognized due to relative lack of severe signs and symptoms. Methemoglobinemia is the major life-threatening situation associated with poisoning of DDS. Hence, any delay for medical attention can lead to increased rate of mortality. In this case, we describe acute DDS poisoning in a 3-year-old child and the successful management using intravenous methylene blue.

Key words: Dapsone; Methemoglobinemia; Ascorbic acid; Methylene blue; Hemolysis

Core tip: Dapsone (DDS-diamino diphenyl sulphone), a sulfone antibiotic poisoning in children is rarely reported. Methemoglobinemia is the major life-threatening situation associated with DDS poisoning. Delay in seeking medical attention can lead to increased rate of mortality. Methylene blue 0.1% (2 mg/kg) as slow *iv* is the first line therapy. Furthermore, therapies like exchange transfusions and hyperbaric oxygen therapy are options especially in cases where contraindicated in glucose-6-phosphate dehydrogenase deficiency or if methylene blue therapy is ineffective.

poisoning in a 3-year-old child: Case report with review of literature. *World J Clin Cases* 2015; 3(10): 911-914 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/911.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.911

INTRODUCTION

Dapsone (DDS-diamino diphenyl sulphone), a sulfone antibiotic being used for the prophylactic therapy of various infections in an immunocompromised individual[1]. DDS poisoning in children are rarely reported. In initial stages of acute poisoning, there will not be any major manifestations and hence there may be delay in seeking medical attention. The life threatening events occur as a result of DDS-induced methemoglobinemia which will eventually affect the oxygen delivery to cells[2]. Hence, it will be worthwhile to discuss the manifestations and managements of DDS poisoning in order to prevent its adverse effects. In this case study, we present a 3-year-old child with accidental ingestion of DDS.

CASE REPORT

A 3-year-old boy brought to the hospital with complaints of accidental ingestion of DDS. At the onset of admission, the symptoms were lethargy, vomiting and unsteadiness. The child had persisted vomiting and later developed lethargy. He was conscious with blood pressure 106/68 mmHg, respiration rate 68/min, temperature 98.6 °F and pulse rate 150 beats/min. Oxygen saturation (SpO_2) was 91%. He had mild peripheral cyanosis, ataxia and nystagmus. Pupils were equally reacting to light; reflexes were brisk with plantar withdrawal with tone increased in all limbs. Later, the child becomes agitated and stuporous. Arterial blood gas (ABG) analysis showed pO_2 84 mmHg with hematocrit 29% and SpO_2 91.6% (Table 1). Evidence for hemolysis characterized by progressive drop in haemoglobin levels and hematocrit values. Packed red cell transfusion was given on 2nd and 3rd day as there was ongoing hemolysis. The initial methemoglobin (MHbA) level was 19.4%. Acute DDS-induced methemoglobinemia and CNS involvement was confirmed. O_2 inhalation and ascorbic acid (CELIN-1000 mg) was administered *via* nasogastric tube along with ranitidine and ondansetron as *iv* Methylene blue 0.1% (2 mg/kg) as slow *iv* was given. SpO_2 was increased to 96%, pO_2 88 mmHg with hematocrit 29%. Liver function test showed abnormal rise in enzymes till 5th day (Table 1). The renal function test and urinalysis were normal. On 5th day, the MHbA level was found to be 10.2%. On the day 7, another dose of methylene blue was given as he became lethargic with SpO_2 of 82%. The child was improved and discharged on day 14th after admission. During the follow-up, he had no neurological deficits and haemoglobin level was 11.8 g/dL.

DISCUSSION

DDS is an antimicrobial used to treat leprosy, dermatoses, malaria, *etc*[1]. The most frequent reaction that occur with higher doses of DDS toxicity is hemolytic anemia and methemoglobinemia[3]. Landers *et al*[4] reported decrease in hemoglobin (1-2 g/dL) and reticulocyte count (2%-12%) levels in patient with DDS toxicity. Therefore, when the methemoglobinemia causes symptomatic hemodynamic instability, discontinuation of DDS therapy is recommended.

The possibilities for DDS ingestion and poisoning in children are high. The blood MHbA level determines the clinical severity of the symptoms and signs. Most of the patients are found to be asymptomatic until approximately 30% of hemoglobin is presented as MHbA[1]. However, levels especially greater than 15% may be associated with cyanosis. In this child, the initial MHbA was 19.4%. Headache, lethargy, tachycardia and dizziness may be presented at levels between 20%-45%, whereas dyspnea, acidosis, seizures, cardiac dysrhythmias, heart failure and coma may occur at level above 45%. Furthermore, high mortality rate is associated with levels above 70%[5]. The patient in this case study had metabolic acidosis as evidenced from the lowered blood pH and bicarbonate level one day after the admission.

Acquired methemoglobinemia can be caused by nitrites and nitrates, nitric oxide, sulphones (*e.g.*, dapsone), local anesthetics (*e.g.*, benzocaine), aniline dyes, chlorates, pyridium, phenacetin, sulphonamides, *etc*[6]. Use of topical DDS as treatment for acne vulgaris has also been associated with MHbA levels as high as 20%[7]. In oxygenated and deoxygenated hemoglobin, iron remains in the ferrous (Fe^{2+}) form which is essential for the oxygen transportation. Oxidation of Fe^{2+} to ferric form yields MHbA, which does not bind to oxygen. Followed by the MHbA formation, the oxygen affinity of any remaining Fe^{2+}-hemes in the hemoglobin tetramer is increased and the oxygen dissociation curve is "left-shifted". Therefore, the circulating MHbA as well as the remaining oxyhemoglobin which has increased oxygen affinity can cause impaired oxygen delivery to the tissues. The net effect is that patients with acutely increased concentrations of MHbA have a functional anemia (*i.e.*, the amount of functional hemoglobin is less than the measured level of total hemoglobin). The existence of underlying diseases of lung, heart or blood may exacerbate the toxicity of MHbA. About 3% of the Fe^{2+} of deoxy Hb is slowly oxidized to MHbA per day. The intra-erythrocytic MHbA reducing enzyme systems such as NADH-dependant cytochrome b5 reductase, mainly and NADPH–MHbA reductase and NADPH-glutathione reductase, to a lesser extent help to keep its level below 1%. Level of MHbA above 2% is abnormal.

Management of DDS includes oral administration of activated charcoal and intravenous treatment with methylene blue. In this patient, we could not administer activated charcoal due to persistent vomiting. The

Table 1 Laboratory investigations

Investigations	1 d after admission	5 d after admission

Methaemoglobin (%)	19.4	10.2

plasma elimination half-life of DDS was found to be dose dependent which varies from 10 to 80 h. The renal excretion of unchanged DDS is limited to approximately 20% of the administered dose. DDS is metabolised in the liver for its elimination resulted a moderate elevation of SGPT (150-162 U/L) during the initial few days but normalised on 14th day (45 U/L). After the initial dosage of methylene blue, an additional dose may be repeated if there is an insufficient response. In this case, an additional dose of methylene blue was given since the MHbA level was high on 5th day. This may be due to the enterohepatic circulation of DDS which resulted in a rebound methemoglobinemia as high as 60% up to 18 h of methylene blue injection.

Treatment with methylene blue can be complicated by the presence of underlying glucose-6-phosphate dehydrogenase deficiency. Therefore, alternative therapies like exchange transfusions and hyperbaric oxygen therapy are the remaining options in patients with glucose-6-phosphate dehydrogenase deficiency or if methylene blue therapy is ineffective[8]. But the efficacy of these therapies not yet been elucidated. Ascorbic acid rarely reduces the cyanosis associated with chronic methemoglobinemia but has no role in treatment of acute acquired methemoglobinemia. Furthermore, Cimetidine, used as a selective inhibitor of N-hydroxylation, may be effective in increasing patient tolerance to dapsone, chronically lowering the MHbA level by more than 25%. Since it works slowly, cimetidine is not helpful for the management of acute symptomatic methemoglobinemia arising from the use of DDS.

Methylene blue is a phenothiazine-related heterocyclic aromatic molecule most commonly used as a reducing agent in the treatment of methemoglobinemia and for the treatment of cyanide and carbon monoxide poisoning[3,9]. It has dose-dependent effect on cardiac index and pulmonary artery occlusion pressure as well as oxygen delivery and lactate concentrations. The dosing of methylene blue is not entirely clear, but 1-2 mg/kg is used for the treatment of methemoglobinemia. However, methylene blue above 7 mg/kg is associated with adverse effects such as paradoxical induction of MHbA, hemolytic anemia and detrimental effects on pulmonary function[10,11]. Therefore, methylene blue should not be recommended in patients with pulmonary hypertension, underlying glucose-6-phosphate dehydrogenase deficiency and acute lung injury[11]. Clinicians should also be aware of potential adverse effects and drug interactions with serotonergic agents when considering therapy with methylene blue[12].

According to Wright *et al*[13], the diagnosis may be complicated by the effect of MHbA on arterial blood gas and pulse oximeter oxygen saturation results. In the presence of the increased MHbA fraction, pulse oximeter values will trend toward 85% underestimating the actual oxygen saturation. Guay[14] demonstrated the discrepancy between the pulse oximeter saturation ($\leq$ 90%) and the arterial oxygen partial pressure ($\leq$ 70 mmHg) in subjects with MHbA. Therefore, the routine pulse oximetry is generally inaccurate for monitoring oxygen saturation in the presence of methemoglobinemia. Acute hemolytic anemia in DDS can be explained with the DDS-induced continued oxidative stress or may also be due to the doses of methylene blue[15]. Charcoal hemoperfusion has also been reported for the rapid clearing of dapsone[16].

This case report concluded that patient with dapsone poisoning should be evaluated for serial measurements of methemoglobin levels following treatment with methylene blue in order to evaluate for the subsequent worsening and the need for additional treatment.

COMMENTS

Case characteristics

A 3-year-old boy presented with persisted vomiting and lethargy.

Clinical diagnosis

The patient had mild peripheral cyanosis, ataxia and nystagmus.

Differential diagnosis

Other causes for the drug induced acquired methemoglobinemia.

Laboratory diagnosis

Methemoglobinemia greater than 2% and lowered haematocrit value.

Treatment

Methylene blue 0.1% (2 mg/kg) as *iv*.

Related reports

Accidental acute dapsone poisoning in children are rarely reported. Management includes charcoal hemoperfusion, exchange transfusions and hyperbaric oxygen therapy.

Term explanation

Dapsone, a sulfone antibiotic being used for the prophylactic therapy of various infections in an immunocompromised individual, induces methemoglobinemia at higher doses. The level of methemoglobin in the blood determines the clinical severity of the symptoms and signs.

Experiences and lessons

Patient with dapsone-induced methemoglobinemia required serial measurements of methemoglobin levels following treatment with methylene blue in order to evaluate the subsequent worsening and the need for additional treatment. Routine pulse oximetry is generally inaccurate for monitoring oxygen saturation in the presence of methemoglobinemia.

Peer-review

This is a useful review of dapsone poisioning and its treatment.

Abstract

Primary mediastinal neuroendocrine tumors are a rare malignancy that accounts for < 10% of all mediastinal tumors. The case presented here involves a 52-year-old man who had been suffering for 3 mo from chronic cough, anorexia and substantial weight loss, as well as 2 wk of jaundice prior to his admission. A computed tomography scan showed a 4.3 cm × 6.6 cm mediastinal mass with multiple liver nodules scattered along both hepatic lobes. Endoscopic ultrasound showed a large heterogeneous hypoechoic mass at the mediastinum with multiple target-like nodules in the liver. Fine-needle aspiration specimens revealed numerous, small, round cells with hyperchromatic nuclei, scarce cytoplasm, and frequent mitotic features. Immunohistochemical study revealed positive results for AE1/AE3, CD56 and chromogranin A, with negative findings for synaptophysin, CK20, vimentin, CK8/18 and CD45. The patient was subsequently diagnosed with a poorly differentiated neuroendocrine carcinoma, small cell type. A bone marrow biopsy also revealed extensive involvement by the carcinoma.

Key words: Bone marrow metastasis; Liver metastasis; Lymphoma; Mediastinal mass; Neuroendocrine tumor

Core tip: Neuroendocrine tumors are rare tumors that arise from the gastrointestinal tract and bronchopulmonary system. Primary mediastinal neuroendocrine

tumors are exceptionally rare malignancies, accounting for < 10% of all mediastinal tumors. The common clinical manifestation of this rare tumor is a mediastinal mass, but the condition can mimic lymphoma in advanced cases. The liver is the most common site of metastasis.

Mediastinal small cell carcinoma with liver and bone marrow metastasis, mimicking lymphoma. *World J Clin Cases* 2015; 3(10): 915-919 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/915.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.915

INTRODUCTION

The most common malignancy of the mediastinum is Hodgkin's lymphoma, which usually involves the anterior mediastinum and typically presents as adjacent organ invasion, superior vena cava obstruction, pleural effusion, or erosion of the sternum. The most common site of metastasis for Hodgkin's disease is the liver[1]. In contrast, primary mediastinal neuroendocrine tumors are a rare malignancy that account for < 10% of all mediastinal tumors, with a reported incidence of 0.2-2.0 per 100000 people. These tumors are typically detected as incidental findings from chest radiography, as 40%-70% of advanced cases present with chronic cough, chest pain, dyspnea, or superior vena cava obstruction syndrome[2].

According to Travis[3], pulmonary neuroendocrine tumors are classified as: (1) typical carcinoid tumors; (2) atypical carcinoid tumors; (3) large cell neuroendocrine carcinomas; and (4) small cell neuroendocrine carcinomas. The prognoses of these mediastinal neuroendocrine tumors differ, with typical carcinoids associated with the best prognosis due to their slow growth and late metastasis, and the worst prognosis found with small cell neuroendocrine tumors[4]. Only a few cases of these tumors have been reported, with the liver as the most common site of metastasis[5,6]. This report describes a rare case involving a mediastinal mass with clinical manifestations mimicking lymphoma. To our knowledge, this is the first case report of primary neuroendocrine carcinoma with bone marrow and liver metastases.

CASE REPORT

A 52-year-old man presented to our hospital with a chronic cough, anorexia and substantial weight loss that had occurred over the previous 3 mo. He also presented with painless jaundice that had appeared 2 wk prior to his admission. He reported that he was a heavy smoker and had not experienced fever or shivering. His physical exam showed marked pallor and moderate jaundice, with a normal chest examination. The abdominal examination revealed hepatomegaly without splenomegaly and a negative finding for peripheral lymphadenopathy. Laboratory blood tests showed marked anemia with 6.8 g/dL hemoglobin (reference range: 12.0-18.0 g/dL), and normal white blood cell (7.7×10^3 cells/μL; reference range: 4-11 × 10^3 cells/μL) and reduced platelet (139×10^3 cells/μL; reference range: 150-440 × 10^3 cells/μL) counts. Liver chemistry results were as follows: total bilirubin, 4.2 mg/dL (reference range: 0-1.2 mg/dL); direct bilirubin, 3.7 mg/dL (reference range: 0-0.3 mg/dL); aspartate transaminase, 138 U/L (reference range: 0-32 U/L); alanine transaminase, 141 U/L (reference range: 0-32 U/L); and alkaline phosphatase, 403 U/L (reference range: 35-105 U/L). A markedly elevated lactate dehydrogenase level was noted at 3971 U/L (reference range: 240-480 U/L). Carcinoembryonic antigen measured 3.1 ng/mL (reference range: 0-5.0 ng/mL), with carbohydrate antigen 19-9 at 60.6 U/mL (reference range: 0-37.0 U/mL) and alpha-fetoprotein at 3.02 ng/mL (reference range: 1.09-8.04 ng/mL). The anti-HIV test was negative.

A computed tomography (CT) scan of the chest and upper abdomen showed a 4.3 cm × 6.6 cm mediastinal mass (Figure 1) with multiple liver nodules scattered along both hepatic lobes without any noteworthy pulmonary lesions. The provisional diagnosis was lymphoma, and the patient was therefore scheduled for endoscopic ultrasound and tissue sample collection. After deep sedation was induced using intravenous propofol with full anesthetic monitoring, a curvilinear endoscopic ultrasound scope (EG530UT2; Fujifilm, Minato-ku, Tokyo, Japan) was used for scanning. The echoview showed a large heterogeneous hypoechoic mass > 6 cm in diameter at the mediastinum, with multiple target-like nodules in the liver (Figure 2). Next, fine-needle aspiration of the mediastinal mass was performed with four passes using a 22-gauge needle (EchoTip Procore; Cook Group Inc., Bloomington, IN, United States) (Figure 3). A diagnosis of primary mediastinal lymphoma with liver metastasis was strongly suspected.

The patient's clinical status worsened despite administration of intravenous corticosteroids. The histopathologic results finally revealed numerous small, individual, round cells with hyperchromatic nuclei, scarce cytoplasm, and frequent mitotic features. An immunohistochemical study was positive for AE1/AE3, CD56 and chromogranin A (Figure 4), but negative for synaptophysin, CK20, vimentin, CK8/18 and CD45. Based on these findings, a diagnosis of poorly differentiated neuroendocrine carcinoma, small cell type was made.

A bone marrow biopsy was also performed, which showed extensive involvement by the carcinoma (Figure 5). However, intravenous chemotherapy was not administered due to the poor performance status at this point. The patient subsequently died a few weeks later, after developing progressive liver failure, edema in both legs, and a sudden onset of dyspnea and cyanosis, due

Figure 1 Computed tomography findings. A 6.6 cm × 4.3 cm mediastinal mass was observed.

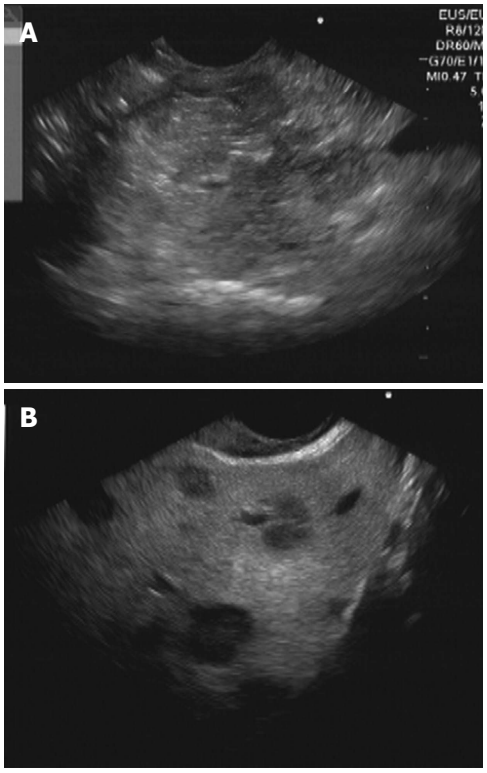

Figure 2 Endoscopic ultrasound findings. A: Echoview showed a large mediastinal mass; B: Liver nodules with target-like appearance were also observed.

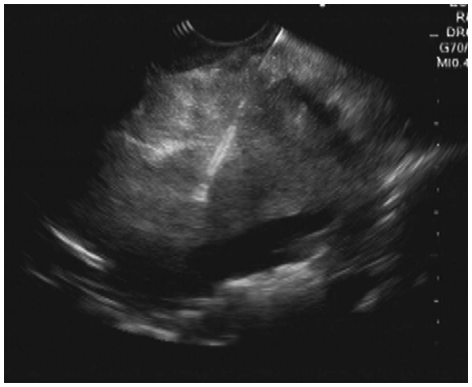

Figure 3 Fine-needle aspiration cytology was performed.

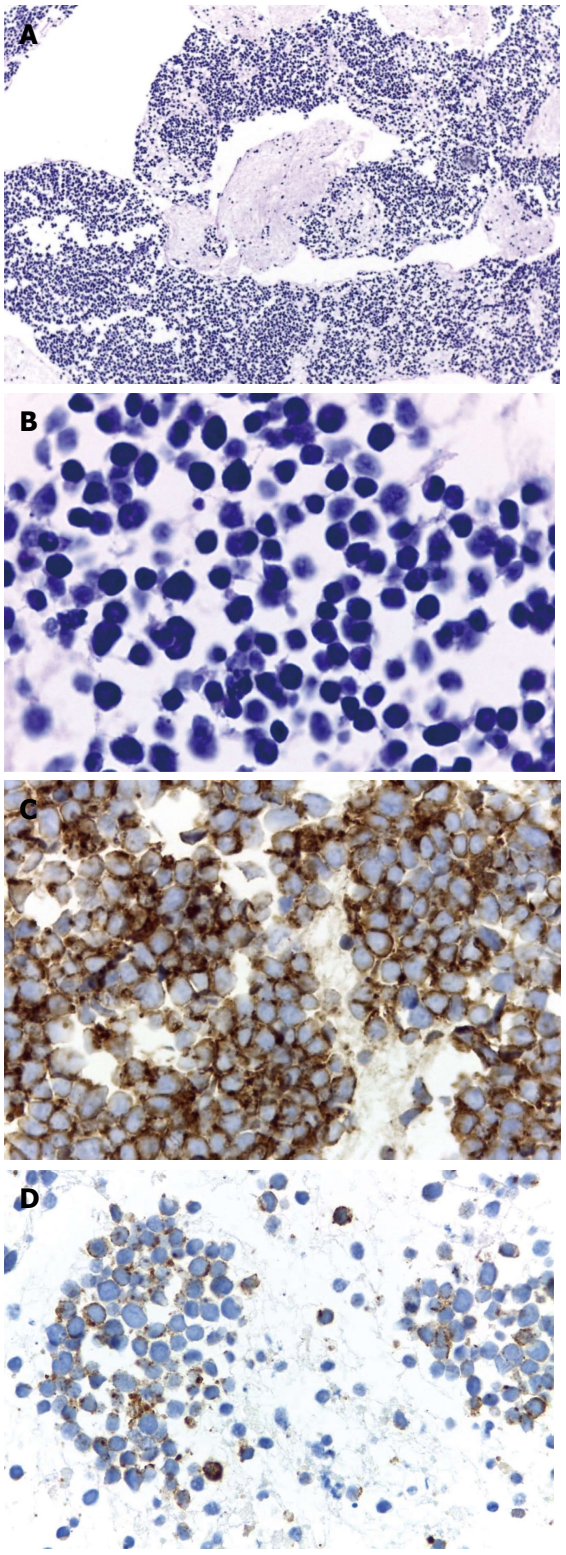

Figure 4 Histopathologic findings. A and B: Cell-block preparation from fine-needle aspiration of the mediastinal mass showed numerous small, individual, round cells with hyperchromatic nuclei, scarce cytoplasm, and frequent mitotic features. Rare instances of nuclear molding were also observed (hematoxylin-eosin staining, magnification × 10 and × 40, respectively); C and D: Immunohistochemical study revealed that the tumor cells were positive for AE1/AE3 (C) and chromogranin A (D; magnifications × 40).

to a suspected acute pulmonary embolism. No autopsy was performed in this case.

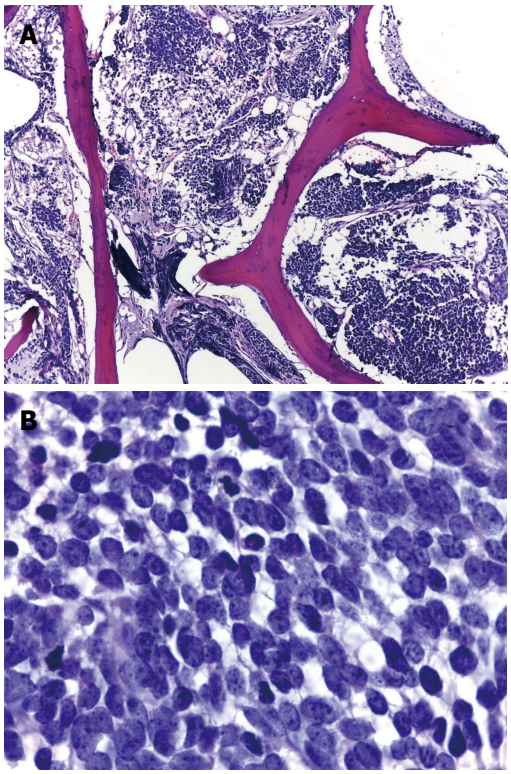

Figure 5 Bone marrow biopsy showed extensive infiltration by cohesive sheets of small, round cells with fine granular chromatin and scarce cytoplasm.

DISCUSSION

Neuroendocrine tumors are rare tumors that typically involve the gastrointestinal tract and the broncho-pulmonary system. Primary mediastinal neuroendocrine tumors are extremely rare[7-13], and can present as lymphoma, particularly Hodgkin's type. Indeed, the case described here initially presented with similar clinical symptoms, such as chronic cough, anorexia, weight loss, and a bulky mediastinal mass with liver metastasis. However, a final diagnosis of a poorly differentiated neuroendocrine tumor, small cell type was made after histopathologic and immunohistochemical study. The multiple liver nodules were strong indicators of liver metastasis, and this is the first reported case of mediastinal neuroendocrine tumor with liver and bone marrow metastases.

Li *et al*[14] reported a case series of six patients with primary small cell neuroendocrine carcinoma and found that most of the cases were in advanced stages, with tumors > 6 cm. Moreover, more than two-thirds of those cases involved the anterior-middle mediastinum with 44% scattered punctate calcification on CT. However, the immunohistochemical studies were positive for different markers, indicating the tumors had differentiated from a carcinoid tumor, mediastinal lymphoma, germ cell tumor of mediastinum, and thymoma. The poor prognosis for primary small cell neuroendocrine carcinoma was demonstrated by only half of the cases responding to chemotherapy, and the 2-year mortality rate of 50%[14].

The patient described in this case report had an advanced stage neuroendocrine tumor with fatal outcome. Definitive treatment for this small cell carcinoma should be guided by the definite histopathological and immunohistochemistry results.

COMMENTS

Case characteristics

A 52-year-old man presented with a chronic cough, weight loss, anemia and progressive jaundice.

Clinical diagnosis

Metastatic small cell neuroendocrine tumor with liver and bone marrow involvement.

Differential diagnosis

Lymphoma; Carcinoid tumor; Mediastinal lymphoma; Germ cell tumor of mediastinum; Thymoma.

Laboratory diagnosis

Hemoglobin, 6.8 g/dL; White blood cell count, 7.7 × 10^3 cells/μL; Platelet count, 139 × 10^3 cells/μL; Total bilirubin, 4.2 mg/dL; Direct bilirubin, 3.7 mg/dL; Aspartate transaminase, 138 U/L; Alanine transaminase, 141 U/L; Alkaline phosphatase, 403 U/L; Lactate dehydrogenase, 3971 U/L; Carcinoembryonic antigen, 3.11 ng/mL; Carbohydrate antigen 19-9, 60.62 U/mL; Alpha-fetoprotein, 3.02 ng/mL.

Imaging diagnosis

Computed tomography scan of the chest and upper abdomen showed a 4.3 cm × 6.6 cm mediastinal mass with multiple liver nodules scattered along both hepatic lobes without any marked pulmonary lesions.

Pathological diagnosis

Poorly differentiated neuroendocrine carcinoma, small cell type.

Treatment

Palliative treatment.

Related reports

Neuroendocrine tumors are a very rare malignancy of the mediastinum, and there are very few reports in the literature.

Experiences and lessons

Mediastinal neuroendocrine tumors may have a clinical presentation similar to lymphoma of the mediastinum. Histologic diagnosis and immunohistochemical study are crucial for definite diagnosis.

Peer-review

The authors describe a case of primary mediastinal neuroendocrine tumor with liver and bone marrow metastases, which mimicked lymphoma. This is a rare tumor with malignant lymphoma as the primary differential diagnosis.

Abstract

Gastric varices (GV) are one of the most common complications for patients with portal hypertension. Currently, histoacryl injection is recommended as the initial treatment for bleeding of GV, and this injection has been confirmed to be highly effective for most patients in many studies. However, this treatment might be ineffective for some types of GV, such as splenic vein thrombosis-related localized portal hypertension (also called left-sided, sinistral, or regional portal hypertension). Herein, we report a case of repeated pancreatitis-induced complete splenic vein thrombosis that led to intractable gastric variceal bleeding, which was treated by splenectomy. We present detailed radiological and pathological data and blood rheology analysis (the splenic artery - after a short gastric vein or stomach vein - gastric coronary vein - portal vein). The pathophysiology can be explained by the abnormal direction of blood flow in this patient. To our knowledge, this is the first reported case for which detailed pathology and blood rheology data are available.

Key words: Splenic vein thrombosis; Intractable gastric variceal bleeding; Recurrent pancreatitis; Review

Core tip: Here, we report a case in which chronic

pancreatitis-induced complete splenic vein thrombosis led to intractable gastric variceal bleeding, which is effectly treated by splenectomy. We have provided details regarding the imaging and pathology data, and we describe the hemodynamic characteristics. Then, we reviewed the disease onset and treatment methods, which may provide a reference for the clinical diagnosis and treatment of similar patients.

Repeated pancreatitis-induced splenic vein thrombosis leads to intractable gastric variceal bleeding: A case report and review. *World J Clin Cases* 2015; 3(10): 920-925 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i10/920.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i10.920

INTRODUCTION

Gastric varices (GV) are among the most common complications affecting patients with portal hypertension, which has a mortality rate that can reach as high as 20% within 6 wk[1]. Currently, histoacryl injection is recommended as the initial treatment for bleeding GV, and this approach has been confirmed to be highly effective for most patients in many studies[2-5]. However, this treatment might be ineffective for some types of GV, such as splenic vein thrombosis-related localized portal hypertension (also called left-sided sinistral or regional portal hypertension). Herein, we report a case of recurrent pancreatitis-induced complete splenic vein thrombosis that led to intractable gastric variceal bleeding, which was treated by splenectomy. We present detailed radiological and pathological data and blood rheology analysis results (splenic artery - after a short gastric vein or stomach vein - gastric coronary vein - portal vein). The pathophysiology can be explained by the abnormal direction of blood flow in this patient. To our knowledge, this is the first reported case for which detailed pathology and blood rheology data are available.

CASE REPORT

A 58-year-old man was admitted to our hospital due to recurrent melena lasting for over a month and vomiting lasting for two hours. His past history revealed a history of heavy drinking of at least 200 g daily that exceeded 30 years; however, approximately 7 years before, his alcohol consumption had decreased. Over the past 7 years, he had experienced recurrent pancreatitis five times, and all incidences resolved. Approximately one month prior to admission, this patient began to experience melena with no obvious cause. Endoscopy showed that the gastric mucosa was elevated with fundal varices without active bleeding. After conservative treatment, the melena became intermittent. Then, another endoscopic examination revealed severe GV, and the patient received five histoacryl injections. Subsequently, he experienced intermittent melena and vomited approximately 200 mL of blood. Physical examination showed anemia, splenomegaly spanning three ribs across the liver, and active bowel sounds (7/min). Blood examinations revealed the following: Red blood cell, 2.98×10^{12}/L; hemoglobin concentration, 67 g/L; and platelet count, 90×10^{9}/L. Both liver and kidney functions were normal. Abdominal enhanced computed tomography (CT) showed cirrhosis and an enlarged portal vein.

The patient was diagnosed with alcoholic cirrhosis, portal hypertension, splenomegaly and GV. Then, emergency endoscopy revealed bleeding GV, and a second histoacryl injection treatment was performed. However, this patient was also experiencing intermittent vomiting, which had become more frequent because the histoacryl injection did not effectively stop the bleeding from fundus varices. Emergency transjugular intrahepatic portosystemic shunt placement was performed as a hemostatic treatment. Portal vein puncture was successful, and portal vein radiography showed an enlarged portal vein; however, the splenic vein and gastric coronary vein were not imaged (Figure 1). Then, another abdominal enhanced CT and portal systemic vascular reconstruction were performed. The enhanced CT scan revealed an enlarged portal vein from the origin of the gastric coronary vein and an enlarged and circuitous gastric coronary vein (Figure 2A). The splenic vein did not show any flow signals in the portal venous phase (Figure 2B). The portal systemic vascular reconstruction image did not show the splenic vein or spleen signals. These data indicated that the intractable gastric variceal bleeding was not induced by alcoholic cirrhosis or portal hypertension but rather by regional portal hypertension promoted by complete splenic vein thrombosis after recurrent pancreatitis.

Taking into account the poor general condition of the patient, splenic artery embolization could have led to serious complications. Therefore, laparotomy was performed for splenectomy. After opening the abdomen, normal liver size, color and texture were observed. During surgery, we found adhesions of the spleen to organs and tissues, such as the stomach, transverse colon and kidney. Approximately two hours were spent separating the extensive adhesions.

After separation of the surrounding tissues and ligation of the splenic artery and short gastric vessels, we successfully removed the spleen and found that the pancreas was very hard to the touch. After anatomical resection of the spleen, we found that the splenic vein was completely blocked by thrombosis (Figure 3A), and the pathology results further confirmed splenic vein thrombosis (Figure 3B). One month after splenectomy, endoscopic examination revealed that the fundal varices had markedly reduced, and ultrasound examination revealed a normal-sized portal vein.

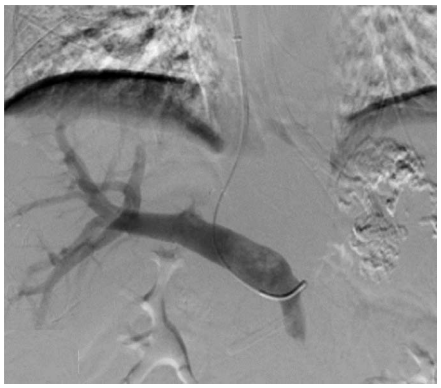

Figure 1 Direct portal vein radiography shows an enlarged portal vein; however, the splenic vein and gastric coronary vein could not be imaged.

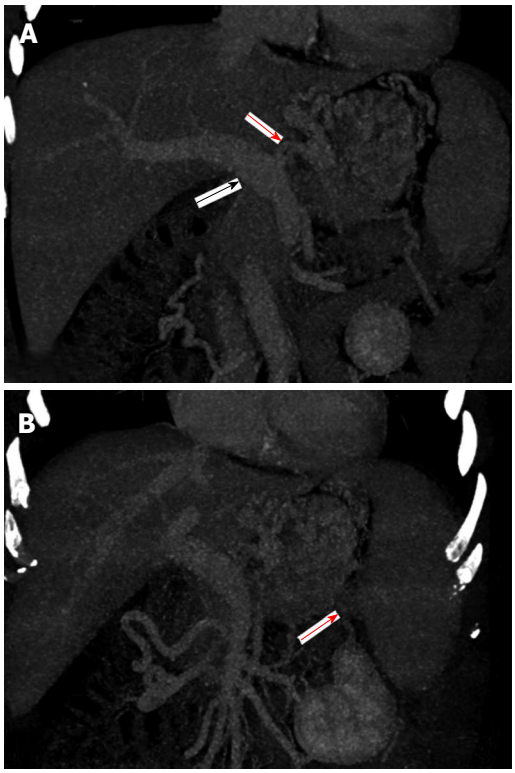

Figure 2 Enhanced computed tomography scan. A: An enlarged portal vein from the origin of the gastric coronary vein and an enlarged, circuitous gastric coronary vein; B: Splenic vein flow signals in the portal venous phase are absent.

DISCUSSION

Gastric variceal bleeding due to regional portal hypertension with splenic vein thrombosis is a severe, life-threatening condition, which is very difficult to control[6]. Patients with splenic vein thrombosis-induced GV, who usually have normal hepatic function, are unlike those with generalized portal hypertension[7], and their mortality risk is higher than that of patients with variceal hemorrhage due to other causes[6,8]. A previous study has shown that as many as 37 different specific etiologies lead to splenic vein thrombosis[9], the most common of which is pancreatitis[10]. The rate of splenic vein thrombosis is 7% to 20% in patients who have previously suffered from pancreatitis[11]. Splenic vein thrombosis induced by pancreatitis was first reported by Hirschfeldt[12]. Other causes of this disease include myeloproliferative neoplasm[13,14], gastrointestinal, pancreatic and hepatobiliary cancers, liver cirrhosis[15], abdominal compression and vibration[16], pancreatic exocrine cancer[17], factors secondary to splenic metastatic cancer[18], minimally invasive distal pancreatectomy[19], and splenic laceration[20].

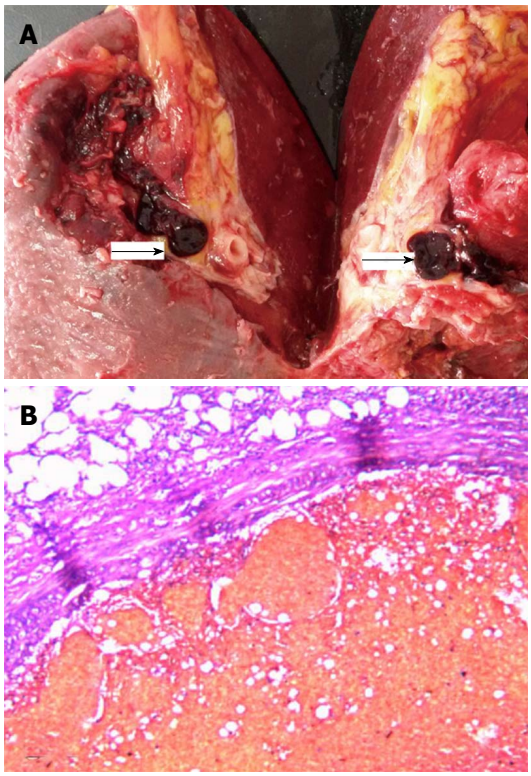

Figure 3 Anatomical resection of the spleen and hematoxylin-eosin staining staining. A: The splenic vein is completely blocked by thrombosis; B: The splenic vein is completely filled by thrombosis.

The splenic vein originates in a large and non-tortuous vessel from the spleen, lies inferior to the splenic artery, and runs behind the pancreatic body and tail. Therefore, the splenic vein endothelium can be damaged by inflammation in the nearby pancreatitis, which can induce splenic vein thrombosis and obstruction. Since the first report of splenic vein thrombosis induced by pancreatitis in 1920[12], five types of pancreatitis have been identified, including chronic, acute, familial, traumatic and autoimmune pancreatitis (Table 1), the most common of which is chronic pancreatitis[11,21-24]. Recently, we have reported a patient with chronic pancreatitis-associated splenic vein thrombosis caused by regional portal hypertension who was treated by partial splenic artery embolization[25]. Acute pancreatitis has been reported to be another common cause of splenic vein thrombosis[23,26,27]. In addition, familial[28], traumatic[29] and autoimmune[30] pancreatitis-induced splenic vein thrombosis and GV have been reported.

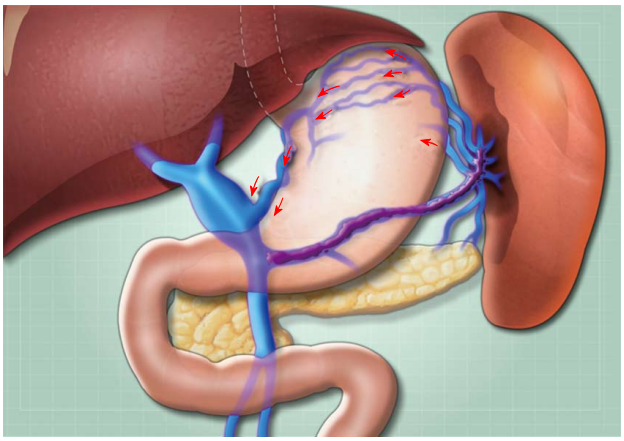

Figure 4 A schematic diagram of the pathophysiological and blood flow changes in this patient.

Herein, we report a case of pancreatitis-induced complete splenic vein thrombosis that led to intractable gastric variceal bleeding. This patient was first misdiagnosed with alcoholic cirrhosis-induced portal hypertension. After direct portal venography and portal vein reconstruction, the patient was finally diagnosed with regional portal hypertension induced by complete splenic vein thrombosis after pancreatitis. Normally, blood flows through the splenic artery and short gastric vein from the fundus back to the portal vein. After passing through the spleen, blood flows through the splenic vein[31]. However, when the splenic vein is completely blocked, splenic artery blood cannot flow back through the splenic vein, which causes the spleen to become congested and enlarged. Blood must reflux to the gastric fundus vein through the short gastric vein, which results in a significant increase in gastric fundus pressure, varices, and reflux to the vena cava through the stomach, the renal vein shunt and other branches. When the pressure of the gastric fundus vein is higher than that of the portal vein, the gastric coronary vein will become enlarged, and blood will reflux to the portal vein through the gastric coronary vein, inducing portal vein enlargement (Figure 4). Therefore, these blood rheology findings explain all of the symptoms, signs, laboratory test results and imaging data of the patient.

Antithrombotic therapy has been recommended for venous thromboembolic disease[32-34]. An institutional (Mayo clinic) database search has revealed that a total of 2454 patients were diagnosed with acute pancreatitis from January 1996 to December 2006, with splenic vein thrombosis noted in 45 (1.8%) patients, and the use of oral anticoagulation was considered to be reasonably safe in these patients[35]. However, for chronic pancreatitis, the incidence of splenic vein thrombosis can reach 20% to 40%[36-38]. For complete splenic vein thrombosis patients, antithrombotic therapy may aggravate the risk of bleeding due to fundal varices. Therefore, splenic artery embolization is one of the best treatments for bleeding GV induced by splenic vein thrombosis[14,39-42]. However, "post-embolization syndrome" is a common side effect experienced after splenic artery embolization and includes abdominal pain, fever, vomiting, and purulent infection depending on the arterial embolism size and the patient's condition. Another study has suggested that transjugular endovascular recanalization of the splenic vein is a safe and effective therapeutic option in patients with regional portal hypertension and is not associated with an increased risk of procedure-related complications[43]. As the condition of the patient in the present report was poor due to massive blood loss, we chose splenectomy *via* laparotomy, which was successful.

This paper describes a case of chronic pancreatitis-induced complete splenic vein thrombosis, which led to intractable gastric variceal bleeding. We have provided details regarding the imaging and pathology data and have described the hemodynamic characteristics. In addition, we have reviewed the disease onset and treatment methods, which may provide a reference for the clinical diagnosis and treatment of similar patients.

COMMENTS

Case characteristics

A 58-year-old man with recurrent melena lasting for over a month and vomiting lasting for 2 h.

Clinical diagnosis

Chronic pancreatitis-induced complete splenic vein thrombosis led to intractable gastric variceal bleeding.

Laboratory diagnosis

Red blood cell, 2.98 × 10^{12}/L; hemoglobin concentration, 67 g/L; and platelet count, 90 × 10^{9} /L.

Imaging diagnosis

Enhanced computed tomography scan revealed an enlarged portal vein from the origin of the gastric coronary vein and an enlarged and circuitous gastric coronary vein. The splenic vein did not show any flow signals in the portal venous phase.

Treatment
Laparotomy was performed for splenectomy.

Experiences and lessons
This is the first reported case for which detailed pathology and blood rheology data are available.

Peer-review
A very interesting paper.

Abstract

Airway evaluation and its management remains an ever emerging clinical science. Present airway management tools are static and do not provide dynamic airway management option. Visualized procedures like ultrasound (US) provide point of care real time dynamic views of the airway in perioperative, emergency and critical care settings. US can provide dynamic anatomical assessment which is not possible by clinical examination alone. US aids in detecting gastric contents and the nature of gastric contents (clear fluid, thick turbid or solid) as well. US can help in predicting endotracheal tube size by measuring subglottic diameter and diameter of left main stem bronchus. US was found to be a sensitive in detecting rotational malposition of LMA in children. Also, US is the fastest and highly sensitive tool to rule out a suspected intraoperative pneumothorax. In intensive care units, US helps torule out causes of inadequate ventilation, determine the tracheal width and distance from the skin to predict tracheotomy tube size and shape and assist with percutaneous dilatational tracheostomy. US can help in confirming the correct tracheal tube placement by dynamic visualisation of the endotracheal tube insertion, widening of vocal cords (children), and bilateral lung-sliding and diaphragmatic movement. Thus, ultrasonography has brought a paradigm shift in the practise of airway management. With increasing awareness, portability, accessibility and further sophistication in technology, it is likely to find a place in routine airway management. We are not far from the time when all of us will be carrying a pocket US machine like stethoscopes to corroborate our clinical findings at point of care.

Key words: Airway; Ultrasound; Evaluation; Difficult; Management

Core tip: Airway evaluation and its' management is conventionally based on clinical examination and

radiological imaging. They remain static and do not provide dynamic airway management option. Visualized procedures like ultrasound (US) provide point of care real time dynamic views of the airway in perioperative, emergency and critical care settings. US also aids in detecting gastric contents and the nature of gastric contents (clear fluid, thick turbid or solid). This detection is important for preventing complication of aspiration during airway management. The ultrasonography has brought a paradigm shift in the practise of airway management. With increasing awareness, portability, accessibility and further sophistication in technology, it is likely to find a place in routine airway management. We are not far from the time when all of us will be carrying a pocket US machine like stethoscopes to corroborate our clinical findings at point of care.

Garg R, Gupta A. Ultrasound: A promising tool for contemporary airway management. *World J Clin Cases* 2015; 3(11): 926-929 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/926.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.926

Contemporary anaesthesia practise is richly blessed with technology based solutions. Technology has served to reduce human error in enumerable ways. Ultrasonography is one such extremely useful tool which is finding increasing applications in anaesthesia. It is already being considered as "gold standard" for central venous cannulations and peripheral nerve blockade. Visualized procedures improve safety and outcomes as compared to conventional techniques. In recent past, accumulated evidence is favouring its utility for various aspects of airway management for preoperative airway assessment, intraoperative management, predicting weaning from ventilation and successful extubation[1-3]. Various closed claim database and national level audits continue to implicate failure in airway management as a major contributor to perioperative morbidity and mortality[4-6]. Hence, constant efforts have been directed towards finding a "fail-safe" device for assisting us with airway management. Ultrasound (US) is turning out to be one such promising tool.

US provides point of care real time dynamic views of the airway inperioperative, emergency and critical care settings. It is free of ionizing radiation, painless, portable, convenient, reproducible, accurate and easily mastered skill and anaesthesiologist need not be dependent on their radiology colleagues. Because of superficial location of larynx, US can provide images of even higher resolution than advanced imaging modalities like computed tomography (CT) or magnetic resonance imaging (MRI)[6].

Conventional airway assessment fails predict difficult intubation in all patients. US can provide dynamic anatomicalassessment which is not possible by clinical examination alone. Various studies have suggested that US can help in predicting difficult airway by measuring the soft tissue thickness measured on anterior aspect of trachea along with neck circumference[1], hyomental distance ratio[7], width of tongue base and lateral pharyngeal wall thickness[8]. Intraoral sublingual approach to US is being investigated as a useful approach to predict difficult airway[9]. If difficult airway is suspected US can assist in preparing the airway (superior laryngeal and recurrent laryngeal) for awake intubation[10] and identify the cricothyroid membrane so that transtracheal cricothyrotomy cannula can be placed in a "cannot ventilate cannot intubate" (CVCI) scenario[11,12]. Though fasting guidelines are well known, however, gastric emptying is quite variable. US aids in detecting gastric contents and thenature of gastric contents (clear fluid, thick turbid or solid) as well[13].

US can help in predicting endotracheal tube size by measuring subglottic diameter and diameter of left main stem bronchus (for placement of double lumen tube) and help in deciding the appropriate size of the endotracheal tube (ETT)[14,15]. US can also be used to confirm correct laryngeal mask airway (LMA) placement[16]. Its use instead of fiberoptic confirmation averts the hypercapnia associated with the later[17]. US was found to be a sensitive in detecting rotational malposition of LMA in children[18]. Also, US is the fastest and highly sensitive tool to rule out a suspected intraoperative pneumothorax[2].

In intensive care units, US helps to rule out causes of inadequate ventilation, determine the tracheal width and distance from the skin to predict tracheotomy tube size and shape and assist with percutaneous dilatational tracheostomy (PDT)[19,20]. US guided PDT provides real time visualisation of the needle path and guide wire placement using linear array probe. It permits visualisation of pretracheal blood vessels, selection of puncture site, decreases posterior tracheal wall puncture, decreases injury to thyroid isthmus and increases the overall success[21-23]. US has been found to be a better alternative to FOB guided PDT and may replace it in coming years.

US scan help in confirming the correct tracheal ETT placement by dynamic visualisation of the ETT tube insertion, widening of vocal cords (children), and bilateral lung-sliding and diaphragmatic movement[23-25]. Additional advantage of US guided ETT placement is that esophageal intubation can be diagnosed prior to initiation of mechanical ventilation, thus reducing gastric insufflations and its consequences. Recent studies have suggested that bedside US is feasible and faster substitute to conventional techniques (auscultation and waveform capnography) and may replace them in future[24].

Expanding literature in recent years is indicating the utility of US in diagnosing various pathologies that can have implication in clinical decision making, *e.g.*, vocal cord malfunction[3], swallowing abnormalities[25], sialolithiasis[26], supraglottic hemangiomas[27], respi-

ratory papillomatosis[28], laryngeal stenosis[29], Zenker's diverticulum[30-34], *etc*.

Recent advances in airway US include transesophageal US which can provide distal airway images from mid-trachea to bronchi[33]. Additionally, endoscopic high frequency US of larynx has been described where a thin catheter high frequency probe with rotating mirror can produce 360° image of larynx[34]. With advent of multiplanar 3D US in airway imaging, spectrum of its application has further widened as spatial information obtained is more detailed and measurements obtained are more precise[35]. A recent report describing the use of 3D US concluded that airway anatomy, anteroposterior diameter of subglottic area and transverse diameter of upper trachea can be accurately measured and correlated with MRI findings[35]. Pocket sized smartphone based system can increase its applicability even in remote areas[36].

US has steep learning curve as depicted by many studies[37]. Inexpensive training models like gel phantom model can help improve US assessment and interventional skills and safety[38]. However, like and any other skill based technique, a degree of manual dexterity and knowledge is required to be proficient in its use. Hence, its accuracy remains operator dependent.

To conclude, ultrasonography has brought a paradigm shift in the practise of airway management. With increasing awareness, portability, accessibility and further sophistication in technology, it is likely to find a place in routine airway management. We are not far from the time when all of us will be carrying a pocket US machine like stethoscopes to corroborate our clinical findings at point of care.

Abstract

Disruptive behaviors in health care can have a significant adverse effect on staff interactions that can negatively impact staff satisfaction, staff performance, and patient outcomes of care. As referenced in a previously published article, the Obstetrics and Gynecology specialty is one of the service areas where these behaviors occur more frequently. Despite growing evidence of the ill effects of these types of behaviors many organizations are still having a difficult time in addressing these issues in an effective manner. Gaining a better understanding of the nature, causes, and impact of these behaviors is crucial to finding the right remedies for solution. Nobody intentionally starts the day planning to be disruptive, it's just that things get in the way. A combination of deep seated factors related to age and gender preferences, culture and ethnicity, life experiences, and other events that help shape values, attitudes and personalities, and more external factors related to training, environmental pressures, stress and burnout, and other personal issues all contribute to the mix. Given the complexities of today's health care environment, each person needs to recognize the importance of being held accountable for appropriate actions and behaviors that affect work relationships and care coordination that impact patient care. Early recognition, early intervention, and taking a pro-active supportive approach to improve individual behaviors will result in better relationships, less disruption, more satisfaction, and better outcomes of care.

Key words: Disruptive behaviors; Patient safety; Patient outcomes; Staff relationships; Communication; Teamwork

Core tip: Disruptive behaviors in health care can have a significant adverse effect on staff interactions that can negatively impact staff satisfaction, staff performance, and patient outcomes of care. Disruptive incidents are more likely to occur in high risk settings such as the Obstetrical arena. Despite growing evidence of the ill effects of these types of behaviors many organizations are still having a difficult time in addressing these issues in an effective manner. Gaining a better understanding of the nature, causes, and impact of these behaviors and providing appropriate early and supportive interventions is crucial to finding the right remedies for solution.

INTRODUCTION

It's been several years since I published a paper on the impact of disruptive behaviors in the Obstetrical setting highlighting its negative impact on staff relationships, care coordination, and patient outcomes of care[1]. Follow up reactions to the article have been very positive, but due to the nature of problem, and issues around reporting, internal organizational dynamics, and confidentiality, it's difficult to assess valid statistics as to how this has impacted the frequency of occurrence or consequences of these episodes. There have been a number of recent reports suggesting that the problem continues despite recurring evidence linking disruptive behaviors to patient harm[2-4]. Further evidence of its continued recurrence comes from research we conducted for an upcoming article in a law journal where we found a large number of cases reaching the appeal courts for incidents related to physician disruptive behaviors. The question is, why does this continue to be an ongoing problem?

HISTORY

We first reported on the impact of physician disruptive behaviors in 2002 highlighting the types of disruptive behaviors, the frequency, the specialties most involved, and its impact on nurse satisfaction and retention[5,6]. Phase two of our research extended the scope of analysis to include the incidence of disruptive behaviors in nursing and other disciplines and its impact on behaviors affecting communication and task performance leading to medical errors and other adverse events negatively impacting patient care. Our article in *The Joint Commission Journal of Quality and Patient Safety* was timed with the release of the Joint Commission Sentinel Event Alert #40 and the initiation of the new Joint Commission accreditation standard requiring hospitals to have a disruptive policy in place and to provide resources for its support as one of the leadership standards for accreditation[7,8]. During our research we noted that disruptive behaviors had the greatest likelihood of occurrence in high risk settings such as Obstetrics, Surgery, and the Emergency Department, and we reported on special studies conducted specifically in these areas[1,9,10]. In actuality, disruptive behaviors can occur anytime and anywhere across the full spectrum of care with similar detrimental effects on organizational culture, patient and staff satisfaction, morale, work relationships, task accountability, care efficiency, patient safety, and quality of patient care.

Table 1 Barriers

Organizational responsiveness (code of silence)
Reluctance to act (financial/hierarchy)
Structure and process (policy/reporting)
Process review (bias/conflicts of interest)
Intervention (skill sets)
Recommended action
Physician liabilities (personality)

PROGRESS?

We have definitely made some progress in this area. Many organizations have initiated a culture of zero tolerance for disruptive behaviors supported by setting appropriate behavioral standards described in either a code of conduct or disruptive behavior policy holding individuals accountable for their actions with set ramifications for non-compliance. Some organizations have taken a more pro-active approach in trying to reduce the incidence of disruptive behaviors by providing specific training programs in diversity management, cultural competency, emotional intelligence, conflict management and/or additional training to improve communication and team collaboration skills[11]. Programs focusing on skills taught in the airline industry (crew resource management), NASCAR (pit crew mechanics), and the nuclear power industry have shown significant benefit for team based care in Obstetrics, Surgery and Critical Care[12]. But problems still persist.

BARRIERS

Table 1 lists a number of different barriers that influence organizational effectiveness in addressing disruptive behaviors.

One of the first barriers is the issue of organizational responsiveness. This starts with organizational awareness. Many events go unnoticed or are not reported due to a hidden code of silence, an inconsistent reporting system, or fears of repercussion or retaliation for making a report. Ways to enhance organizational awareness include distributing a confidential internal survey assessment and making it safe for individuals to speak up. The second part is responsiveness. The underlying organizational culture and leadership need to develop and support a zero tolerance policy for disruptive behaviors and be willing to take the necessary steps to intervene when they occur.

A second more disturbing barrier is that of tolerance and acceptance. Many of these behaviors occur in physicians who are high revenue producers and the organization may be reluctant to confront the physician in fear of an antagonistic response and threats to bring his or her patients elsewhere. There may also be issues related to hierarchy, boundaries, or "sacred saints" leading to an unwillingness to

Table 2 Risks of non-action

Organizational morale
Recruitment and retention
Staff/patient satisfaction (HCAHPS)
Community reputation
Patient complaints/malpractice
Care efficiency (process flow/delays/utilization/productivity)
Poor compliance (documentation/metric based performance)
Communication gaps/medical errors/adverse events

HCAHPS: Hospital Consumer Assessment of Healthcare Providers and Systems.

intervene.

A third issue is that of structure and process. Do you have the right policies and procedures in place? Do you have a consistent reporting process? Do you have a standardized intervention plan where evaluation, assessment, and recommendations can be made in professional non- biased manner?

One of the key liabilities of any disruptive behavior policy is the process for event review, assessment, and follows up intervention. Some organizations may turn the issues over to the Chief Medical Officer, a Department Chair, or another delegated individual or task force, but do they have the right skills necessary to adequately assess the full situation, avoid preconceived biases or conflicts of interest, diffuse anger, resolve conflict, maintain focus on the key issues, offer support, and provide appropriate recommendations for next steps? In many cases the success of the intervention is more dependent on the effectiveness of the individual doing the intervention than the scope of the disruptive behavior described.

Probably the biggest challenge has to do in dealing with the underlying personality traits of the physician involved. Physicians are by nature very competitive, task driven, perfectionists, with very strong egocentric personalities. Medical training further accentuates the problem with its focus on gaining scientific knowledge (at the expense of developing interpersonal skills) which breeds a sense of autonomy, dominance, and need to control (at the expense of emotional sensitivity). All these factors can lead to a challenging personality who may at time be difficult to deal with.

As far as the question as to whether or not disruptive behavior will go away, recent changes in the health care environment may actually make the situation worse. Issues around Health Care Reform, changing models, metrics, and financial incentives for care, and greater accountability for performance outcomes have dramatically increased physician frustration, dissatisfaction, and levels of stress and burnout which can lead to both physical and emotional states that adversely affect attitudes and behaviors[13,14]. Recognizing these underlying issues are critically important when it comes to making appropriate recommendations for improvement.

Table 3 Recommendations

Awareness and responsiveness
Address organizational culture
Solicit project champions
Develop policies and procedures
Implement a consistent reporting and review process
Follow established process
Document all interactions
Intervention with trained personnel
Prevention
Provide physician/staff education (recognition/accountability)
Provide physician training (diversity/conflict management/communication skills)
Offer physician assistance and support (coaching/counseling/behavioral intervention)
Enhance physician engagement (input/motivation/alignment/satisfaction)
Recognize efforts

RISKS OF NON-ACTION

Sometimes we have to deliver a wake-up call for the organization to take appropriate action. Budget issues, resource issues, and the naïve sense of "no harm done" may override thoughts and willingness for organizational time and investment. Actually, it's quite the opposite[15]. Table 2 lists a number of different "costs" that may result from inaction.

One of the most obvious impacts is on employee morale. Perceptions of working in a "toxic" non-caring work environment leads to problems with staff retention and turnover and problems in recruiting new staff. The average cost to recruit a new nurse is over $60000 and at least twice as much to recruit a new physician. Anger and frustration lead to not only staff dissatisfaction, but also filters through to patient dissatisfaction which for Medicare is a key metric affecting hospital reimbursement[16]. With the growing public focus on the effects of workplace bullying, a further consequence is a tarnished community reputation which may impact market share and contract negotiations. More extreme situations may lead to patient complaints and a higher risk of costly malpractice suits[17].

Care efficiency can also suffer. Failure to follow best practice guidelines, failure to comply with hospital policies and procedures, failure to return calls, failure to collaborate, and failure to document can lead to wasted dollars related to inappropriate utilization, waste, duplication, process delays, mistakes, and reduced reimbursement.

The most serious effects occur when these behaviors disrupt care leading to costly medical errors and adverse events[15].

RECOMMENDATIONS

The discussion above highlights opportunities for improvement which are summarized in Table 3.

The first and most obvious need is organizational awareness of what is happening and the willingness to respond. The case for inaction is inexcusable.

At the core of reaction is organizational willingness to endorse and support a culture that values staff contributions and work ethic and reinforce the importance of a positive work environment which will not tolerate inappropriate behaviors. There are many articles emphasizing the importance of organizational culture and its relationship to staff satisfaction and patient outcomes of care[18]. Soliciting the help of project champions (both clinical and non- clinical) provide an excellent opportunity to further advance organizational initiatives.

Policies and procedures need to be developed to define appropriate standards of behavior and establish a consistent process for review. The organization then needs to follow due process in how it moves forward with the intervention. Not following due process and/or lack of documentation are two key issues to be considered if subsequent legal action is initiated.

The actual intervention process is probably the most critical part of the entire process and should be conducted by individuals trained in facilitation and conflict resolution techniques. The degree of intervention will depend upon the circumstances. Many disruptive behaviors occur unknowingly by the physician. In these cases just raising awareness and discussing alternative reactions will often help them self-correct. These types of informal interventions are often described as "coffee time" discussions. For more serious and repetitive disruptive behaviors the organization needs to take a more formal approach concluding with specific recommendations of what the physician needs to do to avoid these types of behaviors in the future. Depending on the circumstances additional training in diversity management, anger management, stress management, or conflict management may be appropriate. More severe cases may require individualized coaching or counseling services. These interventions can either be conducted internally or through a variety of outside programs offered by organizations that specialize in dealing with disruptive individuals. In some cases more intense behavioral modification therapy is needed which may includes assessment of possible substance abuse. In cases where the physician is resistant to change, sanctions, suspension, or termination of privileges may be the only alternative.

The best overall strategy is prevention. Most physicians don't plan to be disruptive, it's just that things may get in the way. Training in emotional intelligence, communication, and team collaboration skills will help provide essential tools to improve staff relationships and lower the incidence of disruptive events. If stress and burnout is an issue providing support services through either human resources, Physician Wellness Committees, a Physician EAP (Employee Assistance Program), or through the use of outside agencies to help the physician better adjust to the pressures of today's health care environment will ease some of their emotional liabilities.

Even better, take a proactive stance in trying to increase overall physician engagement. Take time to educate them about Health Care Reform and other current issues impacting their medical practice. Provide opportunities for discussion, listen to them, and respond to some of their needs and concerns. This can be done through discussion forums or town hall meetings, agenda items at Department meetings, or though one on one discussions[19]. Allowing physician input and participation around health care matters will increase physician alignment, engagement, satisfaction, and compliance, all of which will reduce the likelihood of a disruptive event. Be responsive to their needs and when possible offer appropriate administrative, operational, or clinical support to help ease the burden of running a demanding clinical practice.

In the end, physicians, and all staff, should be regarded as a precious resource. Show them respect, recognize and thank them for what they do, and work with them to re-invigorate their passion for providing medical care.

CONCLUSION

Disruptive behaviors can have a significant impact on patient care. Most physicians are just trying to do their job and in many cases don't even recognize the downstream effects of inappropriate behaviors. Many of these problems occur with strong personality traits further perpetuated by medical training that results in dominant, authoritative, egocentric, demanding behaviors with little emotional intelligence about the world around them. The current changes in today's medical environment are putting even more pressures on physicians which are increasing levels of stress and burnout that can change attitudes, perspectives, and behaviors that impact patient care. Physicians often don't recognize that they're under stress or what it does, and even if they do, feel like they can handle it themselves. Egos and concerns about competency and confidentiality with further limit their willingness to seek outside help. All of these issues can lead to disruptive behaviors. Yes organizations need to have policies and procedures in place to address the issue and definitely need to intervene when staff relationships and patient care may be compromised. Unfortunately, that's the punitive approach. Better yet would be for the organizations to take a different direction by taking a more pro-active approach to gaining insight into physician concerns, providing education, training, guidance, and behavioral support, and providing additional resources to help ease the burden of medical care. We can't leave it up to physicians to take care of themselves. Compassion and early intervention will do the job.

Abstract

AIM: To develop a framework for the clinical and health economic assessment for management of *Clostridium difficile* infection (CDI).

METHODS: CDI has vast economic consequences emphasizing the need for innovative and cost effective solutions, which were aim of this study. A guidance model was developed for coverage decisions and guideline development in CDI. The model included pharmacotherapy with oral metronidazole or oral vancomycin, which is the mainstay for pharmacological treatment of CDI and is recommended by most treatment guidelines.

RESULTS: A design for a patient-based cost-effectiveness model was developed, which can be used to estimate the cost-effectiveness of current and future treatment strategies in CDI. Patient-based outcomes were extrapolated to the population by including factors like, *e.g.*, person-to-person transmission, isolation precautions and closing and cleaning wards of hospitals.

CONCLUSION: The proposed framework for a population-based CDI model may be used for clinical and health economic assessments of CDI guidelines and coverage decisions for emerging treatments for CDI.

Key words: *Clostridium difficile* infection; Guidance; Cost-effectiveness; Model; Standardisation; Decision making

Core tip: Current clinical guidelines seldom include cost-effectiveness evaluations. Conclusions are typically based on clinical data only and sometimes referral is made to prices of therapies for justification of the treatment sequence advised. However, the price of a therapy as such is just a single criterion and does not reflect the balance between effectiveness and costs associated with the application of that therapy. This results often in a restricted position of new therapies in the treatment algorithm. Integration of cost-effectiveness using the population-based variant of cost-effectiveness evaluations as an instrument in guidelines for *Clostridium difficile* infection may be provide better decision making framework.

Cost-effectiveness in *Clostridium difficile* treatment decision-making. *World J Clin Cases* 2015; 3(11): 935-941 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/935.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.935

INTRODUCTION

Escalating costs resulting from ageing of the population and an increase of innovative, expensive, medical technologies have become a major concern for health care professionals, decision-makers and the public. In addition to considering clinical benefits and the price of the new treatment, decision makers have taken a broader perspective by including cost-effectiveness evaluations, which also include related costs in the health care system.

Clostridium difficile infection (CDI) is considered a hospital-acquired infection. Diarrhea due to pathogenic *Clostridium difficile* (*C. difficile*) can occur if the bowel microbiota (bacterial content of the bowel) of a patient is disturbed, which is usually the result of antibiotic use prior to the CDI. With the increasing use of broad-spectrum antibiotics over the past two decades, the incidence of CDI has risen[1,2] and CDI is responsible for 15%-25% of cases of antibiotic associated diarrhea (AAD)[1]. CDI is usually self-limiting, but severe disease leading to colectomy and intensive care admission may occur. Mortality rates of 2%-7% have been reported[2,3], and seem even higher with the hypervirulent strain polymerase chain reaction (PCR) ribotype 027[4-6]. The chance of contracting CDI increases with a longer hospital stay[7] and both spread of *C. difficile* between patients as well as auto-re-infection, by this spore forming bacterium, have been demonstrated. In 55% of hospitalized patients with CDI, hospital stay was prolonged to more than 4 wk[8].

Pharmacotherapy of an initial episode of CDI with oral metronidazole or oral vancomycin is the recommended treatment in most guidelines[9-11]. However, following antibiotic treatment of CDI, recurrence and re-infection within 30 d occurs in approximately 15%-35% of patients, while 33%-65% of patients with > 2 previous CDI episodes will recur[12]. Recurrence of CDI is a serious and difficult-to-treat problem, impacting on the length and overall cost of hospitalisation[13]. The guidelines of the European *Society of Clinical Microbiology and Infectious Diseases* (ESCMID) have identified recurrence as being the most important challenge in the treatment of CDI[14].

Recently published guidelines[11-13] have incorporated relatively new treatments strategies with the antibiotic fidaxomicin and fecal microbiota transplantation (FMT or donor feces infusion), although their role is restricted because of the high price of fidaxomicin and the complexity (unconventional and unstandardized nature) of FMT. The latest Netherlands guideline suggests weighing fidaxomycin's high price versus the advantage of fewer recurrences[10,12,15]. English guidelines also recommends oral metronidazole for initial treatment in non-severe CDI, because it is cheaper than oral vancomycin, and because of concern about the selection of vancomycin resistant enterococci[13]. The median cost to treat a patient with CDI was €33840, showing an almost five fold higher and significant difference compared with the non-infected matched controls[16]. The estimated cost of CDI within the European Union (EU) is about €3 billion per year[17], and may further increase with aging. In most studies, hospitalisation is the main cost driver in patients with CDI[18]. Patients with CDI spend on average an extra 7-21 d in hospital, compared with non-infected controls[16,19,20]. The high rates of treatment failure and high rates of currently recommended antibiotics (metronidazole and vancomycin)[15,21,22] significantly affects costs[23]. The influence on clinical outcome and costs of this limited treatment efficacy is particularly apparent for patient groups with multiple comorbidities and a high risk of recurrence. In addition, minimizing the risk of person-to-person transmission of *C. difficile* in hospital wards seems of utmost importance. Taken together it is evident there is a large socio-economic and clinical unmet need to evaluate all these different factors in a single decision support model[1].

MATERIALS AND METHODS

Classic patient-based cost effectiveness model for infectious diseases tend to ignore the supra-patient social-economic consequences such as, for example, person-to-person transmission and closing of hospital wards due to infectious outbreaks. Preparing for an

Table 1 Summary of the most relevant therapeutic issues in *Clostridium difficile* infection

Level	Issues
Patient level	Recurrence of CDI is a serious and difficult-to-treat problem[26]
	Patient groups at high risk of recurrence or those for whom the impact of recurrence would be most dramatic include those with multiple comorbidities, who are immunocompromised, who are receiving certain concomitant antibiotics[26], who have had CDI previously, who are renally impaired, who are aged 65 yr or over, patients awaiting further treatment (for example chemotherapy) or rehabilitation (for example after cerebrovascular event)
Population level	The rate of person-to-person transmission of *C. difficile* is a complicating problem
	The risk for development of vancomycin-resistant enterococci or other antibiotic induced resistant bacteria, although it is not a major issue in daily practice

CDI: *Clostridium difficile* infection.

Table 2 Summary of the most relevant economic issues in *Clostridium difficile* infection

Level	Issues
Patient level	The cost of recurrence of CDI is high
	CDI leads to additional costs: extra diagnostic tests, extra antibiotics and other medication, time spent by nurse and physician on the ward
	The additional circumstances of these seriously ill patients (*e.g.*, not completing primary therapy, thereby complicating cure or improvement of their disease state) due to CDI should be reflected in the CEA
Population level	The rate of person-to-person transmission of *C. difficile* is a complicating problem with high costs
	The increased length and overall cost of hospitalization with CDI, including the costs of measures to isolate the patient and other clinical measures to prevent person-to-person transmission, as well as the costs of closing and cleaning wards
	The consequences of developing vancomycin-resistant enterococci or other antibiotic induced resistant enterococci are not integrated in standard cost-effectiveness evaluations

CDI: *Clostridium difficile* infection; CEA: Carcinoembryonic antigen.

all-inclusive model an expert procedure was convened considering the clinical and economic issues supposed to have an influence on cost-effectiveness evaluation of preventive and therapeutic measures for CDI. Step one was an extensive literature search on all different aspects of such a model. Subsequently, a base model was constructed and presented to experts. Next, the therapeutic and economic issues that were mentioned by the individual experts were incorporated in the model. This model was the input for a plenary discussion. The most relevant therapeutic and economic issues were defined and discussed. Based on scientific sources (literature and professional guidelines) as well as practice based sources, the issues were validated and a framework for the integration of these relevant issues into cost-effectiveness modeling was finalized. The outcomes of the expert procedure are described below.

Clinical and economic relevant issues

Clinical and economic relevant issues are shown in Tables 1 and 2.

The clinical and economic consequences of CDI in terms of morbidity, survival and costs underline the therapeutic need for innovative cost-effective solutions. Payers require cost-effectiveness analyses when deciding whether or not to reimburse new therapies/approaches for CDI. In such an analysis the first step is typically to develop a patient-based cost-effectiveness model. Such a model for CDI is shown in Figure 1.

Instructions are defined possible different stages for a CDI patient (health states).

Treatment stages hospital setting: (1) In the hospital, discontinuation of the antibacterial therapy that may have precipitated CDI is often not possible; (2) Patients with CDI are usually treated with antibiotics (metronidazole); (3) Patients may die or stay alive and surviving patients may or may not respond to metronidazole; (4) Patients who respond to metronidazole may be cured or experience a recurrence (or re-infection), which may occur during the hospitalization period or after discharge. In both cases the initial treatment with metronidazole is restarted, or vancomycin or fidaxomicin is prescribed instead; (5) If no response to metronidazole is seen, patients may be switched to vancomycin or fidaxomicin; (6) Then again patients may die or stay alive and surviving patients may respond or not respond to vancomycin or fidaxomicin; (7) Patients who respond to vancomycin or fidaxomicin may be cured or experience a recurrence (or re-infection), which may occur during hospitalization or after discharge. In both cases the initial treatment with vancomycin or fidaxomicin is restarted; and (8) Patients not responding will be switched to third-line treatment. For patients failing on third-line treatment, not many treatment options are left. If third line treatment is FMT, this can be repeated several times. Otherwise, patients may have to use vancomycin more or less continuously.

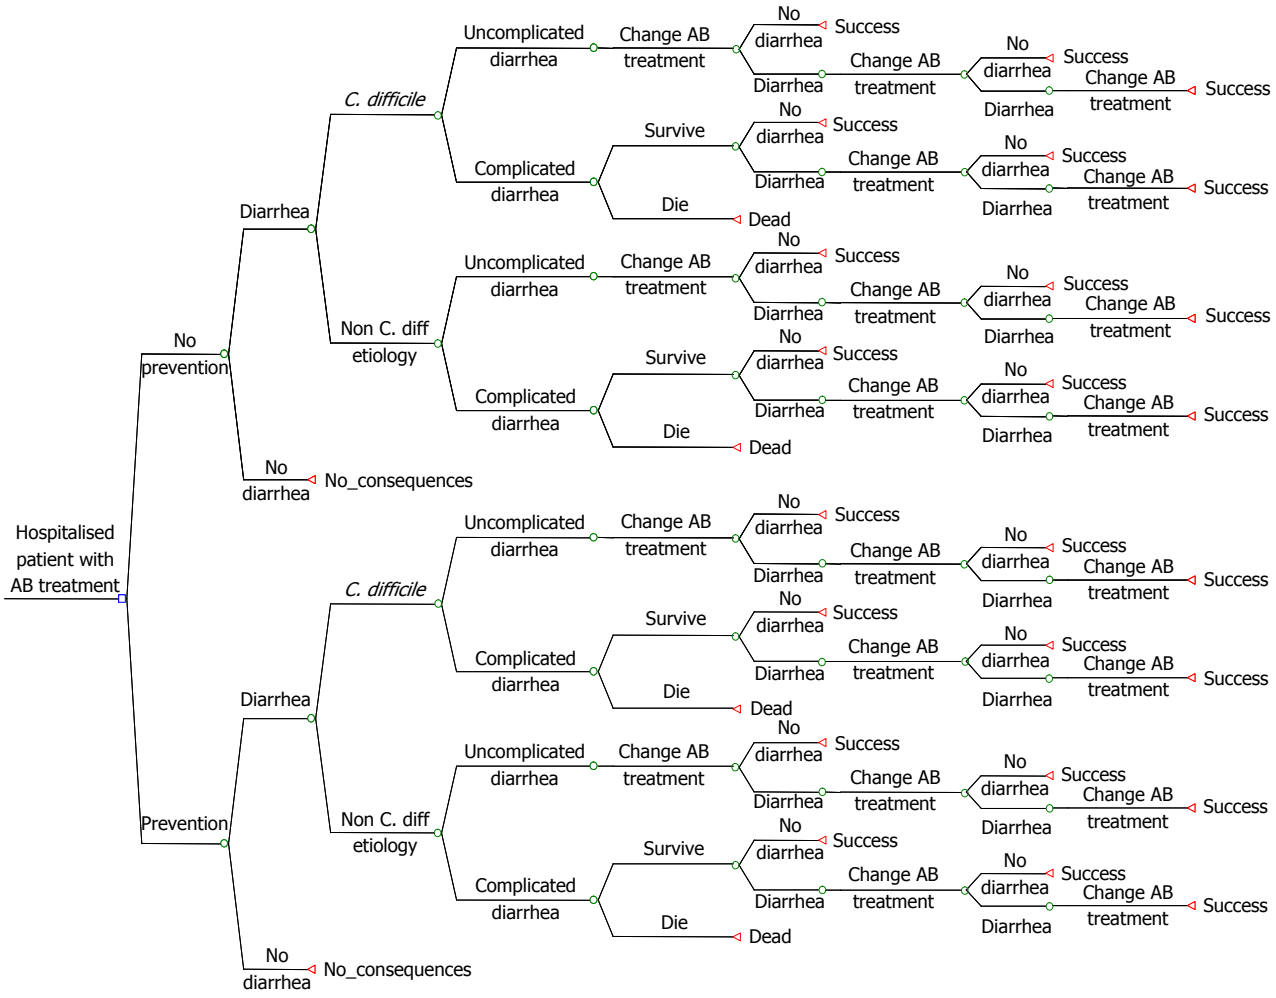

Figure 1 Flow diagram for cost-effectiveness modeling for Clostridium difficile infection.

Treatment stages community setting: The treatment stages are similar, as described above, but the difference is that patients may or may not be hospitalized, whereas in the previous section patients are already hospitalized.

The incremental cost per QALY gained is seen as the preferred cost-effectiveness outcome, but is often of limited value in a health economic analysis, which only covers the hospitalization period. The QALY gain is calculated by combining the utility gain (quality of life gain) with the number of life years gained. QALY gained may therefore be the result of longer life expectancy, utility gain, or both. If the cost per QALY gained is not viewed as the most appropriate outcome (for example when transmission and/or ward contamination are a problem), other cost-effectiveness outcomes may be considered, for example, the cost per recurrence avoided, which reflects the additional costs for the prevention of one recurrence. As recurrence is not only a clinical issue, but also may have major economic consequences, this outcome might be relevant for decision makers.

Population-based model for cost-effectiveness analysis

The cost-effectiveness outcome based on the patient-based model only provides a limited health economic outcome in terms of time horizon and perspective and more importantly, disregards the impact on other patients. The relevant economic issues, such as resistance, person-to-person transmission, isolation measures and closing of wards of hospitals, are all supra-patient effects. These consequences of CDI on hospitals, payers and society, that go beyond the individual scope of the patient, are not integrated in standard CEA's. Therefore, the outcomes of a patient-based cost-effectiveness model should be considered cautiously because they present only a conservative and limited outcome. For all-encompassing cost-effectiveness evaluations of CDI therapies, these supra-patient economic aspects cannot be disregarded. Therefore, we propose performing cost-effectiveness analyses for CDI using a population-based model, which incorporates all of the clinically important elements of the patient-based model as well as the supra-patient therapeutic and economic issues (Table 3).

RESULTS

The flow diagram (Figure 1) does not contain a particular choice for a specific therapy but serves as

Table 3 Similarities and differences between a patient-based and population based cost-effectiveness model

Patient-based cost-effectiveness model	Population-based cost-effectiveness model
Similarities	
Patient-related therapeutic and economic measures for clinical and economic evaluations	
Differences	
	The relevant economic issues, as indicated for CDI like: increasing incidence of CDI, person-to person transmission of CDI, development of vancomycin-resistant enterococci (VRE), or other antibiotic induced resistant bacteria, impact for department of microbiology diagnostic testing isolation measures and closing of wards of hospitals other supra-patient effects
Limited health economic outcome in terms of time horizon and perspective	
The patient-based cost-effectiveness model only captures the short-term time horizon of the CDI episode within the hospital setting at a patient level	

CDI: *Clostridium difficile* infection.

a blueprint for cost-effectiveness modeling. Based on the developments in CDI treatment, we suggest applying different treatment sequences for testing the effects on cost-effectiveness outcomes. Other suggestions for application are stratification of the patient population according to potential co-variables, such as risk factors for recurrence (for example, prolonged hospital stay or ICU admission) or underlying diseases (for example, patients after surgery, patients with a malignancy receiving chemotherapy, and renally impaired patients).

Three types of recent therapies could be candidates for comparison using a population-based model: the antibiotic fidaxomicin, fecal microbiota transplantation (FMT), and preventive use of probiotics.

Fidaxomycin is a novel antibiotic with targeted activity against *C. Difficile* with a similar safety profile as vancomycin. After treatment of an initial episode of CDI, the cure rate after 30 d was increased after fidaxomycin (82%) compared to vancomycin (70%)[16,17,24]. FMT helps restore the normal colonic micro flora in patients with refractory and recurrent CDI[25,26]. The procedure involves single or multiple infusions (*e.g.,* by enema) of a feces based solution from a healthy donor. A recently published randomized trial confirmed the efficacy of FMT in patients with recurrent CDI. For assessment of preventive treatments, the framework (Figure 1) can be used to estimate the costs and benefits of co-prescription of probiotics with antibiotics to prevent CDI. Recently, a patient-based cost-effectiveness evaluation for probiotics showed probiotics "could lead to substantial cost savings"[27]. To further investigate the economic consequences of the use of probiotics to prevent CDI, a population-based model could be applied and although the expected clinical benefit may be limited, total cost savings compared to no preventive treatment, and a predicted (Cochrane) drop in therapy induced side effects, may still be relevant.

DISCUSSION

Current clinical guidelines seldom include cost-effectiveness evaluations. Conclusions are typically based on clinical data only and sometimes referral is made to prices of therapies for justification of the treatment sequence advised. However, the price of a therapy as such is just a single criterion and does not reflect the balance between effectiveness and costs associated with the application of that therapy. This results often in a restricted position of new therapies in the treatment algorithm.

Among health authorities, it is common to include evidence of cost-effectiveness in decision-making about coverage under the health insurance package. Even though the cost per QALY outcome might fall below the threshold of a country, health authorities might decide to reject coverage based on the high weight they place on the budget impact[28]. This may be considered a paradox, because the cost-effectiveness guidelines were written by the same authorities and payers.

Estimates of the cost-effectiveness of a medicine may only have a limited impact on the use of that medicine within a hospital, as a result of a "silo mentality" found within the hospital as well as within the budget management structure existing at the payer, local and national levels. In that case, a treatment (medication or medical therapy) that is more expensive than existing treatments may exceed the amount of money reserved within the hospital budget or the pharmacy budget.

Another paradox, since exceeding this "local" budget might generate a multiplier and create substantial savings in the total system/hospital.

Achieving changes in the "silo structure" within hospitals as well as the budget management structure by payers depends on the generation of basic information on these cost-effective aspects. We propose that usage of the current flow diagram will

generate facts and figures, as well as enable motivated implementation of these facts into guidance documents from professional societies to policy makers and payers (locally or regionally as well as nationally).

Integration of cost-effectiveness using the population-based variant of cost-effectiveness evaluations as an instrument in guidelines for CDI should be considered.

This may help healthcare professionals, patients, hospitals, payers and society to make better decisions about the optimal way to reduce the health and economic impact of CDI.

COMMENTS

Background

Current clinical guidelines seldom include cost-effectiveness evaluations. Conclusions are typically based on clinical data only and sometimes referral is made to prices of therapies for justification of the treatment sequence advised. However, the price of a therapy as such is just a single criterion and does not reflect the balance between effectiveness and costs associated with the application of that therapy. This results often in a restricted position of new therapies in the treatment algorithm.

Research frontiers

Recent high rates of treatment failure and recurrent infection have vast economic consequences emphasizing the need for innovative and cost effective solutions in *Clostridium difficile* infections (CDI). The price of new therapies and approaches cannot always compete with the relatively low, generic prices of current standard therapies with metronidazole and vancomycin. The question is then, how should professional societies integrate new and more effective, but also more expensive, remedies into their guidelines and how health authorities make reimbursement decisions.

Innovations and breakthroughs

The cost-effectiveness outcome based on the patient-based model only provides a limited health economic outcome in terms of time horizon and perspective and more importantly, disregards the impact on other patients. The relevant economic issues, such as resistance, person-to-person transmission, isolation measures and closing of wards of hospitals, are all supra-patient effects. These consequences of CDI on hospitals, payers and society, that go beyond the individual scope of the patient, are not integrated in standard cost-effectiveness analyses. Therefore, we developed a guidance model for coverage decisions and guideline development in CDI based on a population-based cost-effectiveness model.

Applications

The authors propose performing cost-effectiveness analyses for CDI using a population-based model, which incorporates all of the clinically important elements of the patient-based model as well as the supra-patient therapeutic and economic issues.

Terminology

CDI is responsible for 15%-25% of cases of antibiotic associated diarrhea (AAD) and is typically seen in elderly hospitalised patients, resulting in significant morbidity and mortality. Pharmacotherapy of an initial episode of CDI with oral metronidazole or oral vancomycin is the mainstay for pharmacological treatment of CDI and is recommended by most treatment guidelines.

Abstract

Neurotoxicity is an infrequent adverse reaction to iodinated contrast agents. Contrast induced neurotoxicity following coronary angiogram is very rare. Renal disease is a risk factor for contrast induced neurotoxicity. We report a case of contrast induced neurotoxicity following coronary angiogram and intervention using Iohexol (Omnipaque 350) in an end stage renal disease patient on peritoneal dialysis who had prior exposure to iodinated contrast without any adverse reaction. Hemodialysis had to be initiated for rapid removal of the contrast agent with subsequent complete resolution of neurological deficits. This case highlights the need for interventionalists to be aware of an important adverse reaction to iodinated contrast agents, especially in individuals with renal dysfunction, and that neurotoxicity is a possibility even with prior uneventful exposures. The role and timing of hemodialysis in contrast induced neurotoxicity in patients with chronic kidney disease and in those without chronic kidney disease needs further deliberation.

Key words: Coronary angiogram; End stage renal disease; Hemodialysis; Iodinated contrast agent; Neurotoxicity

Core tip: Contrast induced neurotoxicity following coronary angiogram is very rare. Interventionalists should be aware of this rare complication especially in patients with end stage renal disease (ESRD). Iodinated contrast media can be effectively removed from the blood by dialysis. Hemodialysis is a better modality for rapid removal of contrast agent compared to peritoneal

dialysis. Hemodialysis should be considered in life-threatening adverse reactions when supportive care alone is not sufficient. More studies are needed to further delineate the role and timing of hemodialysis following coronary angiogram and the optimal dosage of contrast media in ESRD patients to prevent this infrequent but potentially life threatening adverse reaction.

Contrast induced neurotoxicity following coronary angiogram with Iohexol in an end stage renal disease patient. *World J Clin Cases* 2015; 3(11): 942-945 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/942.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.942

INTRODUCTION

Iodinated contrast agents are an important tool in medical practice. It is estimated that nearly 75 million doses are administered worldwide every year[1]. Modern iodinated contrast agents are mostly nonionic and low osmolar (2-3 times the osmolality of serum) or iso-osmolar (same osmolality of serum). They are safe and adverse reactions, when occur, are mild and self-limiting but serious and life threatening reactions can occur occasionally[2]. Here we describe a case of contrast induced neurotoxicity (CIN) following coronary angiogram in a patient with end stage renal disease (ESRD).

CASE REPORT

A 44-year-old African American female with coronary artery disease, hypertension, severe functional mitral regurgitation, ESRD on peritoneal dialysis, status post failed renal transplant on slow taper of immunosuppressants and diabetes mellitus type 2, was admitted for unstable angina. A month prior to this presentation patient had undergone a diagnostic right and left heart catheterization revealing 70% stenosis of first obtuse marginal branch and 80% stenosis of mid right coronary artery. Seventy ml of Iohexol (Omnipaque 350), a low-osmolar nonionic contrast media, had been used during the procedure. A coronary angiogram with percutaneous coronary intervention was planned. Three days prior to the cardiac intervention, a computerized tomography (CT) of abdomen and pelvis with and without contrast was performed for evaluation of hematuria. Seventy milliliter of Iodixanol (Visipaque 320), an iso-osmolar nonionic contrast media, was used. Patient tolerated this without any untoward events. Three days later patient underwent coronary angiogram and percutaneous intervention with drug eluting stent to first obtuse marginal branch of left circumflex and right coronary artery. Around 190 mL of Iohexol (Omnipaque 350) was used during the procedure. Patient tolerated the procedure without any immediate complications but within few hours developed headache with left sided weakness. A non-contrast head CT, four hours after the coronary intervention, showed extensive intravascular contrast with cortical staining, primarily over the right cerebral hemisphere and left cerebral hemisphere watershed territories (Figure 1). No other acute abnormalities were noted. Subarachnoid hemorrhage was considered unlikely and the clinical picture was considered likely secondary to contrast induced neurotoxicity. Supportive care and manual peritoneal dialysis exchanges were initiated. During this process, patient became more encephalopathic with subsequent seizure like activity. Antiepileptic medications, lorazepam and levetiracetam, were given to control seizures. Patient was transitioned to hemodialysis for rapid removal of contrast agent. A magnetic resonance imaging (MRI) of the brain taken 24 h after the coronary intervention showed hyperintense cortical signal on T2, fluid attenuated inversion recovery (FLAIR) and diffusion weighted images throughout the right greater than left cerebral hemisphere (Figure 2). No definite restricted diffusion was observed. There was mild mass effect without hemorrhage or herniation. An electro encephalogram was negative for seizure

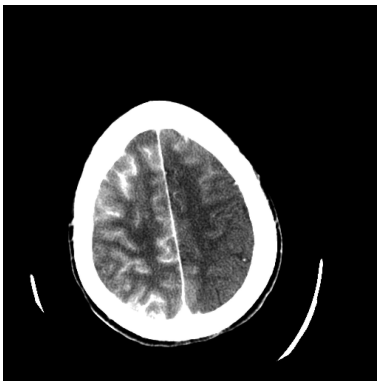

Figure 1 Non-contrast head computerized tomography showing extensive intravascular contrast with cortical staining, primarily over the right cerebral hemisphere.

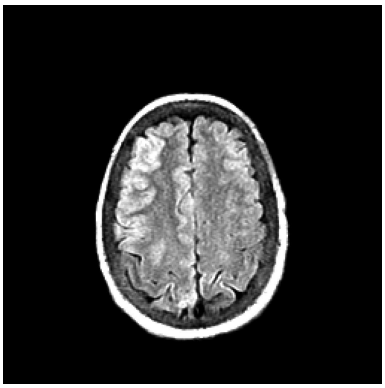

Figure 2 Magnetic resonance imaging fluid attenuated inversion recovery image showing hyperintense cortical signal of the cerebral hemispheres.

activity. These findings were considered consistent with contrast induced neurotoxicity (CIN). Supportive care and hemodialysis were continued for the next three days with gradual improvement and complete resolution of neurological abnormalities. Patient was transitioned back to peritoneal dialysis and discharged from the hospital in stable condition. Repeat imaging was not performed prior to discharge.

DISCUSSION

CIN is an infrequent adverse reaction to iodinated contrast agents. Intraarterial and neurointerventional procedures are more commonly associated with CIN[3]. CIN following coronary angiogram is very rare and the reported incidence is 0.06%[4]. This adverse reaction following coronary angiogram using Iohexol has been noted before[5]. All types of iodinated contrast agents irrespective of their ionic state or osmolality can cause CIN[3]. Neurological deficits are either focal or global. The exact etiology of CIN is unclear. Prior and subsequent exposure may not cause the same complication[4]. It is considered to be an idiosyncratic reaction to the contrast agent. An intact blood brain barrier is impermeable to contrast agents under normal conditions. Direct chemotoxic effects and hyperosmolality result in increased permeability of blood brain barrier and resultant cerebral edema, and also the possibility of increased hydrostatic pressure transmitted during neurointerventional procedures and subsequent changes in cerebral autoregulation predisposing to contrast extravasation has also been postulated[4,6]. Symptoms range from headache to seizures, hemiparesis, ophthalmoplegia, transient global amnesia, and transient cortical blindness. Neurological deficits are mostly transient but could also be persistent, especially with ophthalmic involvement[3,4]. Symptoms appear within 2 to 12 h of contrast injection and usually resolve in 24 to 72 h[7]. Imaging studies are recommended to rule out thromboembolic or hemorrhagic complications. Unenhanced CT images may be normal or show combination of poorly localized cortical and or subcortical enhancement, cerebral edema, and hyperdensity in the subarachnoid space similar to subarachnoid hemorrhage. MRI imaging may demonstrate hyperintense areas on T2, FLAIR, and diffusion weighted images[5]. Risk factors for CIN include renal disease, hypertension, and route, number of administration, and duration of exposure[3,7]. Larger dose of contrast is considered a risk factor but CIN has been reported even with very small doses[4]. Kocabay *et al*[3] recommend a maximum of 170 mL contrast agent for coronary angiograms to prevent CIN but none of the patients in their case series had ESRD. Our patient had ESRD and had prior exposure to iodinated contrast agents including Omnipaque 350 and to Visipaque 320 without any adverse events supporting the concept of CIN being an idiosyncratic reaction. In our case, for the culprit coronary angioplasty procedure, 190 mL of Omnipaque 350 had been utilized. General consensuses for preventive measures include adequate hydration prior to contrast exposure and using lowest possible contrast dose. Treatment is mostly supportive and hydration. Contrast media can be effectively removed from the blood by dialysis[8].

Contrast induced neurotoxicity following coronary angiogram is very rare. Interventionalists should be aware of this rare complication especially in patients with ESRD. Iodinated contrast media can be effectively removed by dialysis. Hemodialysis is a better modality for rapid removal of contrast agent compared to peritoneal dialysis. Hemodialysis should be considered in life-threatening adverse reactions when supportive care alone is not sufficient. More studies are needed to further delineate the role and timing of hemodialysis following coronary angiogram, and the optimal dosage of contrast media in ESRD patients to prevent this infrequent but potentially life threatening adverse reaction to iodinated contrast agents.

COMMENTS

Case characteristics

A 44-year-old female with coronary artery disease and end-stage renal disease on peritoneal dialysis underwent coronary angiogram and intervention for unstable angina.

Clinical diagnosis

Status post coronary angiogram and intervention, patient developed acute encephalopathy with no focal neurological deficits.

Differential diagnosis

Cerebrovascular accident, contrast neurotoxicity.

Imaging diagnosis

A non-contrast computerized tomography of the head showed extensive intravascular contrast with cortical staining, primarily over the right cerebral hemisphere. A magnetic resonance imaging showed hyperintense cortical signal of the cerebral hemispheres.

Treatment

Hemodialysis and supportive care.

Related reports

Contrast induced neurotoxicity is very rare following coronary angiogram. Correct diagnosis will avoid erroneous treatment for cerebrovascular accident.

Term explanation

Contrast induced neurotoxicity (CIN) is an infrequent adverse reaction to iodinated contrast agents. End stage renal disease (ESRD) is a risk factor for the development of CIN.

Experiences and lessons

Contrast induced neurotoxicity is very rare following coronary angiogram. Prior exposures to iodinated contrast agents may not have resulted in any adverse reaction supporting CIN to be an idiosyncratic reaction. Hemodialysis is an effective tool in contrast removal and management of CIN, especially in ESRD patients.

Peer-review

Very good case report about contrast induced neurotoxicity. It is very well written, summarized but completed.

Abstract

Thymoma and thymic carcinoma are rare epithelial tumors, which originate from the thymus gland. According to the World Health Organization there are "organotypic" (types A, AB, B1, B2, and B3) and "non-organotypic" (thymic carcinomas) thymomas. Type B3 thymomas are aggressive tumors, which can metastasize. Due to the rarity of these lesions, only 7 cases of extradural metastasis are described in the literature. We report the first and unique case of a man with cervical intradural B3 thymoma metastasis. A 46-year-old man underwent thymoma surgical removal. The year after the procedure he was treated for a parietal pleura metastasis. In 2006 he underwent cervical-dorsal extradural metastasis removal and C5-Th1 stabilization. Seven years after he came to our observation complaining left cervicobrachialgia and a reduction of strength of the left arm. He underwent a cervical spine magnetic resonance imaging, which showed a new lesion at the C5-C7 level. The patient underwent a surgery for the intradural B3 thymoma metastasis. Neurological symptoms improved although the removal was subtotal. He went through postoperative radiation therapy with further mass reduction. Spinal metastases are extremely rare. To date, only 7 cases of spinal extradural metastasis have been described in the literature. This is the first case of spinal intradural metastasis. Early individuation of these tumors and surgical treatment improve neurological outcome in patients with spinal cord compression. A multimodal treatment including neoadjuvant chemotherapy, surgery and postoperative radiation therapy seems to improve survival in patients with metastatic thymoma.

Marotta N, Mancarella C, Colistra D, Landi A, Dugoni DE, Delfini R. First description of cervical intradural thymoma metastasis. *World J Clin Cases* 2015; 3(11): 946-950 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/946.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.946

INTRODUCTION

Thymoma and thymic carcinoma are uncommon epithelial lesions, which originate from the thymus gland. To date, the true incidence is not known, but it is estimated to be 0-15 cases/100000 people. Between the fifth and sixth decades of life, this pathology represents 0.2%-1.5% of all malignancies[1]. According to the World Health Organization there are "organotypic" (types A, AB, B1, B2, and B3) and "non-organotypic" (thymic carcinomas) thymomas. Types A, AB, B1 and B2 thymomas are benign tumors. Type B3 thymomas are aggressive tumors of intermediate malignancy[2]. Spinal metastases are very uncommon. In the literature, only 7 patients with spinal extradural metastasis have been described. We report the first and unique case of a man with cervical intradural B3 thymoma metastasis.

CASE REPORT

A thymoma was resected in a 46-year-old male in 1989. He did not submit himself to adjuvant therapy. A year after the procedure he underwent parietal pleura metastasis resection. The patient remained disease-free until 2006, when he complained a reduction of strength of the left arm, for the presence of a cervico-dorsal extradural metastasis. He underwent resection of the lesion and C5-Th1 stabilization (Figure 1). The lesion was totally removed (R0) and the dura mater appeared intact.

In 2013, the patient came to our observation complaining left cervicobrachialgia and a reduction of strength of the left arm. A cervical spine magnetic resonance imaging (MRI) showed a new lesion at the C5-C7 level (Figure 2). The lesion showed a homogeneous enhancement after gadolinium administration in the T1-weighted sequences, and enclosed the spinal cord, especially on the left side. From the imaging, it was not clear if the lesion was extradural or intradural. Intraoperatively, there was not pathological tissue in the epidural space; it appeared only after opening the dura mater. The patient underwent a sub-total resection, in order to preserve the spinal cord from the surgical manipulation. The lesion was intradural-extramedullary. It was adherent to the spinal cord surface in its lateral and anterior portions.

Figure 1 Maximum intensity projection reconstruction from computed tomography images shows C5-Th1 stabilization after the first intervention.

A spinal metastasis of the type B3 thymoma according to the World Health Organization 2004 was diagnosed (well-differentiated thymic carcinoma according to Marino and Muller-Hermelick)[3]. The immunohistochemical examination demonstrated positivity of neoplastic cells for CK19 and p63 and CD1a positive T-cells (Figure 3). Even if the resection was not total, no postoperative neurological deficits were observed. After 3 mo, the cervico-thoracic spine MRI showed a small residual tumor, especially anteriorly to the cervical spinal cord (Figure 4). Subsequently, focal radiotherapy (25.5 grays) was given. Cervical MRI after radiation treatment showed almost total disappearance of the mass (Figure 5). The patient is free of symptoms.

A search was carried out about spinal thymoma metastasis in the English language literature. We excluded one work because it is available only in Japanese language[4] and another because it did not report sufficient data to be included in our series. We used the following key words: "thymoma metastasis", "thymic carcinoma", "spinal cord compression", and "spinal metastasis". The data were extracted according to these parameters: (1) author and year of publication; (2) age; (3) sex; (4) time to spinal metastasis; (5) site of spinal metastasis; (6) sign and symptoms; (7) surgery; (8) follow-up; (9) radiotherapy; and (10) classification of histological type of the thymoma[5-9].

DISCUSSION

We found 6 papers, in which 7 cases were described.

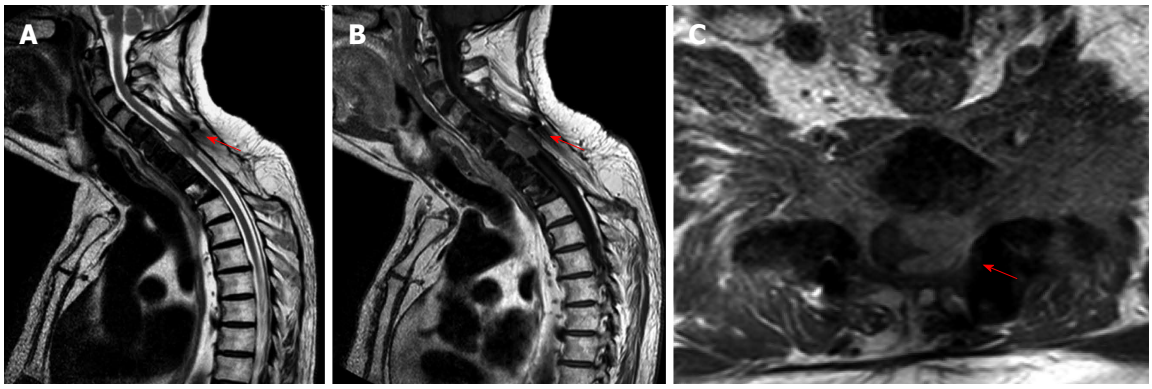

Figure 2 Cervical spine magnetic resonance imaging. A: A C5-C7 lesion with homogeneous enhancement after gadolinium administration in the T1-weighted sequences; B: T2 weighted sequences showing the enclosed spinal cord; C: Especially on the left side (red arrow).

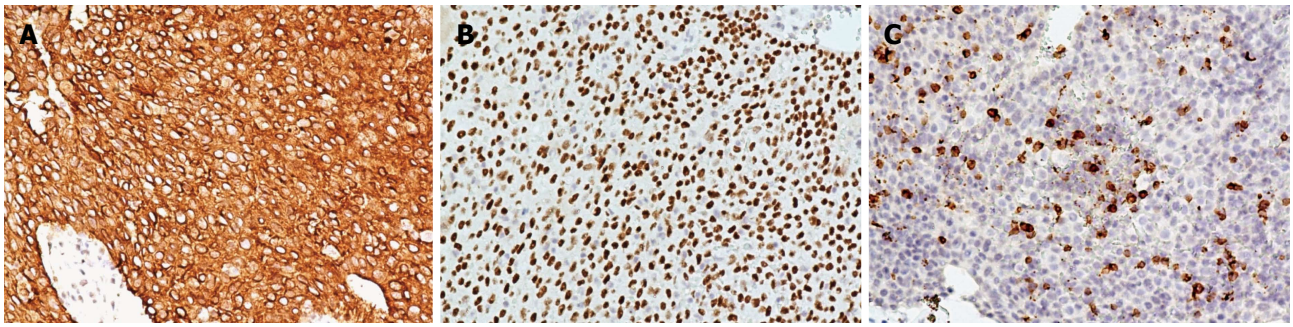

Figure 3 The immunohistochemical examination demonstrated positivity of neoplastic cells for (A) CK19, (B) p63 and (C) CD1a positive T-cells.

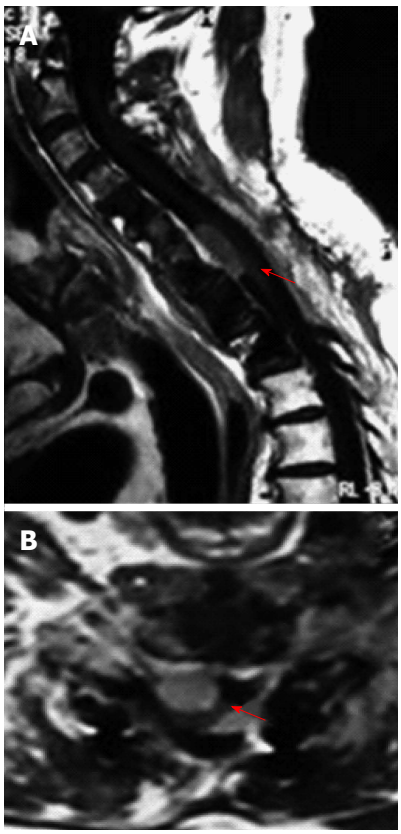

Figure 4 Magnetic resonance imaging of the cervico-thoracic spine at 3-mo follow-up showing (A) a small residual tumor, especially anteriorly to the cervical spinal cord and (B) axial view (red arrow).

We included our case in the review, for a total number of 8 cases of spinal thymoma metastasis. Four patients were male and 3 were female. About the age, the average was 51.4 years old (range, 29-70 years). The median time from thymoma diagnosis to spinal metastasis was 7.9 years (range, 1-17 years); in one case the spinal metastasis was diagnosed before primary tumor; the case with longer time to spinal metastasis was our case. The spinal metastases were localized at the thoracic level in 4 cases, at the cervico-thoracic site in 1 case, cervical level in 2 cases, and lumbar level in 1 case. Patients presented symptoms related to the thymoma in 2 cases (myasthenia gravis); in all cases they had neurological symptoms related to the spinal metastasis (motor deficit, sensitive deficit or pain). All patients underwent surgical treatment. During the follow-up, 3 patients died after 3 mo, 5 mo and 2 years, respectively; 4 patients survived with a time of follow-up from 9 mo to 8 years (our case). Five patients did not receive radiation therapy, and 2 underwent RT. Histological diagnosis was not based on the actual WHO classification in 2 cases; the histological subtype was B2 in 1 case, B3 in 2 cases, and C in 2 cases.

Thymoma and thymic carcinoma are uncommon epithelial lesions, which originate from the thymus gland. Thymoma is a rare tumor, commonly associated with the myasthenia gravis (15%); local dissemination occurs quickly, but distant spinal metastasis may occur up to 16 years after the diagnosis of thymomas. They

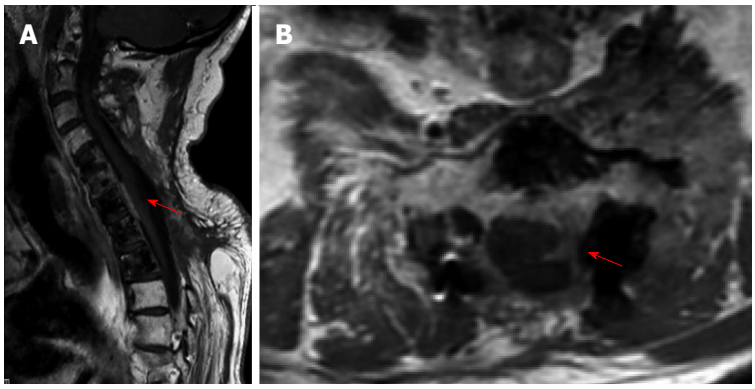

Figure 5 Cervical magnetic resonance imaging after radiation treatment showing (A) almost total disappearance of the mass and (B) axial view (red arrow).

can metastasize to the pleura regional nodes, liver and lung. Spinal metastases are very uncommon. In the literature, only 7 patients with spinal extradural metastasis have been described. We report a unique case of spinal intradural metastasis. On MRI, the vertebral metastases appear hypointense on T1-weighted images and hyperintense on T2-weighted images. Infiltration of the paravertebral muscles and vertebral elements, evident on axial views, is possible. Imaging after gadolinium administration shows an important enhancement. A computed tomography scan shows infiltration of the vertebral body, with both osteolytic and osteoblastic lesions. The spinal metastasis can cause, in fact, vertebral collapse, spinal instability and neurological deterioration. Early diagnosis and surgery have the goal to control pain and reduce motor deficits. It is fundamental to take in account that an invasive thymoma can metastasize both extradurally and intradurally, because patient's survival may be extended by an early diagnosis followed by an appropriate treatment.

We report the first case of spinal intradural metastasis. It is not yet known the gold standard of treatment, but a multimodal treatment which includes neoadjuvant chemotherapy, surgery and postoperative radiotherapy seems to improve survival in patients with metastatic thymoma.

COMMENTS

Case characteristics

Left cervicobrachialgia and a reduction of strength of the left arm.

Differential diagnosis

It is fundamental to take in account that an invasive thymoma can metastasize both extradurally and intradurally.

Imaging diagnosis

The lesion showed a homogeneous enhancement after gadolinium administration in the T1-weighted sequences, and enclosed the spinal cord, especially on the left side.

Pathological diagnosis

A spinal metastasis of the type B3 thymoma according to the World Health Organization 2004 was diagnosed (well-differentiated thymic carcinoma according to Marino and Muller-Hermelick).The immunohistochemical examination demonstrated positivity of neoplastic cells for CK19 and p63 and CD1a positive T-cells.

Treatment

Surgical sub-total resection and focal radiotherapy.

Related reports

The spinal metastasis can cause, in fact, vertebral collapse, spinal instability and neurological deterioration. Early diagnosis and surgery have the goal to control pain and reduce motor deficits.

Term explanation

Extradural, outside the dura mater.

Experiences and lessons

Multimodal treatment which includes neoadjuvant chemotherapy, surgery and post-operatory radiotherapy seems to improve survival in patients with metastatic thymoma.

Peer-review

The present case report is worth publishing, as it documents an extremely rare case of an intradural thymoma metastasis.

Abstract

A littoral cell angioma (LCA) is a primary vascular tumor of the spleen, that can have malignant potential and may present association with other malignancies. This is a case of LCA that was discovered incidentally in a 79-year-old woman who presented with a polycythemia at the time of consultation. The neoplasm was evaluated by ultrasound and computed tomography. The patient underwent a splenectomy that revealed LCA by pathological evaluation. The post-operative outcome was favorable with no complications or recurrent disease. This case presentation, clinical, radiographic, and pathological features of an uncommon splenic tumor can be studied in order to advance our knowledge in our understanding of LCA.

Key words: Laparoscopy; Splenectomy; Splenomegaly; Angioma; Littoral cell

Core tip: We invite readers to read "laparoscopic splenectomy for littoral cell angioma of the spleen: Case report", because we understand how pathological evaluation, after splenectomy, allows the definite diagnosis of this rare vascular neoplasm and given its

potential malignancy and its association with other cancer types, splenectomy should be always performed.

Laparoscopic splenectomy for a littoral cell angioma of the spleen: Case report. *World J Clin Cases* 2015; 3(11): 951-955 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/951.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.951

INTRODUCTION

LCA was first reported by Falk *et al*[1] in 1991. They reviewed 200 surgical specimens of benign vascular tumors of the spleen and described 17 similar tumors correlated to the cells lining the red pulp splenic sinuses[1]. The littoral cell, the original one, presents both epithelial and histiocytic features[1].

Both sexes at any age are affected by this tumor. Usually patients are asymptomatic and the dignosis leads to an incidental founding. When patient presents symptoms they arise later and are splenomegaly, thrombocytopenia and anemia.

The neoplasm take its origin in the sinus of the red pulp of the spleen. These endothelial cells show the same immunoreactivity for markers CD31 and factor Ⅷ, as showed by hemangiomas situated in different places.

Pathogenetic mechanism of this tumor is still uncertain, but has been thought as a possible one an immune system dysfunction because it has been observed an important association with autoimmune disorders like Crohn's disease and metabolic diseases like Gaucher's one[2,3].

CASE REPORT

Our patient, a 79-year-old woman, entered to the hospital for a polycythemia and during medical examinations it was discovered an hypointense lesion of the spleen and splenomegaly without hypersplenism (Figure 1). The patient did not present abdominal pain, nausea, episodes of vomite and changes in bowel habits. Her BMI was 35.8. The evaluation of EPO (5 IU/L) and genetic mutation of Jak2 (30%) revealed a chronic myeloproliferative syndrome. Ultrasound and computed tomography (CT) scan were performed. The ultrasound showed a round, solid, hypoechogenic mass of 45 mm of size at the superior pole of the spleen (Figure 2). A large, solitary, low-density lesion appeared in the early arterious phase of the contrast-enhanced CT (Figure 1). Laboratory tests showed normal liver enzymes and renal function, they only revealed an elevated count of platelets (587000/mcL) and a polycythemia (RBC = 5920000/mm, Hb = 17 g/dL) that was the primary reason why the patient entered to the Hospital.

Figure 1 Computed tomography scan.

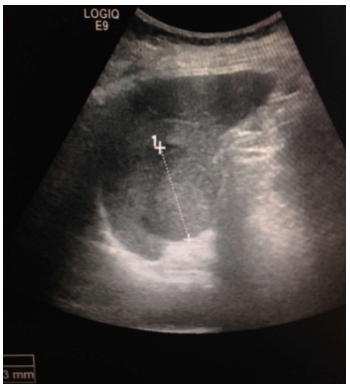

Figure 2 Ultrsound.

Imaging

Our patient underwent CT scan, that showed a hypoattenuating nodule of 4 cm × 5 cm of size with contrast enhancement on the arterious phase (Figure 1) and a hypointense lesion at Ultrasonography (Figure 2). Several studies have described the contrast-enhanced sonographic findings of various splenic lesions[4-6]. Characteristically benign vascular tumors show isoenhancement or a little hyperenhancement during the arterial phase and isoenhancement or hypoenhancement during the venous phase.

Rarely imaging can dignose the benign vascular neoplasm because many other splenic tumors mimic LCA. It is important a differential diagnosis with other splenic tumors that have a similar appearance with LCA like lymphangiomatosis, hamartoma, hemangiomatosis, hemangioendothelioma, hemangiopericytoma, and angiosarcoma; it has to be included in the differential diagnosis also lymphoma, metastases, Kaposi sarcoma and infectious diseases like Pneumocystis and Mycobacterium.

Histopathologic features

The neoplasm arises from the littoral cells in the splenic red pulp sinuses. Hemangiomas of other sites share

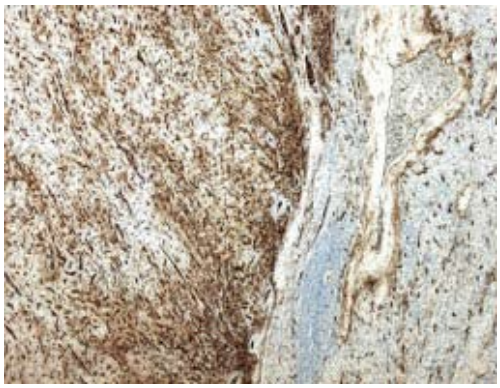

Figure 3 Positivity of vascular proliferation for immunohistochemical marker CD34; on right side there is normal splenic parenchyma (CD3450X).

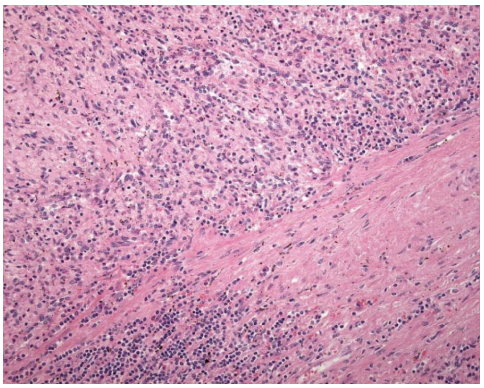

Figure 4 Vascular structures anastomosed (E-E 200 ×).

the same immunoreactivity for vascular endothelial markers CD31 and factor Ⅷ. It is interesting to observe that the tumor cells express histiocytic marker CD68 that explain why this neoplasm may begin in the splenic sinus lining cells or littoral cells.

DISCUSSION

Pathological evaluation, after laparoscopic splenectomy, allowed the definite diagnosis of this rare vascular neoplasm.

The surgical outcome was favorable without post-operative complications or recurrence.

Given certain diagnosis by pathological evaluation, associated to clinical features and imaging of an uncommon splenic tumor can be studied in order to advance our knowledge in our understanding of LCA.

The pathogenesis of LCA is nowadays still indefinite. We speculate as a possible pathogenic mechanism an immune system dysfunction, as demonstrates the association with autoimmune disorders like Gaucher's disease and Crohn's disease.

Pathological evaluation, after splenectomy, allows the definite diagnosis of this rare vascular neoplasm. Given its potential malignancy, splenectomy is usually performed.

The lining of vascular splenic sinuses, made by endothelial cells, presents both phagocytic and hematopoietic characteristics, that is the reason why they are thought to be unique since the 1930s[2].

The littoral cell of the spleen, the cell of origin, presents both epithelial and histiocytic features[7,8]. Overall the incidence of hemangioma of the spleen changes from 0.003% to 14% in autopsy reports[9], however the real incidence of LCA is unrecognized.

From a clinical point of view, the majority of patients with LCA are asymptomatic, while usually symptoms are anemia, thrombocytopenia both can be hypersplenism associated, splenomegaly, or unrecognized fever[10].

Abdominal pain can be also the main symptom at the time of consultation, otherwise the neoplasm is an incidental finding[11].

Our patient infact, entered to the hospital for a polycythemia and during medical examinations it was discovered an hypointense lesion of the spleen and splenomegaly without hypersplenism. She did not describe episodes of abdominal pain.

Normally, splenectomy performed for other reasons leads to diagnosis of LCA.

Only a minority of patients presents with splenomegaly, fever and features of hypersplenism like anemia and thrombocytopenia[12].

The vascular neoplasm can look like a single or multiple lesions in the spleen, while a massive splenomegaly can mimic a pancreatic tumor.

Recently LCA has been associated with tumors of the colon, kidney, pancreas, lung and ovary[13]. Have been described also associations with leiomyosarcoma, melanoma and lymphoma. Considering this malignancy association in patients with LCA, it should be always excluded visceral tumor.

The laparoscopic approach permitted to operate an old age, obese and cardiopathic patient and to dismiss her in 6 d without any postoperative complication.

Reports[10] comparing laparoscopic splenectomy to open splenectomy for diagnosed diseases like idiopathic thrombocytopenic purpura, reveal superiority of miniinvasive procedure because of its several benefits of lower post-operative pain and quicker post-operative recovery. Kercher *et al*[11] found that a laparoscopic approach was beneficial for massive splenomegaly (defined as craniocaudal dimension $\geqslant$ 17 cm and weight $\geqslant$ 600 g), which is also supported by our experience with this patient. Brodsky *et al*[12] also support laparoscopic splenectomy for several splenic diseases, also in case of splenomegaly. Rosen *et al*[13] found laparoscopic splenectomy to be safe for benign and malignant hematologic conditions, including Idiopathic Thrombocytopenic Purpura and a case of LCA, with a conversion rate of 5%.

Our patient was discharged by postoperative day 2 and did not present any complication, so

that splenectomy allowed the definite dignosis of LCA, without compromise the outcome in an old, cardiopathic, obese patient.

Pathological evaluation, after splenectomy, allows the definite diagnosis of this rare vascular neoplasm and given its potential malignancy, even though most of LCAs are benign, and its association with other cancer types, splenectomy should be always performed. So their differential diagnosis must observe primary and secondary malignancy.

This rare case shows the interest of studying vascular tumors of the spleen even most of all are incidental foundings.

Considering these concepts, gold standard management appears to be splenectomy (in our experience and in literature, laparoscopic approach reveals a better surgical outcome) and a strict follow-up to recognize synchronous tumors or metastatic lesions.

COMMENTS

Case characteristics

The authors' patient, a 79-year-old woman, entered to the hospital for a polycythemia and during medical examinations it was discovered an hypointense lesion of the spleen and splenomegaly without hypersplenism (Figure 1). The patient did not present abdominal pain, nausea, episodes of vomite and changes in bowel habits.

Clinical diagnosis

Splenomegaly, polycythemia, chronic myeloproliferative syndrome, elevated counts of platelets.

Differential diagnosis

Lymphangiomatosis, hamartoma, hemangiomatosis, hemangioendothelioma, hemangiopericytoma and angiosarcoma; lymphoma, metastases, Kaposi sarcoma and infectious diseases like Pneumocystis and Mycobacterium.

Laboratory diagnosis

Laboratory tests showed normal liver enzymes and renal function, they only revealed an elevated count of platelets (587000/mcL) and a polycythemia (RBC = 5920000/mm, Hb = 17 g/dL) that was the primary reason why the patient entered to the Hospital.

Imaging diagnosis

CT scan showed a hypoattenuating nodule of 4 cm × 5 cm of size with contrast enhancement on the arterious phase, and US revealed an hypointense splenic lesion.

Pathological diagnosis

Splenectomy revealed at the pathological examination vascular structures anastomosed and positivity of vascular proliferation for immunohistochemical marker CD34 , diagnosing LCA (Figures 3 and 4).

Treatment

Laparoscopic splenectomy.

Related reports

Recently LCA has been associated with neoplasms of the colon, kidney, pancreas, lung and ovary. Have been described also associations with leiomyosarcoma, melanoma and lymphoma. Considering this malignancy association in patients with LCA, it should be always excluded visceral tumor.

Term explanation

LCA is primarily a benign tumor, however may be associated with others visceral neoplasms and may have malign potential.

Experiences and lessons

Pathological evaluation, after splenectomy, allows the definite diagnosis of this rare vascular neoplasm because radiological and clinical foundings do not lead to a certain diagnosis. So, given its potential malignancy, even though the vast majority of LCAs are benign, and its association with other cancer types, splenectomy remains the golden standard in the managment of this disease.

Peer-review

Best management of this disease remains splenectomy (in our experience and in literature, laparoscopic approach reveals a better surgical outcome) and a strict follow-up to recognize synchronous tumors or metastatic lesions.

Abstract

We describe clinical, diagnostic features and follow up of a patient with a vanishing brain lesion. A 14-year-old child admitted to the department of Neurology at September 2009 with a history of subacute onset of fever, anorexia, vomiting, blurring of vision and right hemiparesis since one month. Magnetic resonance imaging (MRI) of the brain revealed presence of intra-axial large mass (25 mm × 19 mm) in the left temporal lobe and the brainstem which showed hypointense signal in T1W and hyperintense signals in T2W and fluid attenuated inversion recovery (FLAIR) images and homogenously enhanced with gadolinium (Gd). It was surrounded by vasogenic edema with mass effect. Intravenous antibiotics, mannitol (2 g/12 h per 2 d) and dexamethasone (8 mg/12 h) were given to relief manifestations of increased intracranial pressure. Whole craniospinal radiotherapy (brain = 4000 CGy/20 settings per 4 wk; Spinal = 2600/13 settings per 3 wk) was given based on the high suspicion of neoplastic lesion (lymphoma or glioma). Marked clinical improvement (up to complete recovery) occurred within 15 d. Tapering of the steroid dose was done over the next 4 mo. Follow up with MRI after 3 mo showed small lesion in the left antero-medial temporal region with hypointense signal in T1W and hyperintense signals in T2W and FLAIR images but did not enhance with Gd. At August 2012, the patient developed recurrent generalized epilepsy. His electroencephalography showed the presence of left temporal focus of epileptic activity. MRI showed the same lesion as described in the follow up. The diffusion weighted images were normal. The seizures frequency was decreased with carbamazepine therapy (300 mg/12 h). At October 2014, single voxel proton (1H) MR spectroscopy (MRS) showed

reduced N-acetyl-aspartate (NAA)/creatine (Cr), choline (Cho)/Cr, NAA/Cho ratios consistent with absence of a neoplasm and highly suggested presence of gliosis. A solitary brain mass in a child poses a considerable diagnostic difficulty. MRS provided valuable diagnostic differentiation between tumor and pseudotumor lesions.

Key words: Vanishing brain mass; Gliosis; Unconfirmed diagnosis; Lymphoma; Granuloma

Core tip: A vanishing brain space occupying lesion is defined as reduction or disappearance of a brain lesion spontaneously or after steroid treatment to ⩽ 70% of its size before establishing its definitive diagnosis. A vanishing solitary neoplastic/non-neoplastic (pseudotumor) (*e.g.*, infection/abscess, granuloma, radiation necrosis, multiple sclerosis) brain mass in a child poses a considerable diagnostic difficulty particularly deeply seated lesions in which tissue diagnosis is difficult to be done. In clinical practice, neuroimaging has to be done every 6-12 mo for at least 3-5 years to follow up after complete remission of the patient. Magnetic resonance spectroscopy (MRS) has been proved to be valuable for diagnostic differentiation between tumor and pseudotumor lesions. MRS provides information related to the metabolic activity in the culprit lesion (*e.g.*, neoplastic processes, demyelination, cell necrosis or gliotic changes).

Hamed SA, Mekkawy MA, Abozaid H. Differential diagnosis of a vanishing brain space occupying lesion in a child. *World J Clin Cases* 2015; 3(11): 956-964 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/956.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.956

INTRODUCTION

Cases with solitary brain space occupying lesions (*e.g.,* tumor, intracranial infection/abscess, granuloma, neurocystocercosis, tuberculoma, multiple sclerosis) may pose a diagnostic difficulty particularly when brain biopsy can't be done due to deep location of the lesion. For such cases, clinicians often start corticosteroids to reduce manifestations of increased intracranial pressure (ICP) (caused by the intracranial mass and the surrounding vasogenic edema) and to give brain radiation if there is a high suspension for the presence of malignant lesion[1,2]. Also such patients should be routinely followed by magnetic resonance imaging (MRI) even after the disappearance of the enhancing lesion for at least 3-5 years[3]. The disappearance or decrease of the initial brain space occupying lesion (SOL) volume to ⩽ 70% either spontaneously or after steroid treatment before establishing the definitive diagnosis, has been referred as a vanishing brain lesion[4].

In the last decade, magnetic resonance spectroscopy (MRS) has been considered as a diagnostic test which helped to distinguish normal from abnormal brain tissue. Proton (1H) MRS measures some unique tissue metabolites which provide valuable information regarding the severity of the brain lesion, pathogenesis, prognosis and response to therapy. Briefly, in MRS, peaks which are proportional to the concentration of the given metabolite, are arranged along a flat baseline according to their radiofrequency (measured in units called parts per million or ppm)[5]. The most commonly defined brain metabolites (^{1}H-MRS spectrum) in which their patterns can be observed and correlate with different types of lesions (from right to left) include: free lipids (Lip), lactate (Lac), N-acetyl-aspartate (NAA), glutamate/glutamine (Glx), creatine (Cr)/phosphocreatine (the Cr peak), choline (Cho; the Cho peak), and myo-inositol (mI). In spectra obtained at long echo time (⩽ 135 ms), the peaks for NAA, Cr, Cho, and lactic acid are prominent and sharp. They are also detected and quantified at short echo time (⩾ 30 ms) MRS. In contrast, Lip, Glx and mI signals are detected only in short echo time MRS. In normal brain, NAA is synthesized in neurons, diffuses along axons and broken down in oligodendrocytes. In MRS, NAA is a marker of intact number of neurons in gray matter and the density of intact axons in white matter. The most prominent peak of NAA in MRS is the resonance at 2.0 ppm and it has concentration of 7.9-16.6 mmol/kg. NAA is a non-specific marker as its value is reduced in any disease associated with neuronal or axonal loss[6]. Cr is present at higher concentrations in the glia and it is a marker of brain energy. The most prominent peak of Cr in MRS is the resonance at 3.0 ppm and concentration of 5.1-10.6 mmol/kg[7]. Cho is a marker of brain injury of non-specific type. Cho level reflects the brain membrane metabolism with cellular turnover. The most prominent peak of Cho in MRS is the resonance at 3.2 ppm and concentration of 0.9-2.5 mmol/kg[6]. Lipids comprise about 20% of brain weight. Lipids are normally absent from 1H spectrum, and its appearance at 0.9-1.4 ppm resonances indicates presence of necrotic tissue (*i.e.*, breakdown of cell membrane and release of fatty acids)[8]. The mI is a marker of glial proliferation. It resonates at 3.6 ppm and concentration of 3.8-8.1 mmol/kg[9]. The glutamate/glutamine peak represents a mixture of excitatory and inhibitory brain neurotransmitters. Glutamate is mainly stored in neurons whereas glutamine concentration is higher in astrocytes. Both, Glx have two groups of resonances, the first group resonances at 3.6-3.9 ppm whereas the second group resonances at 2.0-2.6 ppm and concentration of 6.0-12.5 mmol/kg for glutamate and 3.0-5.8 mmol/kg for glutamine. Excess glutamate in active lesions could contribute to axonal damage, brain atrophy and neurological disability[10].

Malignant brain tumors are differentiated from other focal lesions, including multiple sclerosis (MS), radiation necrosis and infections/abscess by absent

NAA, excess Cho and lip. Spectra with elevated Cho, a Cho/Cr index greater than 1.3 and diminished NAA levels are associated with aggressive neoplasms (*e.g.,* malignant lymphoma and glioma). Tumor recurrence is characterized by high Cho/Cr and Cho/NAA ratios. A multi-voxel Cho/Cr ratio of > 1.54 and Cho/NAA ratio of > 1.05 was found to have 93.1% and 89.7% accuracies for diagnosis of tumor recurrence, respectively[11,12]. In MS, the abnormal increases in total Cr, total Cho, mI, Lac, lipids and macromolecules are markers for acute demyelination in MS. NAA is reduced in acute MS lesions and in normal appearing white matter, even distant to acute and chronic-lesions. Increased NAA to subnormal values occurs during remyelination. mI is increased in chronic MS (a marker for astrocytic gliosis). Reduced NAA peak represents neuronal/axonal dysfunction or loss. Elevated Cho peak represents enhanced cell-membrane turnover and is seen in demyelination, remyelination, inflammation, or gliosis[13]. In radiation necrosis (defined as a death of normal brain tissue caused by radiation therapy), in which the pathological features include progressive cellular necrosis (coagulative necrosis), inflammatory changes and reactive glial cell proliferation and gliosis, MRS shows elevated Cho, mI, lactate and lipid peaks[14].

This paper described a child with a symptomatic parenchymal brain mass but showed marked clinical recovery and disappearance of the original brain mass shortly after starting treatment. In this case report, the phenomenon of a tumor/or pseudo-tumor remission and the problems related to its differential diagnosis and treatments were discussed. The significance of using MRS to distinguish neoplastic from non-neoplastic nature of the intra-axial lesion in our patient was also discussed.

CASE REPORT

At September 2009, a 14-year-old child presented with a history of fever, anorexia, generalized body ache, loss of weight and headache since two months, which progressed to repeated vomiting, nausea, lethargy and blurring of vision in the last month. Prior to neurologic consultation, the patient was admitted to a fever hospital for one week because of the unexplained high grade fever. One year ago, the patient had past history of body aches and recurrent arthritis which was attributed to recurrent tonsillitis and based on the advice of the ear, nose and throat (ENT) physician, the patient did tonsillectomy. The mother said that although it was expected that the patient will be better after tonsillectomy but unfortunately, he had recurrent fever and generalized body aches till the time of presentation. On neurological examination, the child was feverish and looked toxic. He was alert, oriented and his higher mental functions testing were normal. He had right hemiparesis and right upper motor neuron facial paralysis. His fundus examination was normal. MRI-brain [1.5-Tesla, standard (T1W) pre- and post-contrast, T2W, fluid attenuated inversion recovery (FLAIR) brain imaging] revealed presence of a large intra-axial mass (25 mm × 19 mm) in the left temporal lobe with extension to the adjacent brainstem. It showed hypointense signal in T1W, hyperintense signals in T2W and FLAIR images and homogenous enhancement with gadolinium (Gd). It was surrounded by moderate perifocal vasogenic edema with mass effect in the form of compression of the third ventricle with midline shift (Figure 1). The clinical and radiological findings were highly suggestive of a neoplastic lesion (malignant lymphoma or glioma). The patient was examined for lymphadenopathy and organomegaly. He underwent laboratory workup [for complete blood count, erythrocyte sedimentation rate (ESR), glucose, electrolytes, lactic dehydrogenase (LDH), liver and renal functions], abdominal ultra-sonography and chest radiographs to rule out the presence of systemic lymphoma but no bone marrow evaluation was done. Blood tests revealed leukocytosis (16000 cells/μL) and elevated ESR (30/52). In view of the presence of fever, manifestations of increased intracranial pressure (ICP) and the prominent cerebral edema associated with the intracranial lesion; intravenous antibiotics (cefotax 1 g/12 h per 7 d), mannitol (2 g/12 h per 48 h) and dexamethasone (8 mg/12 h) were initiated. The oncologist recommended whole craniospinal irradiation (brain = 4000 CGy/20 settings per 4 wk; spine = 2600CGy/13 settings per 3 wk) which was started 10 d after presentation. Within 15 d and even before the start of radiotherapy, the patient exhibited marked clinical recovery (up to complete improvement) but he developed subjective cognitive deterioration as a side effect of radiotherapy which was recovered after its discontinuation. Tapering of steroids was done over the next 4 mo. Follow up of the patient was done every 3 mo. The follow up MRI after 3 mo from onset showed disappearance of the original mass but presence of small lesion with hypointense signal in T1W and hyperintense in T2W and FLAIR signals in the antero-medial part of the left temporal lobe but did not show enhancement with Gd. At further follow up (September 2010) the patient condition was unremarkable and his MRI had the same small non-enhanced lesion (Figure 2). At August 2012, the patient developed recurrent generalization tonic-clonic convulsions. His EEG showed left temporal focus of epileptic activity. His MRI had the same small non-enhanced lesion (as that of 2010) with no restricted diffusion in diffusion weighted images (DWI) (Figure 3). The seizures frequency was reduced with carbamazepine therapy (300 mg/12 h). At October 2014, his follow up MRI had the same small non-enhanced lesion (as that of 2010 and 2012) with no restricted diffusion in DWI. Single voxel proton (1H) spectroscopy at long and short echo times showed reduced values of choline to creatine (Cho/Cr: long ET = 0.05; short ET = 0.907), N-acetyl-aspartate to

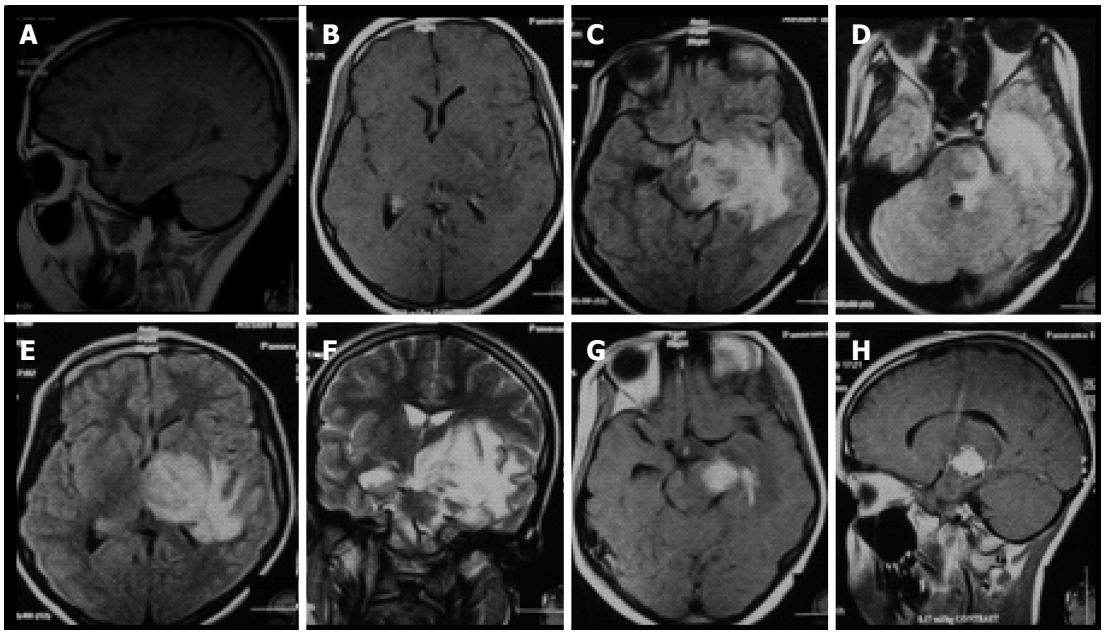

Figure 1 Cranial magnetic resonance imaging brain (on admission at September 2009) showing (A, B) sagittal and axial T1-weighted views with a solitary hypointense lesion in the left temporal lobe; (C-E) axial fluid attenuated inversion recovery and T2-weighted (F) images showing hyperintense lesion in the left temporal lobe encroaching on the adjacent brainstem with perifocal edema and mass effect; (G, H) axial and sagittal T1-weighted views showing homogenous solitary enhanced lesion in the left temporal lobe encroaching on the adjacent brainstem and surrounded by a moderate hypointensity.

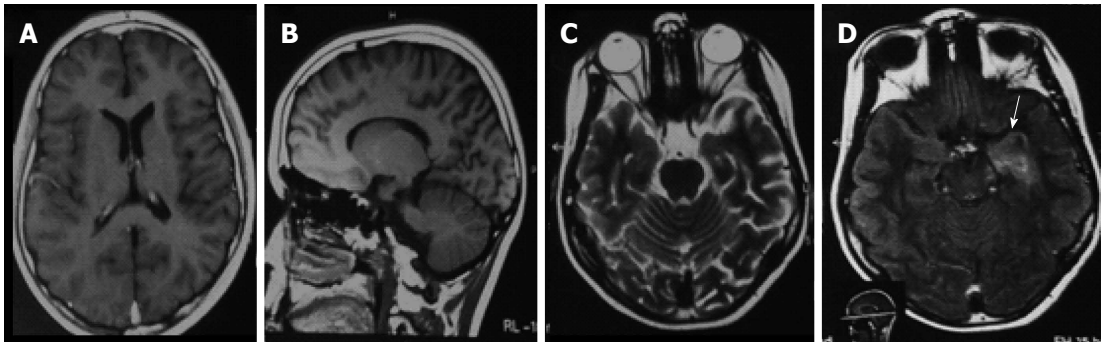

Figure 2 Cranial magnetic resonance imaging brain (September 2010) showing (A, B) normal axial and sagittal TIW and (C) axial T2W images but (D) hyperintense lesion in the antero-medial region of the left temporal lobe (white arrow) in fluid attenuated inversion recovery image.

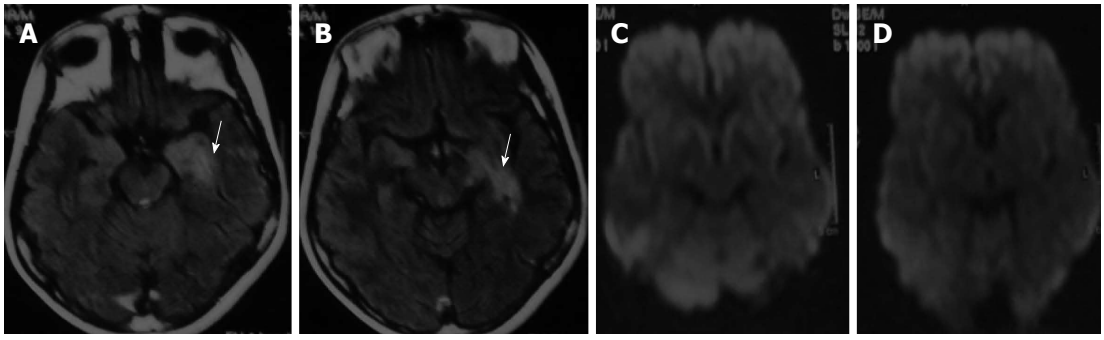

Figure 3 Cranial magnetic resonance imaging brain (August 2012) showing (A, B) hyperintense lesion in the antero-medial region of the left temporal lobe (white arrow) in axial fluid attenuated inversion recovery images (white arrow) and (C, D) normal diffusion weighted axial images.

creatine (NAA/Cr: long ET = 1.31; short ET = 1.107) and N-acetyl-aspartate to choline (NAA/Cho: long ET = 0.037; short ET = 0.38) ratios which confirmed the absence of neoplastic activity but highly suggestive of gliotic lesion (Figure 4).

This study was conducted according to the principles established in Helsinki and approved by Assiut University Hospital ethics committee. Informed written

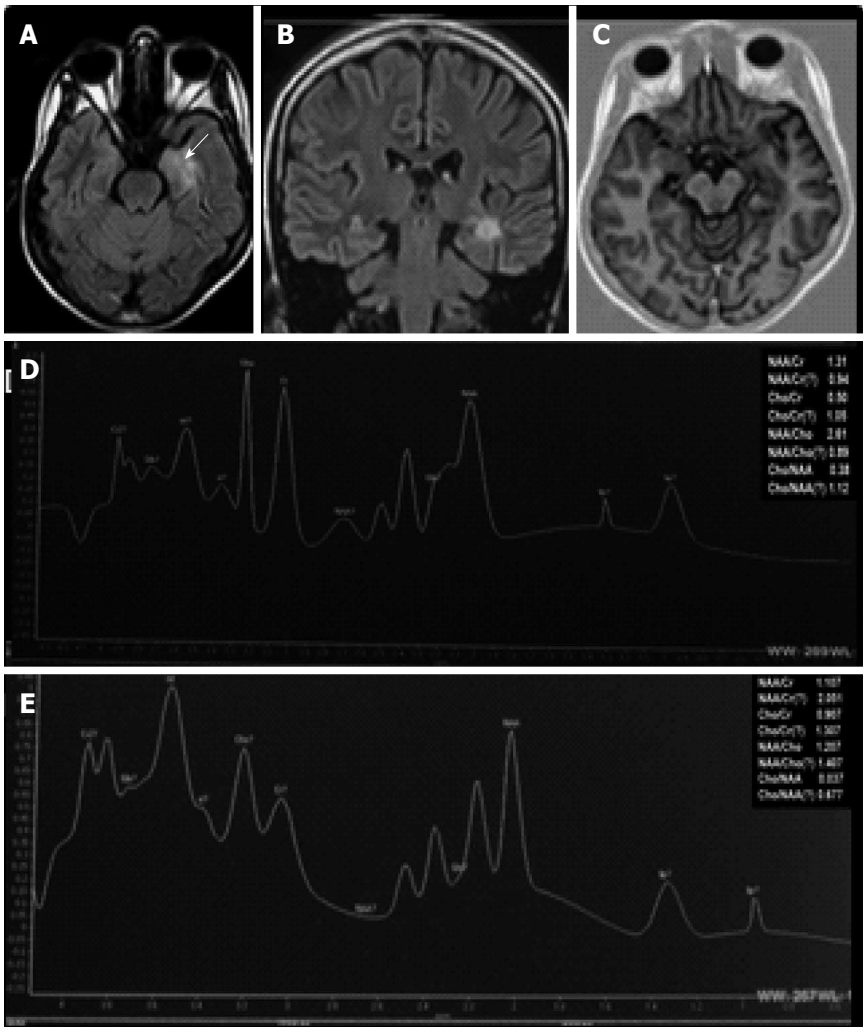

Figure 4 Cranial magnetic resonance imaging and magnetic resonance spectroscopy (MRS) brain (October 2014) showing (A, B) hyperintense lesion in the antero-medial region of the left temporal lobe in axial and coronal fluid attenuated inversion recovery images (white arrow); and (C) no restricted diffusion in axial diffusion weighted axial images; (D, E) long and short time echo MRS showing reduced values of Cho/Cr (long ET = 0.05; short ET = 0.907), NAA/Cr (long ET = 1.31; short ET = 1.107) and NAA/Cho (long ET = 0.037; short ET = 0.38) ratios. NAA: N-acetyl-aspartate; Cr: Creatine; Cho: Choline.

consent was obtained from the patient and his parents to publish the details of his clinical history, laboratory and imaging data.

DISCUSSION

This case is significant as the parenchymal brain mass could not be distinguished from a neoplastic space occupying lesion (*e.g.,* glioma or lymphoma) at presentation. Brain biopsy was not done due to deep location of the lesion. Complete clinical improvement was observed within 15 d on medical treatment including steroids and even before the start of radiotherapy. Corticosteroids were used empirically to reduce the manifestations of increased ICP and improve the surrounding vasogenic edema caused by the intracranial mass. The decision to give whole craniospinal irradiation was based on the high suspicion of a neoplastic lesion (*e.g.,* lymphoma or glioma). Marked reduction of the intracranial mass with disappearance of enhancement was observed in MRI within 3 mo of the onset. Follow up of the patients up to 5 years showed absence of recurrence of the original lesion.

Based on the above findings, the suggestive differential diagnosis of the vanishing space occupying lesion in this child at presentation include: (1) tumor [*e.g.,* primary central nervous system lymphoma (PCNSL) or glioma]; (2) tumor like demyelinating lesion or tumefactive multiple sclerosis (TMS); in clinical practice, most vanishing brain masses are frequently diagnosed as malignant tumors or multiple sclerosis (MS); and (3) intracranial infection/abscess/granulomas or tuberculoma.

For our patient, earlier at presentation, PCNSL was suggested. In patients presented with unclear intra-axial brain masses which regress with steroids, the diagnosis of PCNSL has to be considered[15]. PCNSL is a rare extranodal non-Hodgkin's lymphoma[16]. PCNSL represents approximately 3%-4% of newly diagnosed

central nervous system (CNS) tumors[17]. The typical MRI features of PCNSL include the presence of intra-axial single or multiple masses adjacent to cerebrospinal fluid space (CSF) with intermediate- to low-signal-intensity in T1W images and hypointense signal relative to the gray matter on T2W images, surrounding vasogenic edema, mass effect, restricted diffusion in DWI and intense homogenous enhancement with Gd[18,19]. Although, PCNSL is extremely rare in children and immunocompetent individuals[20,21], we suggested the diagnosis of PCNSL based on the MRI appearance of large solitary deep hemispheric infiltrative lesion[22] and rapid remission with steroid even before the start of radiotherapy. However, PCNSL is a malignant neoplasm and never considered as a self-limiting and recurrence is common within 18 mo. No cases have been reported yet for malignant brain tumors that recurred more than 5 years after spontaneous regression[23]. For our patient, the lacks of recurrence on follow ups for more than 5 years making such diagnosis less likely. This was also confirmed by the findings of MRS which will be discussed in the following section.

Also for our patient, the presence of fever prior to presentation and rapid remission with Ⅳ antibiotics and steroid suggest the diagnosis of TMS[24] or abscess/granuloma[25] but not the diagnosis of tuberculoma[26]. TMS is defined as a solitary large intracranial lesion larger than 2.0 cm in diameter associated with peri-lesional edema and mass effect[24]. TMS represents 1-2/1000 of cases of MS. TMS has been reported to be extremely rare in children in comparison to tumors and abscesses[27]. Diagnosis of MS depends on combination of clinical, neurophysiological, elevation of CSF immunoglobulin G (IgG) index and oligoclonal bands, and MRI of the brain and spine. Immunosuppressants (including steroids) and immunomodulators are the main therapies of TMS[28]. TMS lesion usually appears as open-ring (directed toward the cortical surface or to the basal ganglia) or closed ring or has diffuse, homogeneous, punctate, or concentric enhancement with Gd[29]. Although, CSF examination and gadolinium-enhanced MRI scan should differentiate between the MS and PCNSL, however, CSF may also be normal in fulminant conditions and short duration of the disease[30].

Furthermore, for our patient inflammatory pseudotumors or non-neoplastic lesions (*e.g.,* abscess/granulomas) of unknown etiology and respone to steroids was also suggested[25]. Patients with intracranial infection/abscess/granulomas commonly have history of risk factors (*e.g.,* immunocompromised state, dental, pulmonary or ear abscesses and intravenous drug use), fever, abnormal labs (as high erythrocytic sedemintation rate or C-reactive protein) and abnormal CSF suggesting CNS infection. Presentation is usually of acute onset with manifestations of increased ICP, seizures and focal neurological deficits. MRI-brain of brain abscess usually shows ring enhancement which is often complete with regular margin[31].

Magnetic resonance spectroscopy (MRS) was not done to the patient at presentation (2009) to distinguish neoplastic from non-neoplastic nature of the mass due to lack of availability. However and fortunately, it was available later and was done to the patient when he developed epilepsy (2012). For our patient, the focal lesion in the left antero-medial region of the temporal lobe found in the MRI (2010-2014) is the cause of the patients' left temporal lobe epilepsy with secondary generalization. The suggested differential diagnosis of the lesion according to the conventional MRI include: (1) tumor recurrence; (2) radiation necrosis; (3) multiple sclerosis; and (4) post-infective/inflammatory gliosis. MRS helped to distinguish tissue changes due to different brain lesions as discussed below.

For our patient, the reduced Cho/Cr (short ET = 0.907; long ET = 0.05), NAA/Cr (short ET = 1.107; long ET = 1.31) and NAA/Cho (short ET = 0.38; long ET = 0.037) ratios confirm the absence of tumor recurrence. Furthermore, the lack of reduced diffusion in DWI also confirms the absence of tumor recurrence[32].

For our patient, the diagnosis of radiation necrosis was suggested based on the facts that children are more susceptible to radiation necrosis than adults[33] and it usually occurs approximately 2-32 mo after radiotherapy, with 85% of cases occurring within 2 years. Delayed radiation-induced brain injury is a relatively common complication of radiation therapy representing 3%-24%[34]. Radiation necrosis is usually presented as a solitary periventricular white matter lesion, because of excess oligodendrocytes in these areas and a poor blood supply that produces ischemia[35]. The typical MR appearance of radiation necrosis is a soap bubble or Swiss cheese-like enhancing periventricular mass[36-38] and elevated Cho, mI, lactate and lipid peaks in MRS[39,40]. Radiation necrosis is related to both the volume of irradiated brain and the total administered radiation dose[41]. It has been reported radiation necrosis is extremely rare (5%) at doses < 45 Gy given over 25 fractions, or when the fractional dose is < 2 Gy/d but often occurs with total doses of > 60-70 Gy[34] or when the fractional dose is ⩾ 2 Gy/d. Our patient was given whole brain radiotherapy in a dose of 4000 CGy/20 settings per 4 wk (*i.e.,* < 2 Gy/d) making the diagnosis of radiation necrosis less likely. Also the absence of enhancement of the new lesion further confirms that the lesion in our patient is not a radiation necrosis.

Although, the results of MRS of our patients may suggest remyelination and gliosis following TMS, however, the presentation with seizures and lack of relapse with enhanced lesions after 5 years of follow up makes the diagnosis of MS less likely[13].

For our patient, the reduced values of Cho/Cr, NAA/Cr and NAA/Cho and lack of enhancement of the lesion are consistent with the diagnosis of gliosis. Gliosis is the process of scarring in the central nervous

system[42]. It results from the proliferation of glial cells or in a damaged brain tissue. It represents a healing process of brain injury whatever its nature. When neurons are injured, astrocytes proliferate in the region and manufacture glial-fibrillary acidic protein. This compound causes the astroglia to form a dense and fibrous tissue: The glial scar. Gliosis can take from a few days to many months to reach its final form. Gliosis is diagnosed by immunohistochemistry or MRI[43]. Gliosis occurred as a result of an acquired brain injury (most likely abscess, granuloma, inflammation) and it is the cause of temporal lobe epilepsy. Cr and Cho are glial markers. Gliosis typically presents with reduced levels of Cho, NAA, and Cr and observed lip peaks. Moderate levels of Cho and/or a Cho/Cr index < 1.3 are frequent with gliosis. This is supported by the followings: (1) the development of epilepsy in our patient occurred as a result of a focal lesion in the antero-medial region of the left temporal lobe which is suggestive of gliosis with no evidence of neoplastic activity as confirmed by MRS; and (2) mesial temporal lobe epilepsy (due to hippocampal sclerosis) is characterized by hippocampal atrophy, decreased NAA, and a low NAA/Cr ratio which are attributed to neuron loss and gliosis[39].

ACKNOWLEDGMENTS

I would like to thank the patient's parents for their cooperation and providing approval to publish the clinical, laboratory and imaging results of this case presentation.

COMMENTS

Case characteristics

A 14-year-old child with history of acute manifestations of increased intracranial pressure and right sided hemiparesis which improved completely within two weeks and followed after 3 years by epilepsy.

Clinical diagnosis

The patient was having right sided hemiparesis due to brain space occupying lesion which was complicated by recurrent generalized epilepsy.

Differential diagnosis

Brain tumor (*e.g.,* primary central nervous system lymphoma or glioma); tumor like demyelinating lesion or tumefactive multiple sclerosis and intracranial infection or abscess/granulomas.

Laboratory diagnosis

Blood tests revealed mild leukocytosis and elevated erythrocyte sedimentation rate (ESR).

Imaging diagnosis

Initially at presentation, magnetic resonance imaging-brain showed a large intra-axial mass (25 mm x 19 mm) in the left temporal lobe with hypointense signal in T1W, hyperintense signals in T2W and fluid attenuated inversion recovery (FLAIR) images and homogenous enhancement with Gd suggesting neoplastic lesion (malignant lymphoma or glioma) while follow up after 5 years, MRI showed small non-enhanced lesion in the antero-medial part of the left temporal lobe with hypointense signal in T1W and hyperintense in T2W and FLAIR signal and reduced choline (Cho)/creatine (Cr), N-acetyl-aspartate (NAA)/Cr and NAA/Cho ratios in magnetic resonance spectroscopy (MRS) which confirmed absence of neoplastic activity but suggestive of gliosis.

Pathological diagnosis

Inflammatory brain space occupying lesion complicated by gliotic lesion in the antero-medial part of the left temporal lobe.

Treatment

Brain dehydrating measures, antibiotics, corticosteroids and a course of craniospinal irradiation.

Related reports

In clinical practice; a vanishing brain space occupying lesion is commonly diagnosed as a neoplasm (*e.g.,* lymphoma) or multiple sclerosis.

Term explanation

A vanishing brain space occupying lesion is defined as reduction or disappearance of a brain lesion spontaneously or after steroid treatment to ⩽ 70% of its size before establishing its definitive diagnosis.

Experiences and lessons

In clinical practice, neuroimaging [including MRS or magnetic resonance imaging (MRI)] has to be done every 6-12 mo for at least 3-5 years to follow up after complete remission of the patient with a vanishing brain lesion.

Peer-review

The case report presents a vanishing brain space occupying lesion in a child over 5 years course of recovery and MRI follow-up. The prognosis was fortunately better. Text is well wrote and easily comprehensible with clear figures. The authors discussed the potential differential diagnosis, and recommended that MRS may be helpful to identify a potential vanishing brain space occupying benign lesion from tumor lesion in clinic.

Abstract

Fitz-Hugh-Curtis syndrome is a type of perihepatitis that causes liver capsular infection without infecting the hepatic parenchyma or pelvis. Fitz-Hugh-Curtis syndrome is known to occur commonly in women of childbearing age who do not use oral contraceptives and have sexual partners older than 25 years of age. However, the syndrome has been reported to occur rarely in males. The clinical symptoms are right upper quadrant pain and tenderness, and pleuritic right sided chest pain. The clinical presentation is similar in male and female. We experienced a case of Fitz-Hugh-Curtis syndrome in a 60-year-old man with the chief complaint of right upper quadrant abdominal pain. Despite a previous history of gonorrhea, we have also described our experiences of improved symptoms and recovery with allopathic medicines and have thereby reported the present case with a literature review.

Key words: Male; Right upper quadrant pain; Fitz-Hugh-Curtis syndrome; Perihepatitis; Sexually transmitted disease; Liver capsular infection

Core tip: Fitz-Hugh-Curtis syndrome is known to occur commonly in sexually active women and very rarely in males. We experienced a case of Fitz-Hugh-Curtis syndrome in a 60-year-old man with the chief complaint of right upper quadrant abdominal pain on inspiration. Despite of negative laboratory result, we diagnosed as Fitz-Hugh-Curtis syndrome by symptom and liver computed tomography scan. We have also described our experiences of improved symptoms and recovery with allopathic medicines.

INTRODUCTION

Fitz-Hugh-Curtis syndrome is a type of perihepatitis that causes liver capsular infection without infecting the hepatic parenchyma or pelvis. In 1920, Carlos Stajano first described the surgical confirmation of an adhesion that connected the anterior peritoneum and hepatic parenchyma in a gonorrheal patient who had complained of right upper quadrant abdominal pain. In 1930, Curtis[1] reported an adhesion of the peripheral hepatic parenchyma in a patient with salpingitis. In 1934, Fitz-Hugh[2] identified *Neisseria gonorrhoeae* (*N. gonorrhoeae*) on a peripheral liver adhesion in a patient complaining of right upper quadrant abdominal pain and reported that these findings were associated with the violin string-shaped adhesions around the liver observed in female patients with pelvic infection and salpingitis, which was at that time suggested as a new syndrome in terms of the pathophysiology of venereal diseases. Initially, only *N. gonorrhoeae* was considered a causative bacterium; however, in recent years, additional causative bacteria such as *Chlamydia trachomatosis* (*C. trachomatosis*) have been reported, and this condition was also found to be caused by other bacterial sexually transmitted diseases in addition to gonorrhea[3-5].

Traditionally, Fitz-Hugh-Curtis syndrome is known to occur commonly in women of childbearing age who do not use oral contraceptives and have sexual partners older than 25 years of age; because of unclear statistical results, it is uncertain whether this condition is accompanied by pelvic inflammation. However, since its detection in men after the 1970s[6], more extensive studies of this disease have been performed.

Based on the diagnostic criteria of a disease history and clinical patterns, cases in which a violin string-shaped abdominal adhesion is confirmed through laparoscopy or laparotomy to exclude other diagnoses and in which causative bacteria are identified in the liver capsule exudate are generally diagnosed as Fitz-Hugh-Curtis syndrome. In 2003, Nishie *et al*[7] and colleagues observed more definite hepatic capsule enhancement in the arterial phase relative to other phases during a computed tomography (CT) scan. Using abdominal dynamic CT scans, Joo *et al*[8] detected Fitz-Hugh-Curtis syndrome with a sensitivity of 88% and specificity of 95%, and Woo *et al*[9] diagnosed Fitz-Hugh-Curtis syndrome with 95.5%. In recent years and in consideration of surgical complications, non-invasive diagnoses not requiring surgery have increased for cases with mild symptoms by integrating the outcomes of clinical patterns, culture tests, and CT scan results.

In South Korea, Fitz-Hugh-Curtis syndrome was previously reported in women; however, in 2010, *Mycoplasma genitalium* was first identified *via* blood testing, an abdominal dynamic CT scan, and urine culture testing in a 35-year-old male patient complaining of right upper quadrant abdominal pain[10]. In addition to a literature review, the authors herein report a case of non-invasively diagnosed Fitz-Hugh-Curtis syndrome in a sexually inactive, hepatitis B virus (HBV)-positive elderly patient who presented with right upper quadrant abdominal pain; this diagnosis was achieved *via* blood testing and an abdominal dynamic CT scan, and excluded other diseases despite the inability to identify the causative bacteria.

CASE REPORT

A 60-year-old male patient was admitted to the emergency room with right upper quadrant abdominal pain that had gradually increased in severity beginning three days earlier. This pain was not affected by meals, and became sharp and severe upon inhalation. The patient had a disease history of gonorrhea while in his 20s, although this had completely recovered, and had no family medical history. He was divorced, a non-smoker, drank 1 bottle of soju 3-4 times a week, and had no external injuries. At the time of admission, his vital signs were as follows: Blood pressure, 140/70 mmHg; pulse rate, 80 times/min; respiration, 20 times/min; and body temperature, 36.5 ℃. He presented with acute symptoms, no specific sphygmoscopic findings, a soft abdomen, normal bowel sounds, oppressive pain in the right upper abdominal quadrant, no rebound tenderness or abdominal distension, and Murphy's sign negativity. He did not present with shifting dullness or fluid waves indicative of ascites, enlarged organs or masses, or bilateral costovertebral pain.

Peripheral blood tests revealed the following (Table 1). The following serum biochemical test results (Table 1) were observed: Increased C-reactive protein, aspartate aminotransferase, and alanine aminotransferase. Urine tests revealed no specific findings, and the results of simple chest and abdominal radiography were normal.

An abdominal pelvic CT scan was performed, and linear capsular enhancement of the inferior segment of the liver was observed in the arterial phase (Figure 1A). No specific findings were observed in other abdominal and pelvic organs, including the hepatic parenchyma, gallbladder, biliary tract, and pancreas. Hepatitis virus tests were planned to evaluate the increased hepatosomatic index, and a fluid treatment involving daily intravenous levofloxacin administration (500 mg) as well as experimental antibiotics were planned to treat suspected Fitz-Hugh-Curtis syndrome. Based on the findings observed in known cases of this disease, examinations of previous urinary tract

Table 1 Clinical value on initial admission

Peripheral blood test	
Leukocyte	3610/mm^3
Neutrophils	50.90%
Lymphocytes	35.50%
Hemoglobin	146 g/L
Platelet	164000/mm^3
Erythrocyte sedimentation rate	25 mm/h
Serum biochemical test	
C-reactive protein	15.6 mg/L
Total protein	67 mg/L
Albumin	37 mg/L
Total bilirubin	5.8 mg/L
Aspartate aminotransferase	52 IU/L
Alanine aminotransferase	47 IU/L
Alkaline phosphatase	93 IU/L
Blood urea nitrogen	148 mg/L
Creatinine	6.1 mg/L
Na	134 mmol/L
K	4.01 mmol/L
Cl	98.3 mmol/L
Creatine kinase-myocardial band	2.27 ng/mL
Troponin-T	0.003 ng/mL
Amylase	61 U/L

Table 2 Tumor marker test

Carbohydrate antigen 19-9	0.6 U/mL
Alpha-fetoprotein	19.28 ng/mL
Carcinoembryonic antigen	4.69 ng/mL
Protein induced by vitamin K absence or antagonist Ⅱ	17 nAU/mL

infections or venereal diseases, blood tests, and urine culture tests were performed. In a subsequent examination, the patient reported having 1 sexual relationship 20 d earlier; all results for the following tests were negative: Human immunodeficiency virus (HIV) Ag/Ab combi test, urine culture test, and PCR for *N. gonorrhoeae*, *C. trachomatis*, Ureaplasma urealyticum, M. genitalium, M. hominis, Trichomonis vaginalis, Treponema palladium, *Candida albicans*, Herpes simplex Ⅵ and Ⅶ, Haemophilus ducreyi, and Condyloma 6, 11, which was performed after prostate massage. The hepatitis virus test indicated the following: Hepatitis A virus IgM, HBV surface antibody (enzyme-linked immunoassay; EIA), HBV extracellular antigen (HBeAg), and hepatitis C virus Ab negativity; HBV surface antigen (EIA) and HBV extracellular antibody (HBeAb) positivity; and an HBV DNA copy number of 1.59×10^7/mL. A tumor marker test measured to exclude cancer and showed no abnormalities (Table 2). Gastroscopy and colonoscopy were performed to exclude cancer, and no specific findings were observed besides chronic superficial gastritis and a gastric ulcer. No findings indicative of liver cancer besides the previously observed capsular enhancement of the inferior segment of liver were observed on a liver abdominal dynamic CT scan.

On the second day of hospitalization, the right upper quadrant abdominal symptoms improved and on the third day of hospitalization, the patient's pain upon inhalation had decreased. The patient requested outpatient clinic care and he was discharged from the hospital. Two weeks after the initial medical treatment, the right upper quadrant abdominal pain disappeared during outpatient clinic care, and pain during inhalation decreased to 1-2 times per day. After four weeks of antibiotic treatment, the right upper quadrant abdominal pain improved, and the liver capsule enhancement completely disappeared on a liver abdominal dynamic CT scan performed three months after treatment (Figure 1B).

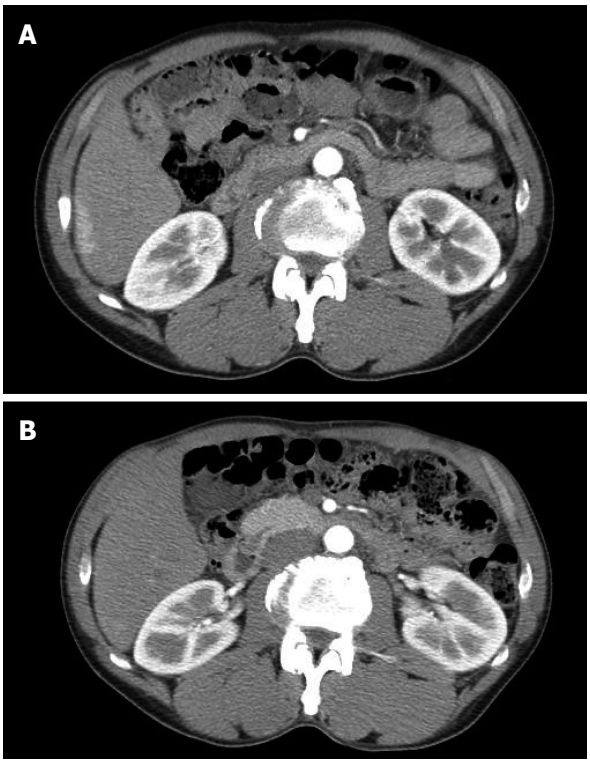

Figure 1 Abdominal computed tomography findings. A: Linear capsular enhancement of the inferior segment of the right lobe is visible on an arterial phase image; B: On an arterial phase image obtained 3 mo after treatment, the liver capsule enhancement over the right lobe has disappeared completely.

DISCUSSION

Fitz-Hugh-Curtis syndrome refers to perihepatitis accompanied by pelvic inflammation in 5%-15% of cases; young women of childbearing age are mainly affected by this disease. The symptoms can be divided into acute and chronic phases. Patients in the acute phase have characteristic pathologic findings of exudative hepatic capsule inflammation with inflammatory reactions and bleeding of the inferior liver and vessels in the abdominal wall adjacent to the liver[11]. Accordingly, in the acute phase, the right upper quadrant abdominal pain is sharp and pleuritic and occasionally radiates to the right shoulder or inside of the arm. In the chronic phase, exudative inflammation causes a violin string-like adhesion between the

hepatic capsule and inferior abdominal wall or between the hepatic capsule and diaphragm. Although this adhesion rarely causes clinically significant symptoms, laparoscopic synecotomy can be performed in cases involving persistent right upper quadrant abdominal pain that are refractory to antibiotic therapy[12].

Previously, *N. gonorrhoeae* was identified as the causative bacterium of Fitz-Hugh-Curtis syndrome, but in recent years *C. trachomatis* has also been identified as a major causative bacterium. In the present case, the patient had a previous history of gonorrhea and was an HBV carrier; however, there are no previous reports of secondary Fitz-Hugh-Curtis syndrome onset resulting from a previous gonorrheal infection and HBV positivity.

Regarding the infection route, traditionally direct infection has been dominant as determined *via* culture tests of the uterine tubes and hepatic lesions. However, blood-mediated infection has been reported in other cases[13] *via* blood culture tests, supporting the use of antibiotic treatment. However, most case reports remain controversial because of a lack of positive culture test results. Infection *via* lymphatic vessels could explain the cases of perihepatitis in both men and women without gonohemia, although as yet there is no clear evidence to support this. Money *et al*[14] suggested an immune reaction-based pathophysiology following a comparison of IgG values in the context of chlamydia infection, but currently this hypothesis remains unconfirmed.

Long-term complications of Fitz-Hugh-Curtis syndrome are rare and include pelvic inflammatory complications, chronic pain, small intestinal obstruction due to adhesion, and infertility.

A suspicion of Fitz-Hugh-Curtis syndrome is most important when diagnosing and detecting pleural or right upper quadrant abdominal pain in young, sexually active women in the absence of clear evidence for other diseases such as acute cholecystitis. As mentioned earlier, invasive surgical procedures such as laparoscopic surgery or laparotomy are required to confirm a diagnosis of Fitz-Hugh-Curtis syndrome, but these are not desirable or practically feasible in many cases. Therefore, in actual clinical settings, it is common to diagnose and treat this syndrome under only a presumptive diagnosis and the identification of characteristic strains after excluding other diagnoses. Blood tests mostly reveal a normal or elevated leukocyte count and erythrocyte sedimentation rate and a normal or slightly increased hepatosomatic index, which assist with the diagnosis. CT scans reveal hepatic capsule contrast enhancement, a characteristic finding of perihepatitis, in the arterial phase and are thereby used as a non-invasive method for diagnosing Fitz-Hugh-Curtis syndrome. Although cervical exudate is mainly used for stain identification, vaginal, anal, urethral, and pharyngeal exudates may also be used. Generally, culture tests are most widely used although genetic tests such as PCR or gene amplification provide better sensitivity and specificity. According to recent studies, however, increasing numbers of cases have been observed with *C. trachomatosis* negative PCR results but positive antigen-antibody reactions, and it is therefore recommended that antibody tests for causative bacteria identification should be performed concurrently[15]. In the present case, both culture tests and PCR were conducted to identify sexually transmitted microbes; however, an antigen-antibody test was not performed and the causative bacteria could not be identified.

Fitz-Hugh-Curtis syndrome can be treated experimentally with antibiotics, according to the principle of using antibiotics suitable for each identified causative bacterium. However, because of the rejection of some patients with venereal diseases, some cases have reportedly been treated with experimental antibiotics in the absence of causative bacteria identification or even attempted identification. Experimental antibiotics use is based on pelvic inflammatory treatment, and antibiotics such as cefotetan, doxycycline, clindamycin, gentamicin, and ofloxacin have been used[16]. Cefotetan and doxycycline are mainly administered intravenously, and levofloxacin and metronidazole can also be used. Intravenous antibiotics are continued for 48 h after the improvement of clinical symptoms, and metronidazole or levofloxacin are used orally for 2 wk. If pain persists even with proper treatment, a peripheral liver adhesion should be confirmed *via* laparoscopy[17].

Fitz-Hugh-Curtis syndrome is known to be extremely rare in men. In 1970, Kimball and Knee first reported a case of Fitz-Hugh-Curtis syndrome caused by *N. gonorrhoeae* in a 22-year-old man[6]. In 1982, Davidson and Hawkins[18] reported the development of this syndrome from gonorrheal sepsis concomitant with pustular bacterid in a 35-year-old bisexual man with an identified *N. gonorrhoeae* infection. In 1985, Winkler *et al*[19] reported a case of Fitz-Hugh-Curtis syndrome and discussed the possibility that *N. gonorrhoeae* entered *via* damaged rectal mucous membranes and directly spread through the abdominal cavity in a 35-year-old homosexual man with a history of acquired immune deficiency syndrome.

In the present case, we have reported a diagnosis of Fitz-Hugh-Curtis syndrome *via* blood tests and abdominal dynamic CT in a 60-year-old man with the chief complaint of right upper quadrant abdominal pain. Blood culture tests, urine culture tests, and PCR of sexually transmitted disease-causing microbes were performed to identify the causative agent, although *N. gonorrhoeae* was not proven to be the causative bacterium, despite a previous history of gonorrhea. We have also described our experiences of improved symptoms and recovery with allopathic medicines and have thereby reported the present case with a literature review.

COMMENTS

Case characteristics

A 60-year-old male patient was admitted to the emergency room with right upper quadrant abdominal pain that had gradually increased in severity beginning 3 d earlier.

Clinical diagnosis

Fitz-Hugh-Curtis syndrome.

Differential diagnosis

Hepatocellular carcinoma (right upper quadrant abdominal pain) -gastroscopy, colonoscopy, abdominal computed tomography (CT), and tumor marker test.

Laboratory diagnosis

Aspartate aminotransferase was 52 IU/L and Alanine aminotransferase was 47 IU/L.

Imaging diagnosis

Abdominal CT showed linear capsular enhancement of the inferior segment of the right lobe is visible on an arterial phase.

Pathological diagnosis

Blood culture tests, urine culture tests, and PCR of sexually transmitted disease-causing microbes were negative.

Treatment

Empirical intravenous antibiotics were administered, maintained oral medication.

Related reports

Fitz-Hugh-Curtis syndrome occurs rarely in male. Cases reported in English and Korean literature were reviewed.

Term explanation

Fitz-Hugh-Curtis syndrome is a type of perihepatitis that causes liver capsular infection without infecting the hepatic parenchyma or pelvis is known to be locally aggressive and requires extensive surgical resection.

Experiences and lessons

Fitz-Hugh-Curtis syndrome was considered as sexually transmitted disease. Although causative pathogen was not proven, we diagnosed and treated patient.

Peer-review

This article can nicely contribute to increasing the awareness of Fitz-Hugh-Curtis syndrome.

Abstract

Meckel diverticulum is an embryonic remnant of the Gastrointestinal duct which causes symptoms < 5% in the 2% population. Painless bleeding and abdominal pain are the most often reported symptoms. Dieulafoy lesion/dieulafoy-like lesion often cause upper gastrointestinal (GI) tract bleeding, but massive lower gastrointestinal bleeding is rare. We reported a 19-year-old male presented massive lower GI tract bleeding caused by Meckel diverticulum synchronous dieulafoy-like lesion.

Key words: Lower gastrointestinal tract; Bleeding; Dieulafoy-like lesion; Meckel diverticulum; Endoscopy

Core tip: Dieulafoy-like lesion often causes upper gastrointestinal (GI) tract bleeding, and meckel diverticulum is another common cause of GI tract bleeding. The two of them happened at the same person is rare. We observed a 19-year-old man complained of upper stomachache was admitted to hospital. He underwent left hemi-colectomy on day 5 after admitted. Pathology confirmed the diagnosis of dieulafoy-like lension of descending colon. The bleeding ceased for 2 d. But another attack came on day 3 after surgery. He underwent a second laparotomy which united endoscopy, a 2 cm × 1.5 cm meckel diverticulum

in terminal ileum was detected. Resection was performed. Pathology revealed meckel diverticulum. He was fully recovered with no sign of bleeding in the next year's following up.

Li SH, Wu GY, Lin XD, Wen ZQ, Huang MT, Yu SP, Zhang H. Lower gastrointestinal tract bleeding caused by dieulafoy-like lesion synchronous meckel diverticulum: A rare case report. *World J Clin Cases* 2015; 3(11): 970-972 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i11/970.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i11.970

INTRODUCTION

A 19-year-old man was admitted to hospital due to upper stomachache for 6 d, hematochezia for 3 d and syncope twice. He had recurrent massive hematochezia and conservative therapy was inefficacy. He had left hemi-colectomy on day 5 after admitted. Pathology confirmed the diagnosis of dieulafoy-like lesion of descending colon. The bleeding ceased for 2 d. He had another attack of hematochezia on day 3 after surgery (day 7 after admitted). He underwent a second laparotomy which united colonoscopy, a 2 cm × 1.5 cm meckel diverticulum in terminal ileum was detected. Resection was performed. Pathology revealed meckel diverticulum, atopia gastric mucosa polyp accompany with chronic ulcer. He recovered well and was discharged 20 d later. The next year's following up shows no sign of bleeding.

CASE REPORT

A 19-year-old man was admitted to hospital due to upper stomachache for 6 d, hematochezia for 3 d and syncope twice. He looked pale and weak when admitted. Blood count reveals RBC 2.44 × 10^{12}/L, Hb 71 g/L, HCT 0.20. There is no sign of abnormal of his colon except retention of fresh blood in the following day's colonoscopy. Tc-99m pertechnetate scan in the third day revealed no positive sign neither. The patient had a third time of hematochezia for about 300 mL. Bleeding from the left hemicolon was highly suspected during the second colonoscopy, but exact bleeding point was not observed. He was treated with hemostasia to stop the bleeding and fluid infusion therapy. A fourth time hematochezia occured in day 5. Digital subtraction angiography supported bleeding from left hemi-colon (Figure 1). He was sent to OR for left hemi-colectomy. Pathology confirmed the diagnosis of dieulafoy-like lension of descending colon (Figure 2). The bleeding ceased for 2 d. On day 3 post colectomy (day 7 after admitted), he had the fifth hematochezia, discharged about 1000 mL of blood. Blood transfusion and blood coagulant were used to stop bleeding. Those treatments did not stop the bleeding. He underwent a second laparotomy united colonoscopy. During the surgery laparotomy united colonoscopy, a 2 cm × 1.5 cm meckel diverticulum in terminal ileum was detected (Figure 3). A wide base, smooth, about 0.6 cm × 0.6 cm hemispherical polyp beside it was observed, resection was performed meanwhile. Pathology revealed meckel diverticulum, atopic gastric mucosa polyp accompany with chronic ulcer. The patient recovered in 20 d with neither bleeding nor other complications and was discharged. There was no more hematochezia in the next year's follow up.

Figure 1 Digital subtraction angiography supported bleeding from left hemi-colon.

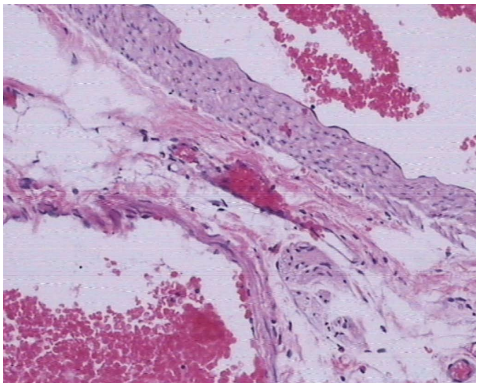

Figure 2 Pathology after left hemi-colectomy confirmed the diagnosis of dieulafoy-like lension of descending colon.

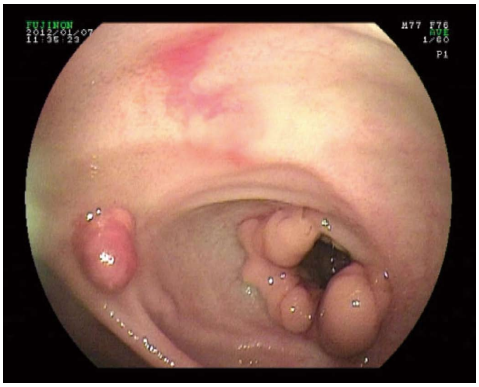

Figure 3 A 2 cm × 1.5 cm meckel diverticulum in terminal ileum was detected by colonoscopy during the second laparotomy which united endoscopy.

DISCUSSION

Dieulafoy lesion/dieulafoy-like lesion is a cause of GI tract bleeding which cannot be ignored, most commonly results the proximal stomach bleeding, but very rare entity that can cause massive lower gastrointestinal track bleeding[1]. Meckel diverticulum is an embryonic remnant of the gastrointestinal duct which is presented in approximately 2% of the population and is estimated to cause symptoms < 5% of the time. It generally results in painless bleeding or abdominal pain[2]. The technetium 99m pertechnetate scan is the best of choice for detecting Meckel diverticulum, with a reported sensitivity of 85% to 90% in the pediatric population[3]. In adults, however, the sensitivity falls on to only 62%[4]. It is an ideal noninvasive and sensitive way to detective meckel diverticulum. We performed surgery though this patient's technetium 99m pertechnetate scan is negative and a meckel diverticulum was found. This case presented of massive lower gastrointestinal bleeding caused by descend colon dieulafoy-like lesion and small bowl meckel diverticulum at same time is a rare condition.

COMMENTS

Case characteristics

A 19-year-old man complained of upper stomachache was admitted to hospital.

Clinical diagnosis

Massive lower gastrointestinal bleeding caused by descend colon dieulafoy-like lesion and small bowl meckel diverticulum at same time.

Differential diagnosis

Tumor of the colon, ischemic colitis, Crohn's disease, Ulcerative colonitis.

Laboratory diagnosis

Blood count reveals RBC 2.44 × 10^{12}/L, Hb 71 g/L, HCT 0.20.

Imaging diagnosis

Tc-99m pertechnetate scan in the third day revealed no positive sign. Digital subtraction angiography supported bleeding from left hemi-colon.

Pathological diagnosis

Pathology confirmed the diagnosis of dieulafoy-like lension of descending colon at the first surgery. Pathology reveals meckel diverticulum, atopic gastric mucosa polyp accompany with chronic ulcer after the second surgery.

Treatment

Left hemi-colectomy and resection of the bowl with meckel diverticulum.

Related reports

Dieulafoy lesion of the colon is reported to be bleeding cause of lower GI tract bleeding, and so does meckel diverticulum.

Experiences and lessons

Massive lower gastrointestinal bleeding caused by descend colon dieulafoy-like lesion and small bowl meckel diverticulum at same time is a rare condition. Both of them may be missed at the first endoscopy examination. Repeated endoscopy examination may be needed when bleeding occurs over and over again.

Peer-review

This case is interesting.

Abstract

Facial nerve palsy is a condition with several implications, particularly when occurring in childhood. It represents a serious clinical problem as it causes significant concerns in doctors because of its etiology, its treatment options and its outcome, as well as in little patients and their parents, because of functional and aesthetic outcomes. There are several described causes of facial nerve paralysis in children, as it can be congenital (due to delivery traumas and genetic or malformative diseases) or acquired (due to infective, inflammatory, neoplastic, traumatic or iatrogenic causes). Nonetheless, in approximately 40%-75% of the cases, the cause of unilateral facial paralysis still remains idiopathic. A careful diagnostic workout and differential diagnosis are particularly recommended in case of pediatric facial nerve palsy, in order to establish the most appropriate treatment, as the therapeutic approach differs in relation to the etiology.

Key words: Facial paralysis; Seventh cranial nerve; Children; Bell's palsy; Therapy

Core tip: Pediatric facial nerve palsy can be congenital or acquired and its etiology can remain unknown. Bell's palsy is the most frequent form of facial paralysis also in children; about 70% of these cases has a favorable prognosis with spontaneous resolution. An accurate differential diagnosis is necessary to assess the prognosis and the therapeutic options. In Bell's palsy, the use of oral corticosteroids is recommended also in children, preferably within 3 d from onset. In children presenting a permanent congenital or acquired facial palsy, the therapeutic strategy consists in surgical techniques associated to rehabilitative approaches.

Ciorba A, Corazzi V, Conz V, Bianchini C, Aimoni C. Facial nerve paralysis in children. *World J Clin Cases* 2015; 3(12): 973-979 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i12/973.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i12.973

INTRODUCTION

Pediatric facial nerve palsy can be congenital or acquired. Despite efforts to define its etiology, the cause of paralysis can often remain unknown. Idiopathic facial paralysis, even in childhood, is commonly known as Bell's palsy,

Table 1 Possible causes of facial nerve palsy in children

Causes of facial nerve palsy in childhood	
Idiopathic	Bell's palsy
Congenital	Delivery traumas:
	Primiparity
	Birth weight > 3500 g
	Forceps
	Cesarean section
	Prematurity
	Syndromic malformative:
	Möbius syndrome
	Goldenhar syndrome
	Syringobulbia
	Arnold-Chiari syndrome
	Genetic:
	Hereditary myopathies
	3q21-22 and *10q21.3-22.1* mutations
Acquired	Infectious:
	Ramsay Hunt syndrome
	Epstein-Barr virus
	Haemophilus influenzae
	Tubercolosis
	Lyme disease
	Cytomegalovirus
	Adenovirus
	Rubella
	Mumps
	Mycoplasma pneumoniae
	Human immunodeficiency virus
	Acute otitis media
	Chronic otitis media/cholesteatoma
	Inflammatory:
	Henoch-Schönlein porpora
	Kawasaki syndrome
	Neoplastic:
	Schwannomas of the Ⅶ c.n.
	Hemangiomas
	Rhabdomyosarcoma
	Temporal bone histiocytosis
	Leukemia
	Parotid gland tumors
	Traumatic:
	Temporal bone fractures
	Iatrogenic

named after the Scottish surgeon Sir Charles Bell, who, in 1821, firstly described a "weakness" of the facial nerve[1].

Aim of this paper is to describe the most common causes of facial nerve palsy in children and therefore the most appropriate available treatments.

STUDY METHODS

Narrative review. PubMed database was searched up to April 2015, for meta-analysis, systematic reviews, and controlled trials, going back for 10 years. The search was conducted independently and was restricted to children. Full text articles were required when the title, abstract or keywords indicated that the study could be suitable for this review. Additional papers were also identified from the references in the chosen literature.

The medical subject heading used included "facial paralysis"; "Bell's palsy"; "children"; "seventh nerve"; "therapy".

EPIDEMIOLOGY AND ETIOPATHOGENESIS

There are many possible causes of facial nerve paralysis in children. These can be classified as congenital (traumatic, syndromic and non-syndromic malformations, genetic) or acquired (infectious, inflammatory, neoplastic, traumatic)[2,3] (Table 1).

Unfortunately, in about 50% of the cases, the etiology remains unknown: these forms are classified as Bell's palsy. In children, Bell's palsy has an estimated incidence of about 6.1 cases per year per 100000 in those aged between 1 and 15 years[2,3]. It is believed that it can be caused by viruses such as Herpes simplex 1. About 70% of Bell's palsy has a favorable prognosis with spontaneous resolution within 3 mo, without sequelae. The paralysis severity at onset can influence the degree of recovery: a severe paralysis hardly obtains a complete recovery of nerve function[4-7].

Congenital facial paralysis can result from developmental defects or delivery traumas. Perinatal traumas are the most frequent causes of congenital paralysis. The main reported risk factors associated to traumatic facial paralysis are: mother's first child, birth weight greater than 3500 g, use of forceps, cesarean birth and prematurity. These cases have usually a favorable prognosis, with infants recovering the full functionality of the seventh cranial nerve within few months without sequelae[8,9].

A congenital facial nerve paralysis, although other cranial nerves such as the Ⅲ, Ⅳ, Ⅴ, Ⅷ can be involved, is presented within the Möbius syndrome. The reported prevalence of this syndrome is about 1/150000 live births[9-12]. It is reported to be due to hypoplasia of the motor nuclei of the cranial nerves within the brainstem, probably due to a hypoxic-ischemic encephalopathy[10]. Those affected by Goldenhar syndrome (hemifacial microsomia, with a spectrum of congenital malformations involving the structures derived from the first and second branchial arch) can also present a congenital facial paralysis[11]. Congenital pseudobulbar palsy (Syringobulbia) is a condition that clinically manifests with facial paralysis, dysphagia and speech difficulties, while in the Arnold-Chiari syndrome, congenital facial paralysis is usually associated to other cranial nerves paralysis (especially the Ⅵ one) due to malformations of the posterior fossa that allow herniation of brain structures through the foramen magnum[12].

Genetic causes of facial nerve paralysis includes hereditary myopathies, such as myotonic dystrophy and myasthenia. Also two loci responsible for isolated hereditary forms of facial paralysis (chromosome 3q21-22 and 10q21.3-22.1) have been identified[9,10,13].

Acquired facial paralysis can frequently be due to viral infections. The reactivation of Herpes Varicella-Zoster

may be responsible, even in children, of Ramsay Hunt syndrome (zoster oticus); in this case, facial palsy can be associated to the presence of vesicular lesions of the external auditory canal and/or of the auricular concha. The incidence of this syndrome under 10 years of age is reported to be 2.7/100000[9,11,14]. Not frequently, a bilateral facial nerve palsy may be the onset of a Epstein-Barr virus, Haemophilus influenza, tuberculosis or Borrelia burgdorferi infection. Lyme disease has become the most common cause of acute facial paralysis in children in those areas where Borrelia Burgdorferi infection is endemic[9,15]. Other agents that may cause facial nerve palsy in children are cytomegalovirus, adenovirus, rubella, mumps, Mycoplasma pneumoniae and HIV[3,13].

Facial nerve palsy may also be present as a complication of several diseases such as acute and chronic otitis media, cholesteatoma, mastoiditis and meningitis[16,17].

Other inflammatory diseases such as vasculitis and Henoch-Schönlein porpora or Kawasaki syndrome can also occur with facial nerve palsy[9].

Rarely, in children, facial nerve paralysis can be due to tumors such as schwannomas or hemangiomas of the seventh nerve or bone tumors such as rhabdomyosarcoma and histiocytosis.

Pediatric facial nerve paralysis has been also described associated to leukemia (in many cases bilateral) or to parotid gland tumors[9,18].

Finally, traumas such as temporal bone fractures (longitudinal, transverse and oblique) can cause facial nerve palsy in children[19], while iatrogenic paralysis can occur after surgery of the parotid gland, middle ear or mastoid[8,9].

CLINICAL FEATURES

The peripheral paralysis of the seventh cranial nerve is characterized by motorial, sensorial and visceral deficits of the hemi-face involved. There is a facial asymmetry at the examination of the face: the facial creases and the nasolabial fold disappear; the affected side also presents a dropping mouth rim (with possible saliva leakage), eyelid widening and lagophthalmos (static signs). Dynamic signs are represented by the inability to whistle, puffing cheeks, frown, close the eyelid. Signs of Bell and Nigro can be present. Hyperacusis, due to paralysis of the stapedius muscle, can be present, too[1,5,15].

The little patient may also report paresthesias or pain of the pinna or of the concha. Lacrimal and salivary production can be reduced (visceral deficit). Lagophthalmos can promote corneal irritation; furthermore the child may complain of a metallic taste in the mouth due to the taste alteration of the anterior 2/3 of the tongue[1,5,10,20].

In a very young children and in newborns, the unilateral facial paralysis can be suspected when, in absence of front and nasolabial groove motility, there is also asymmetry of the face with buccal deviation when crying. In cases of severe paralysis, the child cannot close the eye due to a complete absence of movement on the affected side and there is an asymmetry of the face at rest. In newborns, this condition can also hamper breastfeeding[10,21].

In all the cases, the occurrence of facial nerve palsy in children represents a serious clinical problem also due to the functional and aesthetic outcomes affecting the quality of life; this feature is cause of significant concern in the little patients and their parents as well as in doctors.

DIAGNOSIS

A comprehensive history evaluation is always important for the correct diagnosis. It is necessary to investigate about the onset and the time course of the paralysis and its eventual progression (*e.g.,* a gradual onset, > 3 wk, may suggest a neoplastic etiology). All the associated symptoms should be identified, as well as any other comorbidities affecting the child[14,15,18-21].

During the ENT examination, particular attention should be given to the inspection of the external auditory canal, the eardrum and the mastoid region. The facial nerve evaluation, in terms of facial movements and spontaneous expressions, should be classified according to House-Brackmann grading system, whenever the child is cooperative. Both the eye and palpebral region as well as the lower face should be careful observed at rest and at movement, eventually documenting the asymmetry using a camera or a video-camera. Computer systems can also provide tools for measuring the facial asymmetry[22].

The audiological evaluation is important in order to assess the presence of stapedial reflexes (topo-diagnosis) and eventually to evidence the presence of hearing loss[15,21].

Blood pressure and blood count should be verified in all cases of pediatric paralysis. Particularly, in children it has been described that high blood pressure levels can be associated to recurrent facial palsy[14,21]. Furthermore, a moderate increase of monocytes and lymphocytes is compatible with Bell's palsy, as far as this analysis does not place definitive diagnosis nor exclude an inflammatory process. The lumbar puncture is performed only when suspecting a meningitis (severe headache, fever, papilledema, neck stiffness) or a Guillain-Barré syndrome: in this last case, the analysis of the cerebrospinal fluid shows a characteristic increase in protein not accompanied by a consensual cells increasing (albumin-cytological dissociation)[1,5,9,13,21].

Specific laboratory and imaging tests are not routinely indicated, but are recommended for patients with recurrent paralysis or when there has been no improvement after 3 wk of therapy. With the purpose of diagnose the Ramsey Hunt syndrome in children, an ELISA serum searching for IgM and IgG antibody titer against Herpes Varicella-Zoster is recommended[14]. Serologic tests for Lyme disease should be carried

out when the history of the patient suggests a possible exposure, while in case of clinical suspicion of a neoplastic etiology, the computed tomography of petrous bone and the brainstem magnetic resonance imaging must be performed. Radiological images are required even when the child shows other neurological manifestations or in suspected chronic otitis media, acute mastoiditis or temporal bone fracture[14,15,18-21].

Electrophysiological studies can be useful to identify the cause of the paralysis, to define the prognosis and follow-up of functional recovery, but they are still not considered necessary in all pediatric patients[14,15,18-21].

PROGNOSIS

To assess the prognosis of facial paralysis can be difficult, especially in children, even if the possibility of a complete functional recovery is greater in pediatric cases than in adult ones.

The degree of paralysis represents a prognostic element: patients with partial paralysis have a better prognosis. Actually, the Ⅱ degree according to House-Brackmann scale has a good outcome, while the Ⅲ and the Ⅳ degrees are associated to moderate residual dysfunctions. The Ⅴ and the Ⅵ degrees, instead, have poor possibility of recovery[1,23].

Perinatal traumatic forms usually have a good prognosis, with a possible spontaneous resolution within 4 mo of life[9,13,21]. Bell's palsy has a generally optimal functional recovery in a short period of time; a favorable prognostic indicator is represented by a clinical improvement within 3 wk by the onset[1,13,23]. Ramsey Hunt syndrome has a worse prognosis compared to Bell's palsy: only 10% of severe paralysis due to reactivation of Herpes Varicella-Zoster have a full recovery[14].

The prognosis of facial paralysis caused by tumors is of course related to the type and stage of the tumor and the treatment performed[8,9,13,15,21].

It has been reported that in about 5% of cases, the affected side may develop residual sequelae like contractures, spasms, synkinesis[1,15]. The latter, in particular, affect the symmetry and facial expressiveness and usually recognize three possible pathogenetic mechanisms: an aberrant axonal regeneration, an aberrant nerve impulse transmission and a hyperexcitability of the nucleus of the facial nerve. The most common synkinesis affects the eye and mouth muscles: during a voluntary movement of the mouth, for example a smile, there could be an involuntary eye closure and *vice versa*. Less frequently, involuntary movements of the chin can be seen during voluntary movements of the mouth or the voluntary eye closure[24]. A similar phenomenon can occur with the autonomic fibers: for example, when eating, the activation of salivation causes also lachrymation (phenomenon known as "crocodile tears")[1,15,25].

THERAPY

The treatment of facial palsy is related to the etiology and the severity of the palsy itself. When a specific cause is identified, treatment is aimed to resolve the underlying cause. The therapeutic approach in children often involves a multidisciplinary team, comprehending otolaryngologists, pediatricians, neurologists, ophthalmologists, maxillofacial surgeons, plastic surgeons, physiotherapists (Table 2).

Drug therapy

In the idiopathic cases of facial palsy, the main limitations regarding drug therapy in children concern the lack of controlled clinical trials on children with Bell's palsy and its favorable natural history[9,13]. Since most of these forms in childhood recover spontaneously, aim of the drug therapy is to minimize the possibility of incomplete resolutions and reduce the risk of sequelae, such synkinesis, autonomic dysfunctions (*e.g.,* crocodile tears), facial spasms[26]. When Bell's palsy occurs in adults, it is well known that glucocorticoids in combination with antiviral therapy (acyclovir or valacyclovir) are recommended[27-30]. In children, the use of oral corticosteroids is recommended preferably within 3 d from onset of symptoms (the suggested treatment regimen is prednisone 1-2 mg/kg per day for 10 d, gradually decreasing the dose)[13,31] as the majority of patients improves in the first three weeks[32], although several studies did not find significant differences between the outcomes of children treated with corticosteroids and not[20,33-35]. The Ramsay Hunt syndrome, instead, should be treated as soon as possible with intravenous steroid associated with antivirals in children older than 2 years (*e.g.*, acyclovir 80 mg/kg per day every 6 h for 5 d or, in children older than 12 years, valacyclovir 20 mg/kg three times per day, up to a maximum of 1000 mg three times daily), in order to obtain a full recovery in 75% of cases if treated within the first three days from onset[5,13,36].

The majority of children has a spontaneous recovery, but for both congenital and acquired forms, particular attention should be paid to the corneal protection, resorting to the use of protective devices and lubrication with artificial tears to prevent irreversible corneal lesions. Rarely, persistent paralysis with an important lagophthalmos may require a tarsorrhaphy or the implantation of a temporary weight in the upper eyelid. Moreover, in infants with difficulty in suction due to mouth muscles involvement, it is essential to provide an alternative nutritional support[1,9,13,15,21,37].

Children with persistent severe paralysis require a long follow-up. The absence of signs of functional recovery after six weeks requires a comprehensive reassessment of the diagnostic-therapeutic approach[13].

Infants with congenital paralysis for perinatal trauma, usually have a good prognosis even without treatment. For those presenting a neural damage, there are surgical solutions in combination with steroid therapy, depending on the severity of the case[9]. The direct neurorrhaphy has an excellent prognosis, due to the large neuronal plasticity and the excellent regenerative capacity in the childhood. Alternatively the use of a nerve graft is

Table 2 Therapeutic approaches to facial nerve palsy in childhood

Therapy of facial nerve palsy		Outcome[1]
Drugs	Bell's palsy	
	Oral steroids within 3 d of onset	70% recovery after 3 wk[32]
	Ramsay Hunt syndrome	
	Intravenous steroids as soon as possible	75% recovery at 6 mo if treated within 3 d from onset; 30% recovery at 6 mo if treated after 7 d from onset[36,44]
	Antiviral agents	
	Other conditions	
	Targeted therapies for specific diseases	N/A
Protective measures	Eye protection	N/A
	Artificial tears	N/A
	Tarsorrhaphy	N/A
	Eyelid weight implant	N/A
	Nutritional support	N/A
Surgery	Traumatic palsy	
	Neurorrhaphy within 72 h	N/A
	Nerve grafting within 72 h	N/A
	Other conditions	
	Dynamic facial reanimation	
	Temporalis elongation mioplasty	80% recovery within 1 mo[38]
	Gracilis muscle microvascular free flap	89% recovery within 4-6 mo[45]
	Sural nerve grafting	N/A
	Cross-facial nerve grafting	83% recovery within 1 yr[46]
Rehabilitation approaches	Botulinum toxin	100% recovery (temporary)[24]
	Physiotherapy	N/A
	Biofeedback therapy	N/A
Regenerative therapy	Bioelectrical interface/electrode	N/A
	Stem cells and bio-scaffolds	N/A

[1]When available.

also described, with discrete functional and aesthetic results[3,9]. In both cases, the repair of the nerve should be completed within 72 h from the trauma onset[3,13].

Surgical therapy

In the pediatric population, the surgical decompression of the facial nerve in its labyrinthine segment is not recommended[3,9], primarily due to the lack of systematic clinical studies demonstrating its real effectiveness and secondly due to the risk of sensorineural hearing loss occurrence. In children presenting a permanent congenital or acquired facial palsy, surgical techniques of dynamic facial reanimation can be considered in order to tentatively restore a static and dynamic facial symmetry. Among these, the most performed are locoregional muscles transfers and muscle and nerve grafts[10,13]. In particular, a frequently performed intervention is the temporalis elongation myoplasty: the tendon of the temporal muscle is moved from the mandibular coronoid process to the lips, with 80% of children regaining a sufficient symmetry within a month[38]. A similar intervention is the bilateral anterior third of the masseter muscle transfer above the corners of the mouth. Also the employment of microvascular free flaps of gracilis muscle has been proposed[10,13]. Another microsurgical technique consists of nerve grafts (usually sural nerve) between the branches of the facial nerve of the healthy side of the face and those of the injured side (cross facial nerve grafting). This practice allows the healthy facial nerve to send a symmetrical and synchronous pulse to the paralyzed side[3,10,24,37,39,40]. Children have the best chances of success with this type of surgery[10,15]. When it is not possible to perform a cruciate graft, a neural transposition from a donor site of the same side of the facial paralysis can be proposed (*e.g.*, the hypoglossal nerve or the trigeminal motor branch): the nerve is partly or completely dissected and anastomosed to the distal part of the paralyzed facial nerve[10,15].

Rehabilitation approaches

Among the proposed treatments for synkinesis and emifacial spasms, the botulinum toxin has been proposed also in childhood[15,24]. Unfortunately, the toxin has a temporary effect, making necessary to repeat the injections. Moreover, the periods of relief from synkinesis become more and more short. Better results have been reported with the use of botulinum toxin after a cross facial nerve grafting[15,24]. Although with less evidences, other rehabilitative approaches, such as physical therapy, biofeedback therapy, relaxation exercises with massages therapy, coordination and facial expression exercises, can reduce muscle stiffness, facilitating facial movements. Relatively to acupuncture and electrical nerve stimulation (in order to accelerate healing by stimulating muscle), there are still not enough data in the literature in order to

certify the real efficacy[15,24-27].

Regenerative therapy

In the recent years, innovative technologies are improving the possibilities for facial reanimation with bioelectrical interfaces by using tissue-engineered constructs. An emerging strategy in order to restore a symmetrical smile is a direct neural interface: Inputs of the interfaced nerves induce stimuluses in the injured facial nerve. Regenerative electrodes are used in case of traumatic injuries of the nerve: These could be implanted at the end of the facial nerve and could allow its regrowth through the construct[41].

Among regenerative therapy, peripheral nerve regenerative strategies are clinically not available yet. Experimental procedures described in the literature have shown different achievements and consist of a combination of stem cells and bio-scaffolds.

Different types of stem cells have been proposed in order restore neuronal integrity; among these, embryonic stem cells, nerve and mesenchymal stem cells, adipose and bone marrow derived stem cells and also other types have been proposed[42].

Bio-scaffolds aim to maintain cell feasibility, but should also sustain proliferation and allow intercellular communication and cellular growth. Carbon nanotubes, hyaluronic acid-based scaffolds, polymeric scaffolds and other similar solutions have been proposed with the aim of piloting the neuronal/assonal regrowth[43].

Nonetheless, this therapeutic strategy is indeed complex; if it will become available, hopefully, it could offer new potential approaches for future treatments.

CONCLUSION

Pediatric facial nerve palsy is a condition with several implications, particularly when occurring in childhood. It causes significant concerns in doctors and in parents as well, mainly due to the functional and aesthetic outcomes.

The causes of paralysis in children are many, however idiopathic facial paralysis, or Bell's palsy, is the most frequent form of facial paralysis in children too. A careful diagnostic workout and differential diagnosis are always recommended, in order to establish the most appropriate treatment. Hopefully, in the future, regenerative medicine could offer new options for the treatment of this condition.

Abstract

Thymoma is the most common mediastinal tumor. They have varied presentation ranging from asymptomatic incidental mediastinal masses to locally extensive tumor with compressive symptoms and distant metastases. They have frequent association with various paraneoplastic syndromes (PNS). The most common PNS associated with thymoma is myasthenia gravis (MG). Patients of thymoma with MG have a favourable outcome due to early disclosure of the disease. Histologically they are classified into five subtypes and Masaoka-Koga staging system is used for staging. Surgery, chemotherapy and radiotherapy play an important role along with anti-myasthenia drugs. This review would like to highlight the association of thymoma with MG and associated clinical and therapeutic issues.

Key words: Thymoma; Myasthenia gravis; Surgery; Radiotherapy; Chemotherapy

Core tip: This article is a comprehensive review of literature of a rare neoplasm. This article outlines the various newer details of diagnosis, staging and treatment aspects of thymoma and myasthenia gravis (MG). The importance of association between thymoma and MG is reviewed in detail.

Kumar R. Myasthenia gravis and thymic neoplasms: A brief review. *World J Clin Cases* 2015; 3(12): 980-983 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i12/980.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i12.980

INTRODUCTION

Thymoma is a neoplasm of the thymus gland originating from its epithelial tissue. Thymomas are the most common neoplasm of the anterior mediastinum in adults and the most common tumor of the thymus[1]. They account for approximately fifty percent of the anterior mediastinal masses[1]. But, thymomas are rare human neoplasms accounting for less than 0.5% of all cancers. The incidence of thymoma is 0.15 per 100000 person years[2]. The peak incidence in seen in the fourth and fifth decades of life with 52 years as the mean age at presentation[2]. No sexual predilection exists. They have frequent association with various paraneoplastic syndromes (PNS)[1]. The most common PNS associated

Table 1 World Health Organization histopathological classification

Type	Histologic description
A	Medullary thymoma
AB	Mixed thymoma
B1	Predominantly cortical thymoma
B2	Cortical thymoma
B3	Well-differentiated thymic carcinoma
C	Thymic carcinoma

with thymoma is myasthenia gravis (MG). This review would like to highlight the association of thymoma with MG and associated clinical and therapeutic issues.

CLINICAL ASSOCIATION

Thymomas are associated with PNS in 50% to 70% of cases[3]. The common PNS associated are MG (30% to 50%), Cushing syndrome, hypogammaglobulinemia, pure red blood cell aplasia, rheumatoid arthritis and limbic encephalitis. Thymoma is detected early in patients with MG as compared to patients without PNS due to regular clinical evaluation for treatment of MG[4]. The most common symptom is cough. They usually have a slow growth and spreads by local extension. Metastasic spread is to the pleura, pericardium, or diaphragm, while spread to extrathoracic sites are uncommon[2].

MG is a disease affecting the neuromuscular junction and manifests as muscular weakness and fatigability due to acetyl-choline receptor (AChR) antibodies in 85% of the cases[5]. Thymoma MG is seen in approximately fifteen percent of all MG cases[6]. Basic pathogenesis is caused by humoral immune response to an epitope on the thymoma cells which is similar to the epitope on the neuromuscular junction components[7]. The neoplastic thymoma cells encircled by the T cells expresses epitopes that cross-react with AChR. All patients with thymoma MG have detectable AChR antibodies in serum. The AChR antibody attacks the neuromuscular junction, specifically aimed at the nicotinic AChR at the endplate region of the postsynaptic membrane, resulting in muscle weakness[8]. Other non-AChR autoantibodies are also seen in 95% of thymoma MG cases and in 50% patients with late-onset MG (after 50 years of age) which cross-reacts with striated muscle titin and RyR antigens[9].

PATHOLOGY

Thymomas are classified into 5 World Health Organization (WHO) histopathological subtypes (Table 1)[10]. Thymoma arises from thymic epithelial cells and is associated with a variable degree of T lymphocyte proliferation. These T lymphocytes are generated *de novo* within the thymoma from the bone marrow progenitor cells under the influence of the cortical epithelial cell-like function of the thymoma's transformed epithelial cells. The WHO classification is based on the morphology of these epithelial cells and the amount of associated T lymphocyte, which is an indicator of the biologic function of the thymoma cells. While thymomas of WHO types A, AB, B1, B2, and B3 all show a certain amount of immature T lymphocytes, thymic carcinomas do not have a measurable number of immature T lymphocytes and are thus undifferentiated. Cortical thymoma (Type B2) is associated with MG in 50% of cases while medullary thymoma (Type A) is seldom associated with MG.

STAGING

Different staging systems are used but the most widely used system is Masaoka-Koga staging system, based on the per-operative and histopathological findings (Table 2)[11,12]. TNM staging of thymoma is not widely accepted, because it is not more useful than the Masaoka system[13].

INVESTIGATIONS

Histopathological diagnosis is the gold standard. Contrast enhanced computed tomography (CECT) thorax shows the local and regional extent of the disease. Magnetic resonance imaging aids in better soft tissue delineation and surgical planning. Routine hemogram and blood biochemistry is needed for assessing the patient's status. Metastatic workup requires further ultrasound of the abdomen or CECT abdomen. Serum titers of antiacetylcholine receptor antibody are done to assess the myasthenia status.

TREATMENT

Surgery

Surgery is the mainstay modality for the management of thymomas. Surgery helps for exact histopathological evaluation and staging, and is the first-line treatment modality in most of the cases[14]. Immediate and complete surgical resection is advised for resectable tumors. Surgery can be approached transternally or by video assisted thoracoscopic surgery, both having similar clinical outcome[15]. Radical removal of thymoma is curative for thymic tumors in most of the cases, but patients do suffer from MG after surgery. Thus, pharmacological treatment for MG and continuous followup is necessary even after surgery. In locally advanced cases when the tumour invades pleura or pericardium, complete radical surgery is not possible and adjuvant treatment in form of radiotherapy (RT) and chemotherapy (CT) is required. Presurgical plasmapheresis or immunoglobulin (IgG) intravenous infusion helps in removal of circulating pathogenic antibodies to a significant level[16].

RT

Postoperative adjuvant RT is should be given in patients with incompletely resected tumors[17]. Stage Ⅱ and

Table 2 Masaoka-Koga staging system

Stage	Definition
I	Encapsulated tumor with no gross or microscopic invasion
II	Macroscopic invasion into the mediastinal fat or pleura or microscopic invasion into the capsule
III	Invasion of the pericardium, great vessels, or lung
IVA	Pleural or pericardial dissemination
IVB	Lymphogenous or hematogenous metastasis

Ⅲ patients after complete resection also benefit from adjuvant RT in reducing the local recurrence rates. RT doses ranging from 40 to 60 Gy is advised which includes a radiation boost to the tumor bed in incompletely resected or nonresected lesions, with a fractionation scheme of 1.8 to 2 Gy daily over a period of 4-6 wk[18]. Patients with poor performance status and advanced diseases with compressive symptoms are given palliative RT in doses of 30 Gy in 10 fractions or 20 Gy in five fractions.

CT

CT in thymomas is preferred in locally advanced, unresectable and metastatic disease[18]. The common chemotherapeutic drugs used in thymoma are cisplatin, adriamycin, etoposide, cyclophosphamide and ifosfamide. Various standard CT regimens include the following: cyclophosphamide, adriamycin, cisplatin (CAP)[19]; cisplatin and etoposide (PE)[20]; adriamycin, cisplatin, vincistine, cyclophosphamide (ADOC)[21]; and etoposide, ifosfamide, cisplatin (VIP)[22]. Response to CT is ranges between 32% and 92% and around 10%-43% of patients have complete responses[23]. Adjuvant CT has a favorable influence on survival in stage Ⅲ and Ⅳ A resected thymomas. CT can be used as the initial modality in stage Ⅲ and Ⅳ A unresectable thymomas[24]. For stage Ⅳ B thymomas with disseminated disease, CT is preferred with local RT for palliation of local symptoms[18].

Treatment of MG crisis in thymoma

In MG crisis, the standard management is plasmapheresis and immunoglobulin treatments[25]. Intense pharmacological treatment should be used along with the immunoglobulin and plasmapheresis treatment in these patients.

Pharmacological treatment of thymoma MG

The drug of choice is acetylcholinesterase inhibitors[26]. Immunosuppressive drugs are the second choice when additional drug treatment is required. Several immunosuppressive drugs are used, namely steroids, azathioprine, cyclosporine, tacrolimus, cyclophosphamide, methotrexate, mycophenolate mofetil and rituximab.

PROGNOSIS

Prognostic factors predicting recurrence was evaluated by Detterbeck *et al*[27] in a systemic review. The significant factors were Masaoka Stage and completeness of resection. Other factors such as age, sex, size of tumor and MG were not statistically significant in multivariate analysis.

CONCLUSION

The management of thymoma involves a multimodality approach and needs cooperation between surgeons, radiologists, pathologists and oncologists from establishing diagnosis, deciding the therapeutic strategy and evaluating the prognosis. With advances in medical science in new techniques and drugs, there is a remarkable improvement in the management of thymoma.

Abstract

Mapping nerve deficits during a physical exam after trauma to the upper extremity can help determine not only if the brachial plexus was injured but also which nerve roots were involved. A 28-year-old male presented with simultaneous signs and symptoms of Erb's (C5) and Klumpke's (C8, T1) palsy, with sparing of the C6 and C7 roots. The patient presented several months ago to his local emergency room with shortness of breath, which was determined to be caused by left diaphragmatic paralysis through clinical and radiographical evidence. However, the etiology of the current nerve dysfunction in the upper extremity remained unknown. With persistent questioning and establishing the patient's trust in the caregivers, it was revealed that the patient had attempted suicidal hanging. We describe the clinical features and the likely mechanism of injury leading to this previously unreported combination of brachial plexus injuries. The unique injuries to this patient's brachial plexus can be explained by the sequence of events during the attempted suicidal hanging. The upper brachial plexus was injured during the initial moments where the neck was excessively stretched and the lower brachial plexus was injured due to the patient reaching up and holding himself by his arm for an extended period of time.

Key words: Erb's palsy; Klumpke's palsy; Hanging injury

Core tip: This report describes a unique case in which only the upper and lower roots of the left brachial plexus were injured, sparing the C6 and C7 roots. Careful questioning revealed that the injury was caused during an attempted suicidal hanging. The damage to C5 occurred due to stretching of the neck and the damage to the C7 and C8 roots occurred after the patient reached up to free himself and hung by his arm for a period of

time.

INTRODUCTION

The brachial plexus is a group of nerves from C5-T1 that provide motor and sensory innervation to the upper extremity. Injury to the brachial plexus usually results in a pattern of functional losses that indicate which region of the brachial plexus was injured. Traumatic brachial plexus injuries are the most common type of brachial plexus injury[1]. Total lesioning of the brachial plexus (C5-T1) occurs in 75% of traumatic brachial plexus injuries. Traumatic brachial plexus injuries are typically associated with motor vehicle collisions. The typical presentation of a total brachial plexus injury is the rupture of the C5 and C6 roots (distal to the dorsal root ganglia) and avulsion of C7-T1 roots (proximal to the dorsal root ganglia)[2]. It can be extrapolated from this that the lower brachial plexus is susceptible to greater injury in traumatic brachial plexus injuries.

Erb's palsy or Erb-Duchenne palsy is an upper brachial plexus injury involving nerve roots C5 and C6. Klumpke's palsy or Dejerine-Klumpke palsy describes injury to the lower roots (C8, T1). These are usually brought about by a specific injury mechanism resulting in stretch of either the upper plexus (due to widening of the angle between the shoulder and head) or the lower plexus (seen in hyperabduction of the arm), in a mutually exclusive manner[3].

We report a case of an initially puzzling neurological deficit consisting of both upper and lower brachial plexus injuries. We assume this is the first reported case of such a combination injury.

CASE REPORT

A young male patient was referred to the clinic with a history of weakness and numbness in his left arm. Complaints of shortness of breath when he presented to his local emergency room several months prior had prompted radiographic workup revealing slight elevation of the left hemi diaphragm. Detailed neuroimaging with MRI and MRA were normal.

On motor exam at the clinic, there was difficulty raising the left arm above the horizontal plane against resistance. Slight atrophy of both the deltoid and supraspinatus muscles along with atrophy and weakness of the hypothenar and intrinsic hand muscles of the left side were noted. Full strength and normal muscle bulk were demonstrated in the left biceps and triceps. On sensory exam, reduced sensation to light touch and pinprick were found along the upper lateral shoulder supporting left C5 nerve root involvement. In addition, sensory deficits of the ulnar aspect of the forearm, hypothenar and the fifth digit were consistent with left C8 and T1 nerve root involvement. Denervation and early regeneration potentials were also confirmed for the left C5, C8 and T1 roots at the trunk level of the brachial plexus.

The patient was initially evasive regarding the events leading up to his neurological defects. He had repeatedly denied any trauma. Serological exam did not reveal any inflammatory process. With persistent inquiry, the patient ultimately disclosed that several months ago he had attempted suicide by hanging, using a rope and jumping from height. He reported that just when the rope tightened, his neck was stretched upward. He then reached up and grabbed the rope. He remained hanging on his outstretched arm before he was able to free himself.

Conservative treatment including physical therapy was initiated, with gradual improvement of the deficits over several months. Psychological counseling and psychiatric care were established.

DISCUSSION

There are only a few case reports describing complications of hangings despite its high prevalence. One reason is the high rate of completion of this method of suicide[4]. Additionally, unless the clinician is able to develop a rapport with the patient, patients are less likely to reveal the true scenario which led to the presentation; another potential reason for under reporting.

Based on the radiographic findings and history, it was determined that partial diaphragmatic paralysis was responsible for the shortness of breath the patient experienced. Hanging has previously been shown to cause temporary bilateral diaphragmatic paralysis[5]. In addition, several other mechanisms that can give rise to shortness of breath have been reported in the literature and were considered in the differential diagnosis. Post-obstructive pulmonary edema (POPE) is a common finding in attempted hangings. Young men, such as this patient, are especially susceptible to POPE because of the greater negative intrapleural pressure that is generated in this patient group[4,6]. Lack of pulmonary opacities on radiography made this unlikely.

It is believed that the primary fatal component of suicidal hanging is not from a cervical fracture, airway compression, or sympathetic stimulation, but rather internal jugular vein and carotid artery compression. Venous and arterial compressions are then followed by airway compression that ultimately leads to global hypoxia[4,7,8]. This theory is further reinforced by cases of patients with tracheotomies completing suicide with ligatures above the tracheotomy. Perfusion with hypoxic blood has been shown to be sufficient to produce respiratory distress in animal models, which reinforces this hypothesis[8]. Deaths in

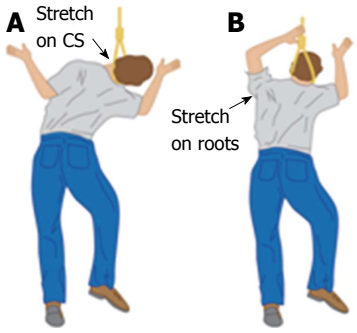

Figure 1 The likely injury mechanism can lead to a similar clinical presentation. A: Artist's rendering of the upper brachial plexus stretch injury; B: Artist's rendering of the lower brachial plexus stretch injury.

attempted hangings are typically associated with respiratory failure or bronchopneumonia[4,8].

In attempted suicidal hangings that did not result in death, nerve lesions have been reported and are described as upper motor neuron lesions caused by damage to the basal ganglia due to cerebral anoxia. Patients present with muscle spasticity and hyperreflexia[9]. Nerve damage due to anoxia in this patient was ruled out during the physical exam, which showed atrophy and decreased strength in the involved muscles, indicating that the deficits were lower motor neuron type lesions. Lower motor neuron lesions without ongoing or past inflammatory episodes in a healthy individual suggests trauma. Although the patient denied any trauma during the initial encounters, it was still high on the differential diagnosis list.

Physical examination of the patient revealed left partial diaphragmatic paralysis with atrophy of the intrinsic muscles of the hand as well as the hypothenar, supraspinatus and deltoid muscles on the left side. The nerves involved in innervating these muscles were studied to determine if there was a pattern in the distribution of nerve loss that could be traced back to the brachial plexus. The diaphragm is innervated by the phrenic nerve from C3-C5. The hypothenar and intrinsic muscles of the hand are innervated by the ulnar nerve from C8-T1. The supraspinatus muscle is innervated by the suprascapular nerve from C5-C6. The deltoid muscle is innervated by the axillary nerve from C5-C6[10]. The pattern of these involved nerves indicate injuries in the distribution of the left C5, C8 and T1 nerve roots. This combination of deficits and electrophysiological findings point to a stretch injury to both the upper and lower plexus. It is noteworthy that the C7 and possibly C6 nerve roots were spared in the case described here. Therefore, it is likely the damages occurred due to successive movements during the course of the hanging attempt that stretched first the upper then the lower regions of the brachial plexus.

Figure 1 shows the likely injury mechanism that can lead to a similar clinical presentation. Tension on the upper plexus likely occurred when the neck was abruptly pulled upward by the tightening rope (Figure 1A). The survival instinct led the patient to reach up and transfer his weight to his outstretched arm, causing stretch of the lower trunk (Figure 1B).

Traction injuries to the brachial plexus make up the majority of brachial plexus lesions. It is advised that the patient should be observed for up to 3-5 mo following the injury as edema should decrease and minor injuries resolve[11]. Natural recovery usually occurs within 6 mo, but recoveries without operative intervention are poorly documented[1]. As expected, this patient was also less symptomatic during subsequent follow-up appointments. Unfortunately we were unable to follow him long-term and address the physical and psychological issues completely, due to the poor compliance of the patient.

This patient's injuries are consistent with a sequence of events resulting in first a lateral stretch of the neck followed by a stretch of the lower brachial plexus. The movements behind these injuries can be explained by the patient's history of an attempted suicide followed by a survival response and extended period of time where the patient's weight was suspended by his arm above his head.

Authors would like to thank Mr. Bryan Moss for illustrations.

COMMENTS

Case characteristics

A young male with numbness and weakness in his left arm and previous difficulty breathing.

Clinical diagnosis

Left diaphragmatic paralysis with atrophy and weakness of the deltoid, supraspinatus, hypothenar and intrinsic hand muscles on the left side with reduced sensation to light touch and pinprick along the upper lateral shoulder, ulnar aspect of the forearm, hypothenar and the fifth digit.

Differential diagnosis

Brachial plexus trauma, nerve impingement.

Laboratory diagnosis

Serological studies did not reveal inflammatory processes.

Imaging diagnosis

Radiographic workup showed slight elevation of the left hemi diaphragm and magnetic resonance imaging/magnetic resonance angiography neuroimaging showed no abnormalities.

Treatment

Conservative treatment including physical therapy was initiated and psychological counseling and psychiatric care were established.

Related reports

To our knowledge, this is the first case report to describe both Erb's and Klumpke's palsy resulting from a suicidal hanging attempt.

Term explanation

Erb-Duchenne palsy refers to damage of the C5 and C6 nerve roots resulting in sensory and motor deficits in the distribution of commonly the suprascapular, musculocutaneous and axillary nerves. Dejerine-Klumpke palsy refers to

damage of the C8 and T1 nerve roots resulting in sensory and motor deficits in the distribution of the ulnar nerve. Post-obstructive pulmonary edema is negative pressure, non-cardiogenic pulmonary edema that can occur during (type Ⅰ) or after relief of (type Ⅱ) a pulmonary obstruction.

Experiences and lessons

This case presents a unique distribution of nerve damage after attempted suicidal hanging that we do not believe has been previously described.

Peer-review

This is an interesting case of a combined upper and lower brachial plexus injury associated with an attempted suicide.

Abstract

Sarcoidosis is a systemic inflammatory condition in which noncaseating epithelioid cell granulomas appear within one or several body sites. Sarcoid reaction (also referred to as sarcoidal or sarcoid-like reaction) occurs in patients who do not fulfill the diagnostic criteria for systemic sarcoidosis but present with similar clinical and histological features. As sarcoma-associated sarcoid reactions are rare, we describe the features of sarcoid reaction that developed in a man with liposarcoma and summarize reports of other oncology patients with sarcoma-associated sarcoid reactions. A 68-year-old man with retroperitoneal liposarcoma presented for evaluation of erythematous dermal plaques on his left leg. Microscopic examination of a tissue specimen revealed multiple epithelioid granulomas in the superficial and mid-reticular dermis. Correlation of the clinical presentation and histopathologic findings established a diagnosis of liposarcoma-associated cutaneous sarcoid reaction. Sarcoid reactions have been described in only seven individuals with sarcoma, including two patients with leiomyosarcoma and one patient with either carcinosarcoma, Kaposi sarcoma, liposarcoma, malignant peripheral nerve sheath tumor, rhabdosarcoma, or synovial sarcoma. Sarcoidal granulomas most commonly develop within the locoregional draining lymph nodes. Sarcoid reactions may also affect other organs, such as the lungs, skin, and spleen.

Key words: Liposarcoma; Malignancy; Sarcoid; Sarcoid reaction; Sarcoidosis; Sarcoma

Core tip: Sarcoid reaction is an inflammatory condition in which noncaseating epithelioid cell granulomas develop within one or several body sites. Several malignancies,

including lymphomas and carcinomas, have been linked to sarcoid reaction. We describe the first case of a patient presenting with liposarcoma-associated sarcoid reaction and summarize the literature on rare patients with sarcoma-associated sarcoid reactions. It is imperative that clinicians consider sarcoid reaction in the evaluation of oncology patients prior to initiating treatment.

INTRODUCTION

Sarcoidosis is a multisystem inflammatory condition characterized by the appearance of noncaseating epithelioid cell granulomas within one or several body sites. Sarcoid reaction-also called sarcoidal or sarcoid-like reaction-refers to the presence of noncaseating epithelioid cell granulomas in patients who do not fulfill the diagnostic criteria for systemic sarcoidosis. Many malignancies-including cancers of the thyroid, breast, and kidney-have been associated with sarcoid reaction. However, sarcoma-associated sarcoid reactions are rare[1].

Sarcoid reactions most commonly affect the lungs, intrathoracic lymph nodes, and skin. In addition, oncology patients often develop sarcoidal granulomas within the locoregional lymph nodes that drain the cancer. Diagnosis is typically established through imaging and/or biopsy. Similar to sarcoidosis, sarcoid reaction is typically asymptomatic and self-limiting; therefore, treatment is seldom required[2]. Immunohistochemical analyses have revealed that granulomas found in sarcoid reactions are B cell-positive while those found in sarcoidosis are B cell-negative.

We describe a man with liposarcoma who presented with cutaneous sarcoid reaction and summarize the characteristics of other sarcoma patients with sarcoid reaction.

CASE REPORT

In July 2014, a 68-year-old man with liposarcoma, which was diagnosed in 2008, presented for evaluation of a red rash on his leg that had been present for 30 mo. The tumor was 20 cm × 15 cm and located in the retroperitoneal space. The liposarcoma was inoperable and therefore treatment with oral pazopanib hydrochloride (200 mg taken four times per day) had been initiated. However, metastasis to the lymph nodes was subsequently detected.

Cutaneous examination revealed multiple smooth-surfaced erythematous dermal plaques affecting his left pretibial area (Figure 1). Pathologic examination of a punch biopsy showed multiple epithelioid granulomas in the superficial and mid-reticular dermis. Histiocytes could also be seen within the interstitium. There was mild lymphocytic and neutrophilic inflammation surrounding the sarcoidal granulomas (Figures 2 and 3). Bacterial, fungal, and mycobacterial cultures of biopsy-obtained skin specimens were negative for organisms.

Laboratory studies revealed an elevated erythrocyte sedimentation rate of 68 mm/h (reference range: 0-20 mm/h). With the exception of his serum albumin level being low at 2.92 g/dL (reference range: 3.5-5.5 g/dL), his serum chemistry levels were normal. Notably, his alpha-2-macroglobulin was elevated at 1.17 g/dL (reference range: 0.6-1.1 g/dL); this finding was consistent with subacute tumor-associated inflammation. Laboratory results for the following studies were negative or normal: anti-nuclear antibody, angiotensin converting enzyme, anti-dsDNA, anti-La (Sjogren's syndrome B), anti-Ro (Sjogren's syndrome A), anti-streptolysin O titer, glycohemoglobin, hepatitis antibodies, lipid profile, rheumatoid factor, Smith antibody, syphilis enzyme immunoassay, thyroxine 4, thyroid stimulating hormone, and vitamin D1,25-dihydroxy.

Based on correlation of the clinical presentation, histopathologic findings, and laboratory studies, a diagnosis of liposarcoma-associated cutaneous sarcoid reaction was established. The patient did not fulfill the criteria for systemic sarcoidosis. His skin condition was asymptomatic; therefore, no treatment was initiated. He died of malignancy-associated kidney failure shortly after the diagnosis of sarcoid reaction was established.

DISCUSSION

The first account of sarcoid reaction can be traced back to 1869, when the British physician Jonathan Hutchinson described a patient with "peculiar patches of dark purplish color on his extremities"[3]. The condition was further characterized throughout the late-19th and early-20th centuries. In 1899, Boeck[4] described 24 patients with "benign miliary lupoids". Twelve years later, Wolbach[5] detailed the histologic features of sarcoidal granulomas in a report of five patients with "widely distributed miliary sized lesions of granulomatous character". However, the association between sarcoid reaction and malignancy was not identified until 1917, when Herxheimer[6] observed sarcoidal granulomas affecting patients with breast, rectal, and cystic duct carcinomas.

Investigators continued to study sarcoid reaction throughout the first decades of the 1900s. By 1937, it was clear that sarcoid reaction could be definitively distinguished from systemic sarcoidosis. In a report of six patients with sarcoidal granulomas, Nickerson explained that sarcoid reaction refers to the localized development of noncaseating epithelioid cell granulomas; sarcoidosis, in contrast, is a multisystem inflammatory disease characterized not only by the development of noncaseating epithelioid cell granulomas, but also by various systemic symptoms and serum abnormalities[7]. Interestingly,

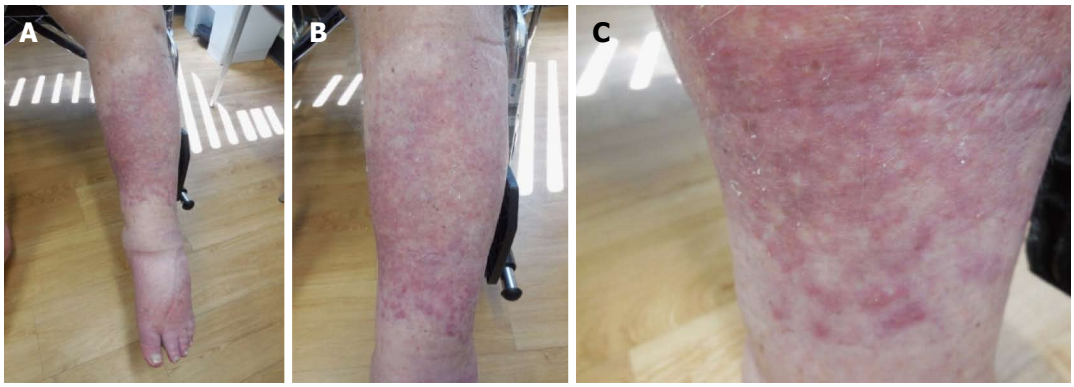

Figure 1 Distant (A), intermediate (B), and close (C) views of erythematous dermal plaques on the left leg of a 68-year-old man. The lesions were later diagnosed as cutaneous sarcoid reaction.

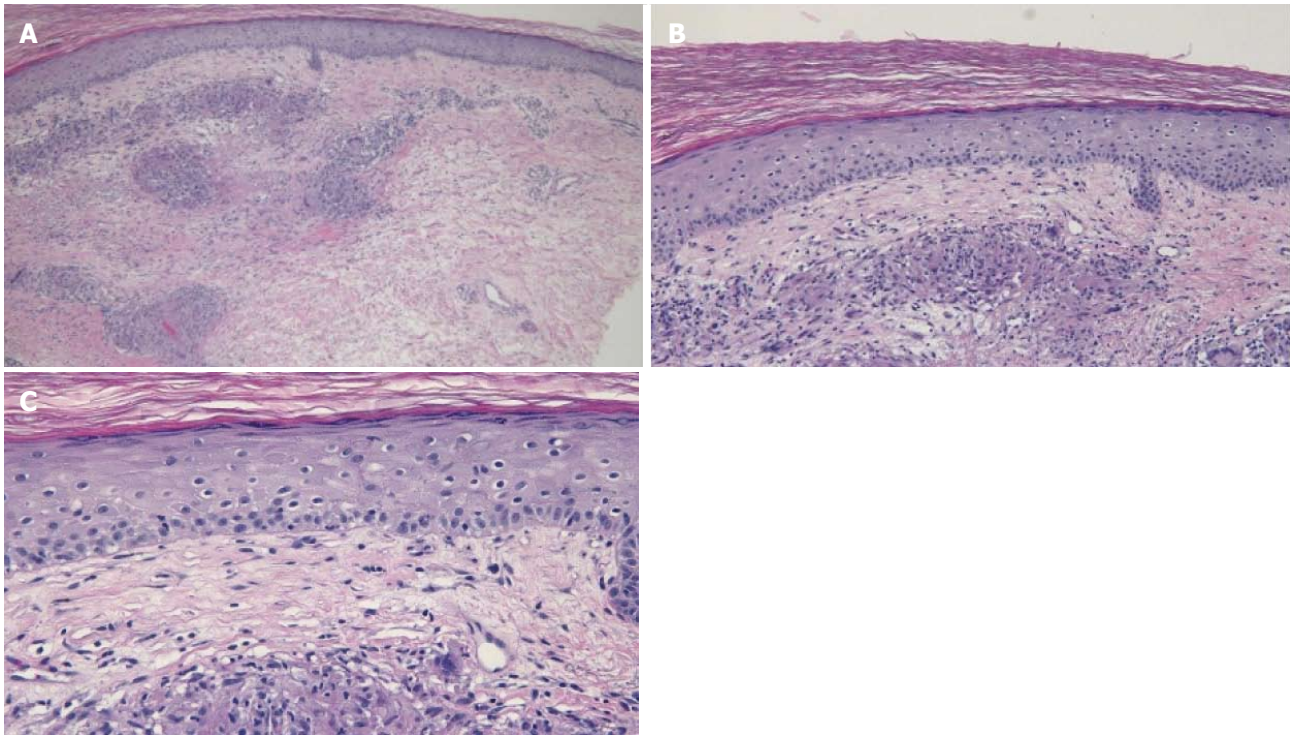

Figure 2 Low (A), intermediate (B), and high (C) magnification views of a sample of a lesion taken from the left leg of a 68-year-old man. Multiple epithelioid granulomas can be observed in the superficial and mid-reticular dermis. Interstitial histiocytes can also be seen within the interstitium (hematoxylin and eosin: A: × 10; B: × 20; C: × 40).

although sarcoidal granulomas are histologically identical in both conditions, immunohistochemical analyses have revealed that granulomas found in sarcoid reactions are B cell-positive while those found in sarcoidosis are B cell-negative[8].

Sarcoid reactions have been described in association with numerous hematologic malignancies and solid tumors[9]. However, sarcoma-associated sarcoid reactions are rare. Indeed, to the best of our knowledge, only eight patients (including our patient) with sarcoma-associated sarcoid reactions have been described in the English literature (Table 1)[10-16].

Leiomyosarcoma-either of the rectum or stomach-was associated with sarcoid reaction in 25% of individuals (two of eight). The other patients had either carcinosarcoma, Kaposi sarcoma, liposarcoma, malignant peripheral nerve sheath tumor, rhabdosarcoma, or synovial sarcoma. However, the number of patients is too small to observe any definitive relationship between specific sarcoma type and the development of sarcoid reaction.

Sarcoma-associated sarcoid reaction was observed in five men and three women. The age at sarcoma diagnosis ranged from 22 to 74 years; the median age was 57.5 years. The women were significantly younger than the men; they ranged in age from 22 to 58 years, with a median age of 48 years. In contrast, men ranged in age from 30 to 74 years; their median age was 60 years.

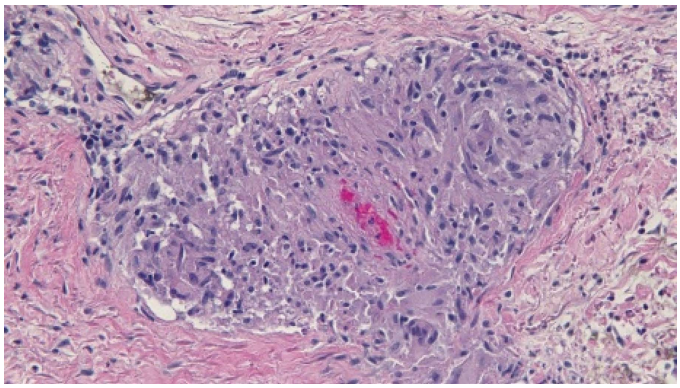

Figure 3 High magnification view of a sarcoidal granuloma from a sample of a lesion taken from the left leg of a 68-year-old man. There is mild lymphocytic and neutrophilic inflammation surrounding the granuloma (hematoxylin and eosin: × 40).

Table 1 Characteristics of patients with sarcoma and sarcoid reaction

C	Dx: SM	Dx: SR	G	Sarcoma	Diagnostic tests	Sarcoid reaction	Ref.
1	22	24	F	Synovial sarcoma of the left thigh	CT; biopsy	Left lower lobe subpleural nodules	[10]
2	30	30	M	Malignant peripheral nerve sheath tumor[1]	FDG PET/CT; biopsy	Hilar and mediastinal lymphadenopathy	[11]
3	48	50	F	Leiomyosarcoma of the stomach	Chest radiograph; biopsy	Bilateral hilar and paratracheal lymphadenopathy	[12]
4	57	57	M	Leiomyosarcoma of the rectum	Biopsy	Granulomas within the tumor tissue	[13]
5	58	59	F	Uterine carcinosarcoma	FDG PET; CT; biopsy	Hilar, pretracheal, and mediastinal lymphadenopathy	[14]
6	60	60	M	Rhabdomyosarcoma of the esophagus	Biopsy	Granulomas within the lymph nodes draining the neoplasm and in the spleen	[15]
7	62	68	M	Retroperitoneal liposarcoma	Biopsy	Red dermal plaques of granulomas	Current report
8	74	74	M	Kaposi sarcoma of the foot	Biopsy	Red-purple cutaneous patches; granulomas within the tumor tissue and in the stroma surrounding the tumor	[16]

[1]Malignant peripheral nerve sheath tumor is also referred to as neurofibrosarcoma, neurosarcoma, and malignant schwannoma. C: Case; CT: Computed tomography; Dx: SM: Age at sarcoma diagnosis (years); Dx: SR: Age at sarcoid reaction diagnosis (years); F: Female; G: Gender; M: Male; FDG PET/CT scan: Integrated 2-[18F]-fluoro-2-deoxy-D-glucose positron emission tomography and computed tomography scan.

The primary site of origin was most commonly the gastrointestinal tract; three of eight cases presented with neoplasms affecting this region. These included tumors from the esophagus, stomach, and rectum. Other sites of origin, each present in one individual, included the genitourinary tract (uterus), pelvic cavity, retroperitoneum, skin (Kaposi sarcoma), and synovium.

Five of eight cases were diagnosed with sarcoma and subsequently developed sarcoid reaction. The interval between the diagnosis of sarcoma and sarcoid reaction ranged from three months to six years, with a mean interval of 2.3 years. The two conditions were diagnosed concurrently in the remaining three patients (cases 4, 6, and 8).

The sites of sarcoma-associated sarcoid reaction in 4 of 8 cases were the lungs and mediastinal lymph nodes. Cutaneous involvement was observed in two patients, including our own. In addition, two individuals-either with Kaposi sarcoma or leiomyosarcoma of the rectum-developed nodules within the tumor tissue. Other sites of sarcoma-associated sarcoid reaction included the locoregional draining lymph nodes, the spleen, and the stroma surrounding the neoplasm.

The diagnosis of sarcoma-associated sarcoid reaction was established primarily by imaging studies and histologic examination of tissue samples. Imaging studies were performed on five patients-either chest radiography (one patient), computed tomography scan (two patients), or combination positron emission tomography and computed tomography scan (two patients). In addition, all eight patients underwent biopsy in order to identify noncaseating epithelioid cell granulomas and exclude disease metastasis. In most patients, sarcoid reactions resolve spontaneously; therefore, treatment is rarely required.

The pathogenesis of sarcoma-associated sarcoid reaction is unknown. It has been postulated that the development of sarcoidal granulomas in oncology patients represents a host immune defense mechanism. Indeed, the occurrence of sarcoid reaction within tumor tissue is associated with a better prognosis, a reduced risk of metastasis or recurrence, or both; T lymphocytes and dendritic cells, which are typically found within granulomas, are thought to play a central role in this

response[17,18]. Sarcoid reaction is characterized by the development of noncaseating epithelioid cell granulomas in patients who do not fulfill the diagnostic criteria for sarcoidosis or sarcomas.

COMMENTS

Case characteristics

A 68-year-old man with a six-year history of retroperitoneal liposarcoma presented for evaluation of a red rash on his leg that had been present for 30 mo.

Clinical diagnosis

Multiple smooth-surfaced erythematous dermal plaques affecting the left pretibial area.

Differential diagnosis

Discoid lupus erythematous, granuloma annulare, lichen planus, lymphocytoma cutis, plaque psoriasis.

Laboratory diagnosis

Elevated erythrocyte sedimentation rate of 68 mm/h (reference range: 0-20 mm/h) and elevated alpha-2-macroglobulin at 1.17 g/dL (reference range: 0.6-1.1 g/dL).

Pathological diagnosis

Multiple epithelioid granulomas in the superficial and mid-reticular dermis.

Treatment

The cutaneous condition was asymptomatic and therefore no treatment was administered.

Related reports

Sarcoid reactions have been described in only eight individuals, including the authors' patient, with various sarcomas; these include two patients with leiomyosarcoma and one patient with either carcinosarcoma, Kaposi sarcoma, liposarcoma, malignant peripheral nerve sheath tumor, rhabdosarcoma, or synovial sarcoma.

Term explanation

Sarcoidosis is a systemic inflammatory disease in which noncaseating epithelioid cell granulomas develop in multiple organ systems. In contrast, sarcoid reaction - also called sarcoidal or sarcoid-like reaction - refers to the presence of noncaseating epithelioid cell granulomas in patients who do not fulfill the diagnostic criteria for systemic sarcoidosis.

Experiences and lessons

Sarcoid reaction may occasionally mimic metastases in patients with solid tumors, including sarcomas, and should therefore be considered in the evaluation of oncology patients in order to prevent misdiagnosis and unnecessary treatment.

Peer-review

This is a straightforward clinical case study reporting on a liposarcoma patient that presents with a cutaneous sarcoid reaction. At the same time the authors review the literature listing all cases of soft tissues sarcoma that are linked to a sarcoid reaction.

Abstract

Probe-based confocal laser endomicroscopy (pCLE) is capable of acquiring *in vivo* magnified cross-section images of the gastric mucosa. Intravenous injection of fluorescein sodium is used for confocal imaging. However, it is still under debate if local administration of the dye to the mucosa is also effective for confocal imaging as it is not yet clear if topical application also reveals the intramucosal distribution of fluorescein. The objective of this study was to evaluate the intramucosal distribution of fluorescein sodium after topical application and to compare the distribution to the conventional intravenous injection used for confocal imaging. pCLE of the stomach uninfected with *Helicobacter pylori* was performed in a healthy male employing intravenous administration and local

mucosal application of fluorescein. The mucosa of the lower gastric body was biopsied 1 min and 5 min after intravenous administration or local mucosal application of fluorescein, and the distribution of fluorescein in the biopsy samples was examined histologically. Green fluorescence was already observed in the cytoplasm of fundic glandular cells in the biopsied deep mucosa 1 min after local mucosal application of fluorescein. It was also observed in the foveolar lumen and inter-foveolar lamina propria, although it was noted at only a few sites. In the tissue biopsied 5 min after the local mucosal application of fluorescein, green fluorescence was more frequently noted in the cytoplasm of fundic glandular cells than in that 1 min after the local mucosal application of fluorescein, although obvious green fluorescence was not identified in the foveolar lumen or inter-foveolar lamina propria. The distribution of intravenously administered fluorescein in the cytoplasm of fundic glandular cells was also clearly observed similarly to that after local mucosal application of fluorescein. Green fluorescence in more cells was observed in many cells 5 min after intravenous administration compared with that after 1 min. The presence of fluorescein in the mucosa was observed within a short time after local mucosal application of fluorescein, suggesting that pCLE images similarly to those after intravenous fluorescein administration can be acquired by local mucosal application of fluorescein.

Key words: Confocal laser endomicroscopy; Fluorescein; Local application; Intravenous; Distribution

Core tip: In this study, we demonstrated the presence of fluorescein administered by local mucosal application in the lamina propria. We consider this study valuable because it demonstrated that confocal laser endomicroscopic images can be acquired by local mucosal application of fluorescein. In addition, the fluorescein distributions after intravenous administration and local mucosal application were the same, which is also of interest.

INTRODUCTION

Probe-based confocal laser endomicroscopy (pCLE) is a novel endoscopic procedure capable of observing in real time *in vivo* horizontal cross-section images of a fixed depth of the gastrointestinal mucosa with a magnifying power of 1000 times using a probe-type endoscope (Cellvizio; Mauna Kea Technology, Paris, France)[1,2]. To visualize gastrointestinal mucosal tissue by pCLE, staining with a fluorescent dye is necessary, and generally, images are acquired by detecting fluorescence of intravenously administered fluorescein[1-3]. It has been assumed that intravenously administered fluorescein visualizes the capillary vascular network in the superficial layer of the mucosa immediately after administration and leaks gradually into the lamina propria, resulting in visualization of the contour of the mucosal gland structure[3,4]. However, its dynamics has not been investigated in detail.

We have reported that pCLE images equivalent to those acquired employing intravenous fluorescein administration can be acquired by local mucosal application of fluorescein[5-7]. However, it has not been investigated whether or not pCLE images were acquired through the distribution of locally-applied fluorescein in the tissue similarly to that after intravenous administration.

In this study we examined whether the fluorescein locally applied on the gastric mucosal surface penetrates the mucosa tissue by histologically investigating the intramucosal distribution of fluorescein of the biopsy. In addition, it was compared with the distribution of intravenously administered fluorescein in the gastric mucosa to verify the validity of pCLE performed using local mucosal application of fluorescein.

CASE REPORT

Subject

The subject was a 39-year-old healthy male (author, Kouichi Nonaka). Before examination, written informed consent regarding gastrointestinal local mucosal application and intravenous administration of fluorescein was obtained. With respect to examination using pCLE and fluorescein administration, approval was obtained from the Ethics Review Board of our hospital.

pCLE and biopsy

Firstly, pCLE was performed without fluorescein administration in the subject, and one site of the probe-contacted mucosa in the lower gastric body was biopsied as a negative control.

For the local mucosal application of fluorescein, 0.1 mL of 10% fluorescein solution was prepared in advance and applied to the dye-spraying tube, so that the dye alternated with air (Figure 1A). Using the prepared dye-spraying tube, 2 drops of fluorescein were topically applied on the mucosa of the greater curvature of the lower gastric body of the subject, followed by pCLE (Figure 1B). One biopsy specimen of the applied mucosa was obtained after 1 min, and another specimen was biopsied from the same region 5 min after local mucosal application.

pCLE employing intravenous administration of 2.5 mL of 10% fluorescein solution was performed in the same healthy subject after 4 wk. One biopsy specimen was obtained from the mucosa of the greater curvature of the lower gastric body, which was the pCLE observation

region, one minute after fluorescein administration. One biopsy specimen was similarly obtained from the mucosa of the same region 5 min after administration.

The 5 biopsy specimens of the gastric mucosa were histologically investigated.

Preparation of frozen sections and observation of fluorescence

Each biopsied specimen was embedded in a cryoembedding medium (Tissue-Tek Optical Cutting Temperature Compound; Sakura Finetek Japan, Tokyo, Japan) immediately after biopsy and fresh-frozen in liquid nitrogen. Using a cryomicrotome (CM1860UV; Leica Microsystems, Wetzlar, Germany), frozen sections with a thickness of approximately 5 μm were prepared.

The prepared frozen sections were dried with cold air and rapidly dipped in pure water and 100% ethanol to remove the embedding medium. The sections were dried again with cold air, covered with a cover glass after adding 5 μL of 4'-6-diamidine-2'-phenylindole dihydrochloride (DAPI) of the HER2 FISH KIT (J17539, JOKOH, Tokyo, Japan), and immediately observed under a fluorescence microscope (BIOREVO BZ9000; KEYENCE, Osaka, Japan) at 20 times objective lens magnification (200 times). Images of green fluorescence were acquired at an excitation wavelength of 470 nm, which were merged with images of nuclei derived from DAPI fluorescence.

Probe-based confocal laser endomicroscopy

Regular round/oval foveolar with homogeneous epithelial cells were visualized on pCLE by both intravenous fluorescein administration and local mucosal application of fluorescein (Figure 2). Foveolar epithelial cells were dark on pCLE of both methods. The foveolar lumen was dark in the intravenous administration whereas it was bright in local mucosal application of fluorescein. Although more clear images were obtained in the intravenous administration, images in the local mucosal application of fluorescein were also of sufficient quality for evaluation. No difference of pCLE images was noted between 1 min and 5 min after fluorescein administration both in the intravenous administration and in the local mucosal application.

Histological assessment

In the negative control, no green fluorescence regarded as derived from the administered fluorescein was observed.

In the mucosal tissue obtained one minute after local mucosal application of fluorescein (Figure 3), green fluorescence was observed in the cytoplasm of fundic glandular cells. It was also observed in the foveolar lumen and inter-foveolar lamina propria, although it was noted at only a few sites. Green fluorescence was more frequently noted in the cytoplasm of fundic glandular cells of the biopsy tissue obtained 5 min after local mucosal application of fluorescein compared with that obtained one minute after local mucosal application of fluorescein, although no fluorescence was observed in the foveolar lumen and inter-foveolar lamina propria (Figure 4).

Intravenously administered fluorescein was also

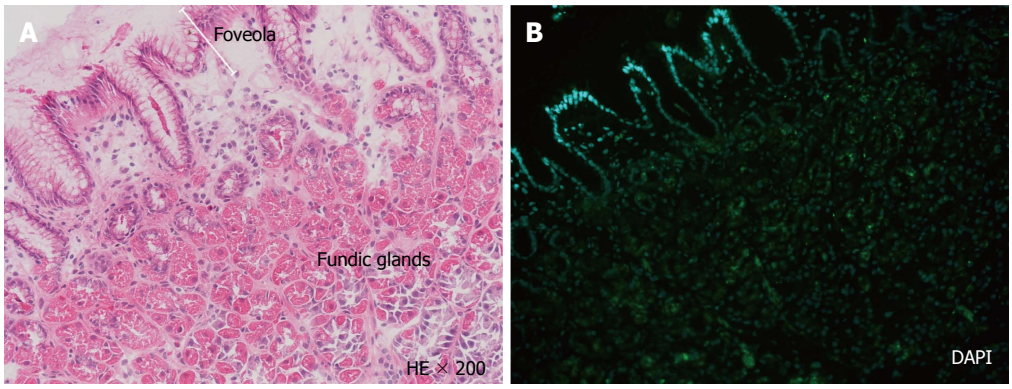

Figure 3 Histology one minute after local mucosal application of fluorescein. A: HE staining of biopsied tissue (original magnification × 200); B: Green fluorescence was observed in the cytoplasm of fundic glandular cells in the deep mucosa (non-HE staining; original magnification × 200). Although it was noted at only a few sites, green fluorescence was also observed in the glandular crypt lumens and lamina propria.

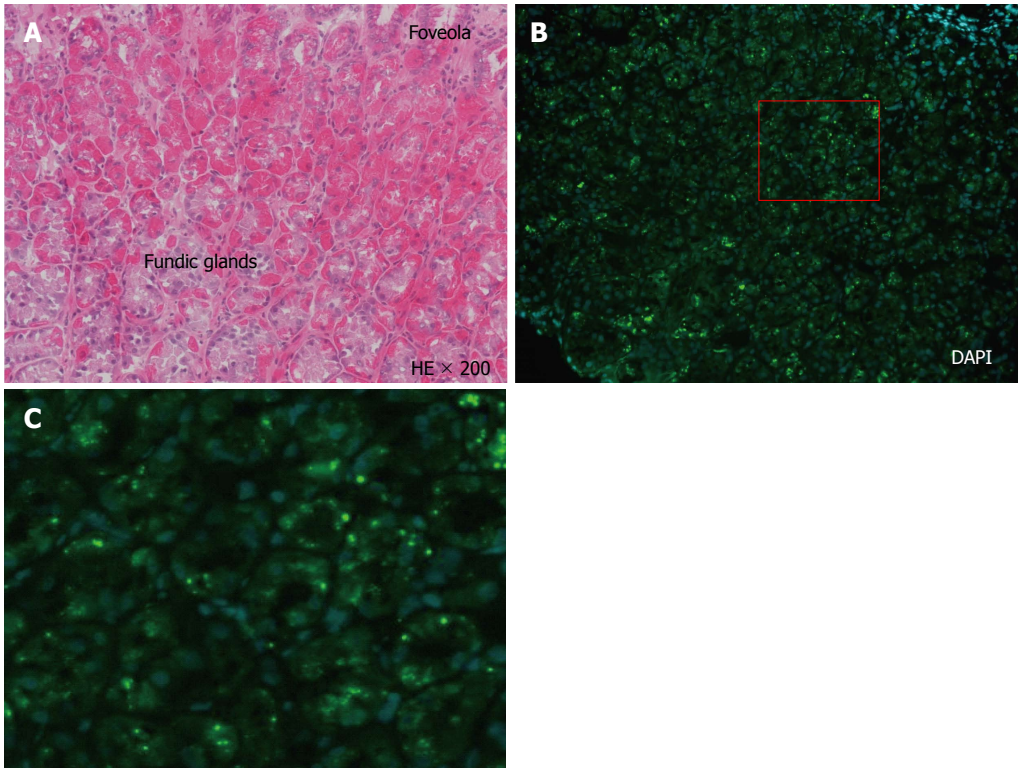

Figure 4 Histology 5 min after local mucosal application of fluorescein. A: HE staining of biopsied tissue (original magnification × 200); B: Fluorescence observed in the serial section of Figure 4A. Green fluorescence is observed in more fundic glandular cells compared with that at one minute (non-HE staining; original magnification × 200); C: The region in the red square is magnified. Green fluorescence is noted around the nuclei (light blue) of fundic glandular cells.

localized in the cytoplasm of fundic glandular cells, and fluorescence was more frequently noted in the biopsy tissue obtained 5 min after administration (Figure 5) than that obtained 1 min after administration (Figure 6), similar to the distribution after local mucosal application of fluorescein.

DISCUSSION

Confocal laser endomicroscopy has been spreading mainly in Europe, and its usefulness to differentiate cancer and non-cancer in the digestive tract and detect dysplasia, cancer in Barrett's esophagus, and inflammatory bowel disease has been reported over the last several years[8-16]. However, only a few studies on the distribution of fluorescein in the mucosa after intravenous administration[4,17], which is essential to acquire black-and-white images of confocal laser endomicroscopy, have been reported. Moreover, the penetration of fluorescein locally applied on the mucosa from the superficial layer has not previously been elucidated, which we investigated in this study.

In this study, in both fluorescein local mucosal application and intravenous administration, the fluorescence was observed in fundic glandular cells showing similar distribution, which suggests that the fluorescein locally

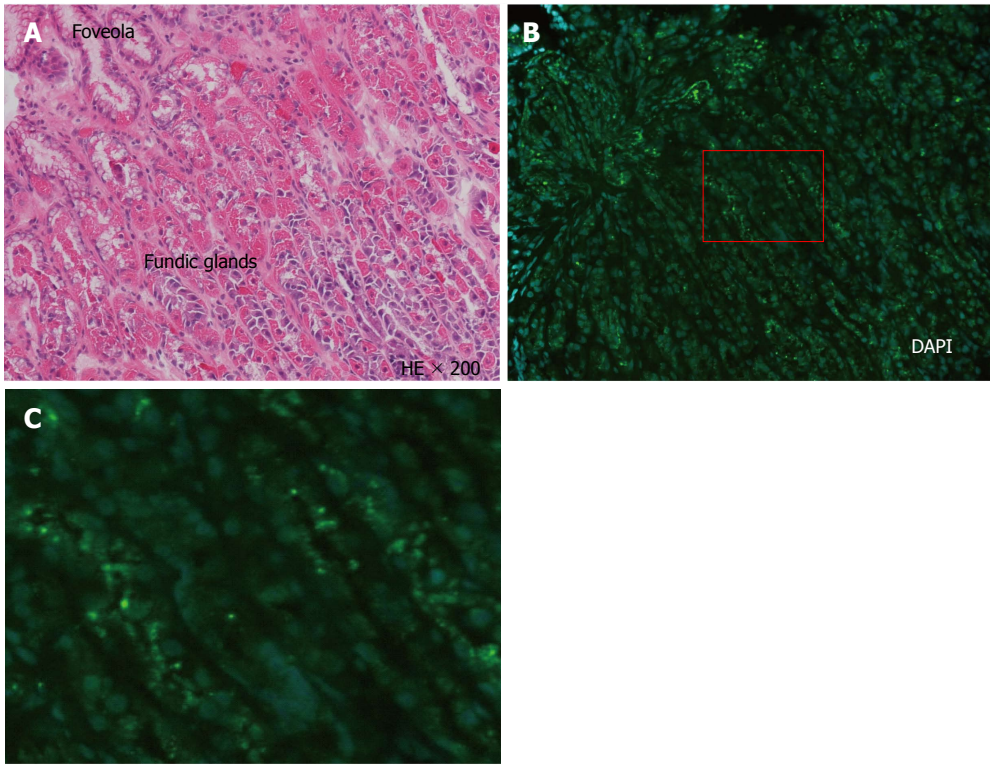

Figure 5 Histology 5 min after intravenous fluorescein administration. A: HE staining of biopsied tissue (original magnification × 200); B: Fluorescence observed in the serial section of Figure 5A. Green fluorescence in the cytoplasm of fundic glandular cells is more clearly observed compared with that at one minute (non-HE staining; original magnification × 200); C: The region in the red square is magnified. Green fluorescence is noted around the nuclei (light blue) of fundic glandular cells, suggesting that fluorescein was incorporated into the cytoplasm of the cells.

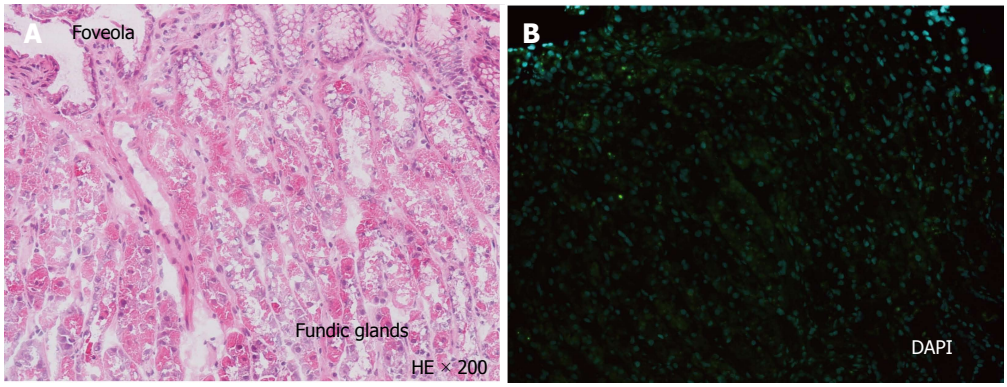

Figure 6 Histology one minute after intravenous fluorescein administration. A: HE staining of biopsied tissue (original magnification × 200); B: Fluorescence observed in the serial section of Figure 6A. Green fluorescence is scattered in the cytoplasm of fundic glandular cells (non-HE staining; original magnification × 200).

applied on the mucosal surface can be incorporated into the mucosal tissue within a short time as with the case for intravenous administration, supporting the validity to pCLE images using local mucosal application of fluorescein.

However, the region observed on pCLE is the foveolar area within the depth of 100 μm from the surface of the mucosa. In this region, just a small amount of fluorescence was observed in the foveolar lumen and inter-foveolar lamina propria of the biopsy sample obtained one minute after local mucosal application of fluorescein. When the air-dried frozen sections were observed without removing the cryoembedding medium in our preliminary experiment, intense fluorescence was noted around the tissue, which made it difficult to identify fluorescence in the tissue (Figure 7). Considering that fluorescein might readily dissolve in the cryoembedding medium (aqueous solution containing polyethylene glycol), the procedure was modified: the sections were dried with cold air and then rapidly dipped in pure water and 100% ethanol to remove the embedding medium surrounding the tissue. Although trying to remove the medium as rapidly as possible, it was plausible that fluorescein was eluted from the tissue while being passed through the solvents (pure water and alcohol).

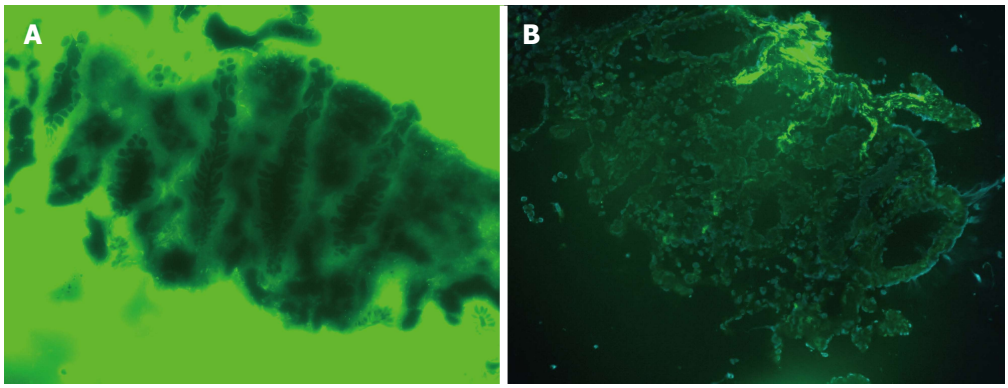

Figure 7 Fluorescence observed in tissue sections with or without removal of the cryoembedding medium. A: Lower gastric body mucosa tissue obtained 5 min after local mucosal application of fluorescein. When fluorescence is observed without removing the embedding medium, intense green fluorescence is noted around the tissue, and it is difficult to observe fluorescence in the tissue; B: Fluorescence in the tissue can be observed clearly after removing the embedding medium.

In addition, the procedure was performed in a room under fluorescent light, which possibly gave rise to additional attenuation of the fluorescence with time. The larger amount of fluorescein might have been present in the tissue before the procedure, and the detection of fluorescence at a low level in the foveolar area may be due to this condition.

Although the level was low, some fluorescence was observed in the foveolar lumen and inter-foveolar lamina propria, which corresponded to bright images of the foveolar lumens on pCLE after local mucosal application of fluorescein and suggested that fluorescein locally applied on the mucosal surface was incorporated into the lamina propria. In contrast, no fluorescence indicating the incorporation of fluorescein into the foveolar epithelium was confirmed, and this may correspond to dark images of foveolar epithelium on pCLE. Ji *et al*[17] reported that gastric epithelium with intestinal metaplasia was positive for fluorescein immunostaining, suggesting that fluorescein is incorporated into the epithelium, but goblet cells were negative. Fluorescein may not be readily incorporated into the foveolar epithelial cells, which have abundant intracytoplasmic mucus similar to goblet cells.

According to the study by Ji *et al*[17], the intercellular permeability of intact foveolar epithelia was low. However, if fluorescein is unlikely to be incorporated into the cytoplasm of foveolar epithelial cells, the locally applied fluorescein is may diffuse into the lamina propria through intercellular spaces of the foveolar epithelia, but it is also possible that it diffuses through the cell membrane and cytoplasm, and reaches the lamina propria without accumulating in the foveolar epithelia. Fluorescein for medical use is water-soluble sodium salt with a molecular weight of 376.27 and a negative charge. The cell membrane is mostly composed of a phospholipid bilayer containing various proteins and glycolipids. Since fluorescein sodium salt is negatively charged as are phospholipids of the cell membrane, repellence of the charge prevents the fluorescein from entering the cell membrane. However, fluorescein has both a hydrophilic region (negatively charged region) and a hydrophobic region corresponding to the lipid fraction, as the lipid bilayer of the cell membrane. This hydrophilic-hydrophobic balance is similar to that of the cell membrane lipid bilayer, which may enable fluorescein to pass through the cell membrane. On the other hand, regarding fundic glandular cells, it was suggested that the fluorescein does not simply pass through the cells, but also is actively incorporated into the cells from the lamina propria or gland lumen side and accumulates in the cells.

This study was performed with only normal gastric mucosa in one subject, so further investigation is necessary. However, it was confirmed that fluorescein locally applied on the gastric mucosal surface was distributed in the mucosa within a short time, validating that pCLE images can be acquired by local mucosal application of fluorescein.

COMMENTS

Case characteristics

A 39-year-old healthy male with no symptoms.

Laboratory diagnosis

All labs were within normal limits.

Imaging diagnosis

Regular round/oval foveolar with homogeneous epithelial cells were visualized on probe-based confocal laser endomicroscopy (pCLE) by both intravenous fluorescein administration and local mucosal application of fluorescein.

Pathological diagnosis

In the mucosal tissue obtained after local mucosal application of fluorescein, green fluorescence was observed in the cytoplasm of fundic glandular cells.

Related reports

Previously it was considered that CLE imaging requires intravenous injection of fluorescein. However, the acquisition of images just by applying a small volume of fluorescein onto the region of interest has been reported recently.

Term explanation

pCLE is a novel endoscopic procedure capable of observing gastrointestinal mucosa at 1000 times magnification in real time.

Experiences and lessons

It was confirmed that fluorescein locally applied on the gastric mucosal surface was distributed in the mucosa within a short time.

Peer-review

The presence of fluorescein in the mucosa was observed after local mucosal application of fluorescein, suggesting that pCLE images similarly to those after intravenous fluorescein administration can be acquired by local mucosal application of fluorescein.

Abstract

IgG4-related disease (IgG4-RD) is an immune-mediated fibroinflammatory disorder that can occur in almost all systemic organs and generally responds to corticosteroid treatment. We report a rare case of an IgG4-related intrapelvic mass lesion that responded to steroid therapy but caused a fistula between the sigmoid colon and bladder. A 71-year-old man was followed after treatment for hepatocellular carcinoma. Follow-up computed tomography (CT) incidentally depicted left hydronephrosis with an ill-demarcated intrapelvic mass lesion. This lesion was histologically diagnosed as IgG4-RD by open biopsy, and peroral steroid therapy was initiated. One month after starting steroids, a colovesical fistula was detected by follow-up CT. A colostomy and urethral catheterization were emergently performed. The patient recovered and the mass lesion was drastically minimized by the initiation of glucocorticoids; however, he still needs urethral catheterization. IgG4-RD develops in various systemic organs and generally responds well to steroids. Clinicians must be watchful for the complications of responses to corticosteroids, such as fistulization, when the mass lesion of IgG4-RD is adjacent to multiple luminal organs.

Key words: IgG4-related disease; Intrapelvic mass; Steroid therapy; Colovesical fistula; Colostomy; Urethral catheterization

Core tip: IgG4-related disease (IgG4-RD) is an immune-mediated fibroinflammatory condition that is effectively treated with glucocorticoids. Progression of this disease may cause serious complications or several symptoms; hence, glucocorticoid therapy is often inevitable. To date, critical adverse events caused by steroid treatment for IgG4-RD have seldom been reported. The current case report describes a rare, but severe, adverse event of colovesical fistula following a good response to glucocorticoids.

Yabuuchi Y, Matsubayashi H, Matsuzaki M, Shiomi A, Moriguchi M, Kawamura I, Ito I, Ono H. Colovesical fistula caused by glucocorticoid therapy for IgG4-related intrapelvic mass. *World J Clin Cases* 2015; 3(12): 1000-1004 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i12/1000.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i12.1000

INTRODUCTION

IgG4-related disease (IgG4-RD) is recognized as an autoimmune disorder that can affect multiple systemic organs through the formation of fibroproliferative and/or tumefactive lesions. Today, the disease concept and diagnostic criteria of IgG4-RD are globally widespread, and opportunities to diagnose and treat this disease are increasing. Patients with active IgG4-RD tend to demonstrate multiple systemic lesions[1,2], and therefore, often meet the indications for glucocorticoid therapy. Glucocorticoid is effective for most IgG4-related lesions; however, the period before a response to steroid is observed may vary depending on the affected organ or the degree of fibrosis[3]. A response is usually recognized in two weeks to a month following the initiation of steroids[1,4].

In general, corticosteroids improve the lesions or symptoms associated with IgG4-RD, while concerns regarding adverse effects of glucocorticoid therapy are well known and limited. We herewith report a patient who developed a colovesical fistula caused by glucocorticoid therapy to treat an IgG4-related intrapelvic mass and subsequently required surgical treatment.

CASE REPORT

The patient, a 71-year-old man with a history of hepatitis C and hepatocellular carcinoma, had been treated with interferon, percutaneous ethanol injection, transcatheter arterial chemoembolization, and radio frequent ablation, and had been continuously followed up with clinical images. Follow-up computed tomography (CT) incidentally revealed left hydronephrosis and an ill-demarcated mass lesion extending to the left lower ureter, left margin of the bladder, and sigmoid colon (Figure 1). ^{18}F-fluorodeoxyglucose positron emission tomography demonstrated strong uptake around the left lower ureter (SUV max: 19.0) (Figure 2). Colonoscopy showed a severe extrinsic compression at the sigmoid colon (Figure 3). Cystoscopy demonstrated whitish edematous protrusions at the upper left area of the bladder but the left ureteral orifice was intact. Under the suspected diagnosis of left-lower ureter cancer invading the adjacent organs, transurethral resection was performed for a histological diagnosis. Histology of the TUR specimens revealed intraepithelial papillary urothelial carcinoma (G1, low grade, pTa), which was not invasive, contradicting our previous diagnosis. An open biopsy was done for a conclusive diagnosis of the intrapelvic mass lesion. Histology of the biopsied material did not show cancerous tissue, but dense fibrous tissue with abundant lymphoplasmacyte infiltration. Immunohistochemistry by using mouse anti-human IgG4 monoclonal antibody in enzyme immunoassay revealed $\geqslant$ 10 IgG4 positive cells per high-power field (Figure 4), although the ratio

of IgG4/IgG positive cells was < 40%. Serum IgG4 was then examined and found elevated (190 mg/dL, normal range: 4.8-105 mg/dL). With these results, we diagnosed "Possible IgG4-RD", based on the comprehensive diagnosis criteria[5]. Glucocorticoid therapy was initiated with 40 mg/d of prednisolone and tapered in the standard pitch[6] to treat the hydronephrosis due to the IgG4-related mass lesion and subsequently recover renal function.

One month later, the patient visited the hospital for evaluation of his steroid response, but he had a continued moderate fever, diarrhea, and urine with a feces odor for a few days. CT demonstrated shrinkage of the intrapelvic mass lesion, as well as extraluminal air in the mass lesion and bladder (Figure 5). The laboratory findings showed leukocytosis (white blood cell: 21480/μL), thrombocytopenia (platelet: 3.4 × 10^4/μL), elevated C-reactive protein (14.87 mg/dL), and renal dysfunction (creatinine: 1.64 mg/dL). Large quantities of bacteria (*Escherichia coli* and *Enterococcus faecalis*, *etc.*) were detected in urine cultures, and fistulization between the urinary bladder and sigmoid colon with enteric bacterial infection of the mass lesion was confirmed. A percutaneous drainage was placed into the infected mass lesion, and colostomy was performed with urethral catheterization and antibiotic administration as emergent management. The patient gradually recovered and was discharged in two weeks. He has been in good health subsequently, and the intrapelvic mass has remained minimized with a maintenance dose of prednisolone (Figure 6). However, he has sometimes experienced urinary incontinence from the anus when the urethral catheter is occluded.

Eight months after steroid initiation with 5 mg/d of prednisolone, the screening cystoscopy revealed a polypoid lesion near the fistula. The recurrence of superficial bladder cancer was ruled out by a repeat TUR. This histology and response to glucocorticoid provided diagnostic confirmation[3,5,7]. Today, the remaining fistula is still visible with a cystoscope, so that the urethral catheter cannot be withdrawn and the artificial anus has been unclosed for nearly two years.

DISCUSSION

Standard therapy for IgG4-RD is peroral steroid therapy in the form of prednisolone initiated at a dose of 0.6 mg/kg with subsequent tapering[3,6,7]. Glucocorticoids are highly effective in treating IgG4-RD and a response to steroids can be seen in most systemic lesions within 2-4 wk as determined by clinical images[1,6]. The current case also responded well to standard glucocorticoid therapy; however, this response caused a fistula between the urinary bladder and sigmoid colon.

To date, severe complications have been described in

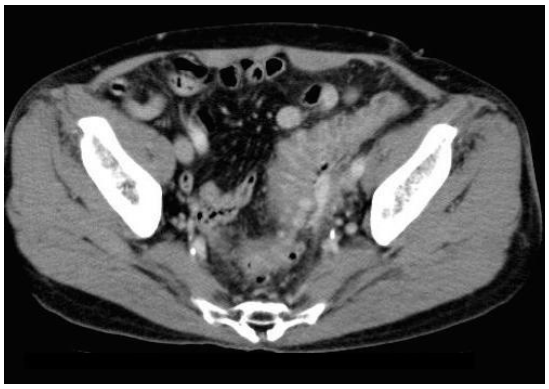

Figure 6 Computed tomography 6 mo after the initiation of glucocorticoid therapy. Computed tomography shows that the mass remains minimized.

many cases with IgG4-RD; however, these are related to the occurrence or progression of the disease, rather than adverse steroid responses. For example, complications of IgG4-RD have included clinical emergencies such as leptomeningitis with rapidly progressive cognitive decline, gastric-pericardial fistula, aortoduodenal fistula, stenosis of the coronary arteries, stenosis of the colon, and splenic haemorrhage[8-13]. A case of IgG4-related inflammatory pseudotumor of the urinary bladder causing a colovesical fistula, similar to the present case, has also been reported[14]. However, these complications are all caused by the progression of the disease and are not results of glucocorticoid therapy. To the best of our knowledge, based on a PubMed keyword survey, this is the first report of a severe complication due to a good response to corticosteroid therapy in a case of IgG4-RD.

A colovesical fistula can occur in various diseases. Common causes are colonic diverticula, inflammatory bowel disease, and carcinomas of the colon, urological, and gynecological organs. A gastrointestinal foreign body, trauma, and iatrogenic injuries are rare causes[15]. A colovesical fistula usually develops as a consequence of the progression of these diseases; however, fistulization rarely occurs in cases of malignancy treated with chemotherapy or radiation therapy[16]. Fistulas are thought to arise simply due to more rapid shrinkage and necrosis of the tumor compared with slow repair of the interstitial tissue. A similar explanation is speculated for the fistula formation observed in the current case.

Predicting the risk of the fistulization is difficult in cases with IgG4-RD. In the present case, the mass lesion was adjacent to multiple luminal organs. This condition might be one of the risk factors that led to fistulization. A widespread area affected by the stromal tissue, the level of inflammatory cell infiltration, and colonic diverticula might be also the risk factors. Earlier detection could increase the chance of a cure or prevention of severe complications.

After the initiation of steroids, we examined abdominal ultrasonography at two weeks and CT at one month, as the response to glucocorticoid can be usually obtained within this timeframe in cases with IgG4-RD[1,6]. Although long-term risk of complications by the accumulated radiation dose is a concern, CT is a suitable modality for the evaluation of the steroid response, colovesical fistula, and adjacent anatomical structures[17]. During the early period after the initiation of glucocorticoids, the IgG4-related mass lesions located at rare sites must be followed using a suitable image modality.

In conclusion, fistulization between the bladder and sigmoid colon occurred after glucocorticoid therapy in a case with IgG4-RD. An intrapelvic mass adjacent to multiple luminal organs, a wide range of spread of the mass lesion and the good response to glucocorticoids may have caused this severe complication. Early follow-up imaging as well as blood examination is necessary for the evaluation of the steroid response as well as the detection of complications arising in response to glucocorticoid treatment.

COMMENTS

Case characteristics

One month after the initiation of glucocorticoid therapy for IgG4-related disease, a 71-year-old man had a continued moderate fever, diarrhea, and urine with a feces odor for a few days.

Clinical diagnosis

The patient slightly had lower abdominal pain.

Differential diagnosis

Fistulization between the bladder and colon due to colonic diverticulitis, inflammatory bowel disease and carcinomas of the colon or urological organs.

Laboratory diagnosis

The laboratory findings showed leukocytosis, thrombocytopenia, elevated C-reactive protein and renal dysfunction, with large quantities of bacteria in urine cultures.

Imaging diagnosis

Computed tomography demonstrated shrinkage of the intrapelvic mass lesion, as well as extraluminal air in the mass lesion and bladder.

Treatment

A percutaneous drainage was placed into the infected mass lesion, and colostomy was performed with urethral catheterization and antibiotic administration.

Related reports

Fistulization have been described in some cases with IgG4-related disease, such as gastric-pericardial fistula and aortoduodenal fistula. However these are related to the progression of the disease.

Experiences and lessons

This case was a rare complication of IgG4-related disease due to the good response to glucocorticoid therapy. Early follow-up imaging is necessary for the evaluation of the steroid response as well as the detection of complications arising in response to glucocorticoid treatment.

Peer-review

This case report is interesting and well documented.

Abstract

A 66-year-old, interferon-ineligible, treatment-naive man who was diagnosed with chronic hepatitis C due to hepatitis C virus genotype 1b began combination therapy with daclatasvir and asunaprevir. On day 14 of treatment, hepatic reserve and renal function deterioration was observed, while his transaminase levels were normal. Both daclatasvir and asunaprevir were discontinued on day 18 of treatment, because the patient complained of dark urine and a rash on his trunk and four limbs. After discontinuing antiviral therapy, the abnormal laboratory finding and clinical manifestations gradually improved, without recurrence. Our case fulfilled the diagnostic criteria of probable drug reaction with eosinophilia and systemic symptom (DRESS) syndrome. Despite the 18-d treatment, sustained virological response 12 was achieved. Based on the clinical course, we concluded that there was a clear cause-and-effect relationship between the treatment and adverse events. To our knowledge, this patient represents the first case of probable DRESS syndrome that includes concomitant deterioration of hepatic reserve and renal function due to combination therapy with daclatasvir and asunaprevir, regardless of normalization of transaminase levels. Our case suggests that we should pay attention not only to the transaminase levels but also to allergic symptoms associated with organ involvement during combination therapy with daclatasvir

and asunaprevir.

Key words: Hepatitis C; Daclatasvir; Renal dysfunction; Asunaprevir; Hepatic reserve deterioration

Core tip: Oral combination therapy with daclatasvir and asunaprevir for chronic hepatitis C demonstrates a relatively favorable safety profile. Although the incidence of hyperbilirubinemia, hypoalbuminemia, and a decreased prothrombin activity have been reported, as well as renal damage, concomitant deterioration of hepatic reserve and renal function without transaminase elevations have not been reported. We observed probable drug reaction with eosinophilia and systemic symptom syndrome, including concomitant deterioration of hepatic reserve and renal function due to the combination therapy, regardless of normalized transaminase levels. Thus, our case highlights the importance of paying attention not only to transaminase levels but also to the allergic symptoms associated with organ involvement during combination therapy.

Probable case of drug reaction with eosinophilia and systemic symptom syndrome due to combination therapy with daclatasvir and asunaprevir. *World J Clin Cases* 2015; 3(12): 1005-1010 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i12/1005.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i12.1005

INTRODUCTION

Combination therapy with daclatasvir and asunaprevir has been approved as oral antiviral therapy for chronic hepatitis C due to hepatitis C virus (HCV) genotype 1b. This new type of therapy resulted in a sustained virological response (SVR) rate of over 80% after 24 wk of therapy for chronic hepatitis C patients with genotype 1b[1,2]. In Japan, combination therapy with daclatasvir and asunaprevir has been recommended for interferon-ineligible patients based on the Japan Society of Hepatology guidelines for managing HCV infection[3].

One of the most frequent adverse events during combination therapy with daclatasvir and asunaprevir is elevated alanine aminotransferase (ALT) levels. In an open-label trial of oral antiviral therapy conducted in Japan[1,4,5], ALT elevations occurred in 17.6% of the patients treated with a combination of daclatasvir and asunaprevir. The incidence of hyperbilirubinemia, hypoalbuminemia or prothrombin activity decrease, which reflect deteriorated hepatic reserve[6-8], were 3.9%, 1.2% or 0.8%, respectively[1,4,5]. The incidence of renal damage was 0.4%[1,4,5]. However, concomitant deterioration of hepatic reserve and renal function without transaminase elevations has not been reported. Here, we report a case of chronic hepatitis C with concomitant deterioration of hepatic reserve and renal function that fulfilled the diagnostic criteria of probable drug reaction with eosinophilia and systemic symptom (DRESS) syndrome[9] due to combination therapy with daclatasvir and asunaprevir. We got written informed consent from the patient in advance.

CASE REPORT

A 66-year-old man, diagnosed with chronic hepatitis C (genotype 1b) at the age of 50, was started on a scheduled 24-wk course of daclatasvir and asunaprevir for elevated transaminase levels. The patient suffered from a duodenal ulcer, bronchial asthma, hypertension and cerebral hemorrhage. He had undergone antihypertensive therapy with nifedipine and olmesartan for 5 years. These drugs were maintained throughout the antiviral treatment. No relevant family history was noted. The patient did not have a past history or predisposing factors for liver disease, except for chronic hepatitis C. He had no history of drug allergies, although he did have bronchial asthma. Combination therapy with daclatasvir (60 mg once daily) and asunaprevir (100 mg twice daily) was selected because the patient was both interferon-ineligible and interferon-naïve due to his past history of hypertension and cerebral hemorrhage. A V170I mutation in the NS3 lesion was detected by direct sequencing prior to the therapy. Before beginning therapy, the following measurements were noted: serum ALT, 57 IU/L; total bilirubin, 0.5 mg/dL; albumin, 4.1 g/dL; creatinine, 0.7 mg/dL; prothrombin activity, 102%; total white cell count, 5000/μL (eosinophils 150/μL); platelet count, 11.1 × 10^4/μL; C-reactive protein, < 0.1 mg/dL, and HCV RNA, 5.9 Log IU/mL.

On day 14 of treatment, the patient's laboratory findings showed concomitant deterioration of hepatic reserve and renal function, without any subjective symptoms. Although the ALT level had decreased to 22 IU/mL, serum total bilirubin had worsened to 1.9 mg/dL, albumin to 3.3 g/dL, creatinine to 1.4 mg/dL, prothrombin activity to 66.4%, total white cell count to 12130/μL (eosinophils 121/μL), platelet count to 7.9 × 10^4/μL and C-reactive protein to 3.5 mg/dL (Table 1). Abdominal ultrasonography revealed splenomegaly, which was not present before the therapy. There was no evidence of biliary obstruction. Daclatasvir and asunaprevir were continued. The patient complained of headache, dark urine and a partly fused erythematous rash on his trunk and four limbs on day 18 of treatment. In view of the skin lesions, a dermatologist diagnosed the skin rash as a drug eruption or untypical urticarial lesion (Figure 1), although the patient's vital signs were normal: temperature 36.5 ℃, blood pressure 121/58 mmHg and heart rate 72/min. Both daclatasvir and asunaprevir were discontinued based on the dermatologist's advice and the patient's request, and an antihistamine was administered for 2 wk. When observed on day 21 of the initiation of treatment,

[1]Hyaluronic acid and collagen-4 were measured before antiviral therapy. Drug resistant variants in the NS3 and NS5A regions were measured by invader method; [2]D168E and Y93H mutations were not detected by direct sequencing. Only V170I was detected by direct sequencing. γ-GTP: γ-glutamyl transpeptidase; Ab: Antibody; AFP: α-fetoprotein; Ag: Antigen; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AMA: Antimitochondrial antibody; ANA: Antinuclear antibody; ASMA: Antismooth muscle antibody; AST: Aspartate aminotransferase; BNP: Brain natriuretic polypeptide; BUN: Blood urea nitrogen; ChE: Cholinesterase; CMV: Cytomegalovirus; CPK: Creatine phospho kinase; CRP: C-reactive protein; D-Bil: Direct bilirubin; DLST: Drug-induced lymphocyte stimulation test; EBNA: Epstein–Barr virus nuclear antigen; EBV: Epstein-Barr virus; fT3: Free triiodothyronine; fT4: Free thyroxine; HAV: Hepatitis A virus; Hb: Hemoglobin; HBc: Hepatitis B virus core; HBs: Hepatitis B virus surface; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HEV: Hepatitis E virus; HHV: Human herpes virus; HSV: Herpes simplex virus; Ig: Immunoglobulin; INR: International normalized ratio; LDH: Lactic dehydrogenase; PIVKA: Protein induced by vitamin K absence or antagonist; Plt: Platelets; PT: Prothrombin time; RBC: Red blood cell; RF: Rheumatoid factor; T-Bil: Total bilirubin; T.Chol: Total cholesterol; TP: Total protein; TSH: Thyroid stimulating hormone; UA: Uric acid; WBC: White blood cell.

the clinical manifestations had disappeared, and the laboratory findings had returned to normal ranges, except for the serum albumin (3.4 g/dL), prothrombin activity (74.5%) and eosinophilia (2673/μL) levels. These measurements also returned to normal ranges, until day 35 of the initiation of treatment. On day 42 of the initiation of treatment, molecular biological analysis detected Epstein-Barr virus (EBV) DNA but not human herpesvirus (HHV)-6 and HHV-7 DNA in the serum. Although daclatasvir and asunaprevir were discontinued on day 18 of treatment, SVR 12 was achieved (serum HCV RNA was negative after 12 wk of treatment). The clinical course of our case and the time course for the critical laboratory values are shown in Figure 2 and Table 2, respectively.

DISCUSSION

Here, we described a case of deteriorated hepatic reserve and renal function during combination therapy with daclatasvir and asunaprevir, regardless of normalized transaminase levels at the development of the symptoms.

Table 2 Time course of critical laboratory values

Figure 1 Skin rash on the patient's trunk on day 18 of the treatment with daclatasvir and asunaprevir.

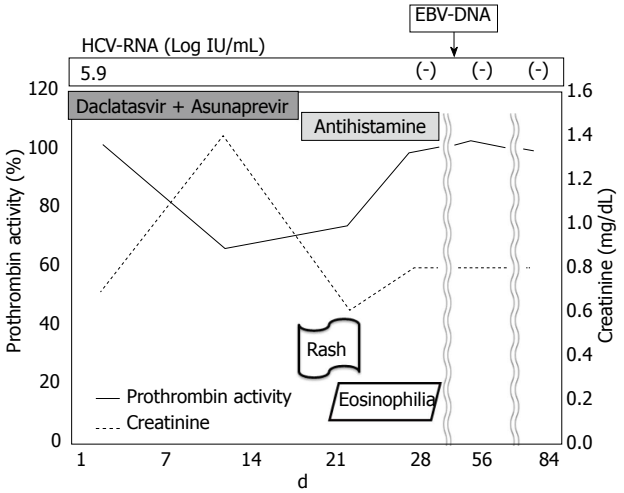

Figure 2 Clinical course of a patient with concomitant deterioration of hepatic reserve and renal function due to combination treatment with daclatasvir and asunaprevir. HCV: Hepatitis C virus; EBV: Epstein-Barr virus.

The decreased cholinesterase and total cholesterol values were also consistent with deteriorated hepatic reserve[10,11]. Drug-induced liver injury generally results in abnormal biochemical liver tests, including transaminase or alkaline phosphatase[12]. In our case, the normal values of transaminase and alkaline phosphatase did not fulfill the diagnostic criteria of drug-induced liver injury. However, the clinical course was similar to that of drug-induced liver injury, key elements of which are drug exposure preceding the onset of liver injury, the exclusion of underlying liver disease, including obstructive jaundice, and improvement after discontinuing the drug[12,13]. Because there have been case reports showing severe liver injury or hepatic decompensation during the therapy of direct-acting antivirals, including telaprevir[14] or simeprevir[15], daclatasvir or asunaprevir may also induce liver injury, with deteriorated hepatic reserve.

The present case also demonstrated renal damage and rash on the trunk and four limbs, which were accompanied by inflammatory reaction and eosinophilia after starting therapy, thereby indicating the possibility of drug-induced hypersensitivity syndrome (DIHS). The patient's atopic background, including bronchial asthma, was also a risk factor of drug allergy[16]. In fact, a case associated with DIHS during combination therapy with daclatasvir and asunaprevir has been reported[17]. The

renal damage was not due to dehydration or urinary tract infection; thus, organ involvement associated with a series of symptoms was considered. Rapidly enlarging rash and deteriorating hepatic reserve, as well as eosinophilia and EBV reactivation[18], are the typical hallmark features of DIHS, which might be responsible for the pathophysiology in our case. However, the lack of fever, lymphadenopathy, and HHV-6 reactivation were inconsistent with DIHS. Thus, our case did not fulfil the diagnostic criteria of even atypical DIHS, according to the diagnostic criteria of DIHS[19]. During this therapy, our case was fundamentally different from the case associated with DIHS[17] because our patient did not have lymphadenopathy, fever, ALT elevation but had other organ involvement, such as renal damage.

However, as a severe, adverse, drug-induced reaction, DRESS syndrome is similar to DIHS. DRESS syndrome is characterized by a delayed onset, usually 2-6 wk after the initiation of drug therapy, as well as the possible persistence or aggravation of symptoms, despite the discontinuation of the causative drug; severe skin eruption, fever, hematologic abnormalities (eosinophilia or atypical lymphocytes) and internal organ involvement are also associated with DRESS syndrome. In this case, the patient showed eosinophilia (more than 1500/μL, with a DRESS score of 2), and skin rash (more than 50%), which were indicative of DRESS; in addition, there was liver and kidney involvement and the absence of other potential causes (each with a DRESS score of 1). There were no enlarged lymph nodes or atypical lymphocytes, and the skin biopsy was not performed, thus each received a DRESS score of 0, and high fever was not observed (less than 38.5 ℃, with a DRESS score of -1). However, the resolution within 15 d is uncertain. If we estimate this evaluation item at a score of -1, the score of our case was at least 5; therefore, our case was considered to be a probable case, according to the RegiSCAR scoring system[9]. The possible mechanisms of the DRESS syndrome are detoxification defects, which can lead to reactive metabolite formation and subsequent immunological reactions, slow acetylation, and reactivation of human herpesvirus, including EBV, HHV-6 and -7[9].

Both daclatasvir and asunaprevir are metabolized by CYP3A, and asunaprevir is a substrate of OATP1B1[20]. CYP3A activity and OATP1B1 activity are known to be decreased in advanced liver disease and cirrhosis[21,22]. Prior to antiviral therapy, the platelet count, hyaluronic acid and type Ⅳ collagen levels suggested hepatic fibrosis in our case[23,24]. Moreover, nifedipine (one of the concomitant drugs) is metabolized by CYP3A and, thus, may compete against daclatasvir and asunaprevir as the substrate. Another concomitant drug, olmesartan, is a substrate of OATP1B1 and, thus, may compete against daclatasvir and asunaprevir as the substrate. Drug interactions may also increase the blood concentration of daclatasvir and asunaprevir. Therefore, higher blood levels of daclatasvir or asunaprevir (based on low hepatic metabolic ability) might cause unexpected adverse events. Indeed, in our case, the achievement of SVR12 supported this hypothesis. As a combination therapy, daclatasvir and asunaprevir are also approved in compensated cirrhosis patients (Child-Pugh A), and careful observation is particularly needed for these patients.

Based on the decreased prothrombin activity and platelet count, disseminated intravascular coagulopathy (DIC) was a differential diagnosis in our case. Unfortunately, we did not measure the fibrin degradation products, D-dimer, and fibrinogen levels at the onset of the deteriorated laboratory data. According to the ISTH Diagnostic Scoring System for DIC, the score in our case was considered to be 5, at most. Thus, we think that overt DIC was a possible but not the probable diagnosis.

In summary, we experienced an unusual case of probable DRESS syndrome due to combination therapy with daclatasvir and asunaprevir. We should pay attention not only to the transaminase levels but also to the allergic symptoms associated with organ involvement during combination therapy with daclatasvir and asunaprevir.

COMMENTS

Case characteristics

Dark urine and a rash on his trunk and four limbs.

Clinical diagnosis

Drug reaction with eosinophilia and systemic symptom (DRESS) syndrome due to combination therapy with daclatasvir and asunaprevir.

Differential diagnosis

The ISTH Diagnostic Scoring System for disseminated intravascular coagulopathy and diagnostic criteria of drug-induced hypersensitivity syndrome.

Laboratory diagnosis

Blood drawing and urine collection showed that hepatic reserve and renal function deterioration, eosinophilia and dark urine, respectively.

Imaging diagnosis

Inspection of skin and photographic evidence of a skin rash.

Treatment

Both daclatasvir and asunaprevir were discontinued and an antihistamine was administered for 2 wk.

Related reports

The reference #1 for the understanding of combination therapy with daclatasvir and asunaprevir, and #9 for the understanding of The DRESS syndrome.

Term explanation

DRESS syndrome: DRESS syndrome is characterized by a delayed onset, usually 2-6 wk after the initiation of drug therapy, as well as the possible persistence or aggravation of symptoms, despite the discontinuation of the causative drug; severe skin eruption, fever, hematologic abnormalities (eosinophilia or atypical lymphocytes) and internal organ involvement are also associated with DRESS syndrome.

Experiences and lessons

We should pay attention not only to the transaminase levels but also to the

allergic symptoms associated with organ involvement during combination therapy with daclatasvir and asunaprevir.

Peer-review

It is a very interesting and well explained case worth sharing with the scientific community.

Abstract

Burkitt's lymphoma (BL) is an aggressive form of non-Hodgkin's B-cell lymphoma with three variants namely endemic, sporadic, and immunodeficiency-associated types. It is endemic in Africa and sporadic in other parts of the world. While the endemic form is widely reported to occur in early childhood and commonly involves the jaw bones, the sporadic form typically presents as an abdominal mass. This presentation reports a rare case of sporadic form of BL clinically manifesting as a generalized gingival enlargement in an immunocompetent adult male which demonstrated an aggressive behavior. The patient reported with a prominent anterior gingival swelling of 6 mo duration which slowly enlarged in size and associated with multiple lymph node involvement. Microscopic examination of the lesion using H, E and immunohistochemical diagnosis confirmed the diagnosis as BL. The patient succumbed to the disease before any therapy could be instituted. Since a wide array of causes can be attributed to gingival enlargements, it is necessary to consider malignancies as one of the important differential diagnosis so as to facilitate the need for appropriate diagnosis and prompt treatment.

Key words: Lymphoma; Diagnosis; Differential; Non-Hodgkin's; Gingival overgrowth; Prognosis; Pathology; Oral; Immunohistochemistry

Core tip: Burkitt's lymphoma (BL) is an aggressive form of non-Hodgkin's B-cell lymphoma with three variants namely endemic, sporadic, and immunodeficiency-associated types. It is endemic in Africa and sporadic in other parts of the world. We report a rare case of sporadic BL presenting as generalized gingival enlargement. The purpose of this case report is to illustrate the fact that gingival enlargements may be caused by any benign non-neoplastic lesions or aggressive malignancies like BL and bespeaks the need for prompt recognition and life-saving referral by the dental practitioner.

INTRODUCTION

Lymphomas are malignant neoplasms of lymphocyte cell lines and ranks second to squamous cell carcinoma in frequency of occurrence in head and neck. They are of two types: Hodgkin's (HL) and Non-Hodgkin's (NHL). HL often presents as a nodal disease with predilection for head and mediastinal nodes. NHL are heterogenous group of neoplasms arising primarily within the lymph nodes but up to 24%-40% cases occur in extra nodal sites such as gastrointestinal tract, skin, bone and Waldeyer's ring[1].

Burkitt's lymphoma (BL) is an aggressive form of non-Hodgkin's B-cell lymphoma that is endemic in Africa and sporadic in other parts of the world. It is usually diagnosed in children and young adults but rarely in middle-aged adults. The endemic form typically involves the mandible, maxilla, and abdomen. BL of orofacial region typically occurs in the jaw bones associated with tooth mobility, dental pain and jaw expansion. Sudden and unexpected development of life threatening complications such as airway and abdominal obstruction and acute renal failure has been reported with BL[2]. In contrast, the sporadic form commonly presents as an abdominal mass involving the mesenteric lymph nodes or ileocecal region. Jaw involvement occurs in only a small number of sporadic cases[3].

A wide range of local and systemic lesions may manifest in the form of gingival enlargements. The most common cause occurs secondary to prolonged exposure to dental plaque resulting as a consequence of poor oral hygiene[4]. Other causes include drug induced enlargement; conditioned enlargements secondary to pregnancy, puberty, vitamin C deficiency; idiopathic enlargements and those associated with chronic microbial infections. While majority of the causes are benign and non-neoplastic in nature, malignant neoplasms also at time manifest in the form of gingival enlargements. Gingival enlargement is an important manifestation of malignancies like leukemia and lymphoma encountered by a dental specialist[5]. In the oral cavity lymphomas of the NHL type occurs as a primary disease or in conjunction with disseminated disease. All the variants of NHL occur in older patients except BL which usually occurs in children. The patient may present with nonspecific pain parasthesia, bony swelling with eventual perforation and soft tissue enlargement[6].

The present article reports a sporadic form of BL in an imuunocompetent adult male manifesting with atypical clinical presentation primarily involving the oral soft tissue.

CASE REPORT

A 38-year-old male patient reported to Oral Pathology clinic at our center for evaluation of an oral mass. Patient's chief complaint was painful swelling in the anterior gingiva with difficulty in eating. He noticed the swelling 6 mo back in the upper anterior gingiva which progressively increased in size and gradually involved the entire gingiva of both the arches. Patient visited a local dentist and oral prophylaxis was performed. No clinical changes were evident post prophylaxis and the lesion attained the present size within seven days. The patient's medical and dental history was insignificant. Personal history included regular tobacco chewing along with lime 5-6 times a day for the past 7-8 years accompanied with occasional alcohol consumption.

On extra-oral examination mild facial asymmetry with elevation of upper lip was noted. No abnormalities were detected on TMJ examination. Multiple, ipsilateral, nontender, matted, submandibular lymph nodes of approximate size 2.5 cm^2 along with superficial cervical lymph nodes of approximate 1.5-2 cm^2 were palpable on right side. Intra oral examination revealed generalized diffuse enlargement of both maxillary and mandibular gingiva. The swelling was particularly prominent in the anterior maxillary region involving both the palatal and labial gingiva extending from right maxillary lateral incisor to left maxillary lateral incisor, of size 3 cm × 3 cm, covering 2/3 of the crown portion of the incisors (Figures 1 and 2). The maxillary central incisors were displaced. The anterior lesion possessed smooth, shiny, non-stippled surface and was red in color. The other areas were red, edematous, stippled with non ulcerated surface. On palpation the texture was soft with bleeding in few areas and fibrous in others. There was no evidence of pulsation or thrill. Generalized Grade 1 mobility of the teeth was present. Oral hygiene status of the patient was poor. A provisional diagnosis of human immunodeficiency virus (HIV) associated gingival enlargement or neoplastic gingival enlargement was considered.

Orthopantamographic examination revealed a generalized horizontal alveolar bone loss. The mass was primarily located in the soft tissues. No other bony changes related to the swelling were observed.

Routine blood investigation was performed and all parameters were within normal limits. ELISA and Western blot were negative for HIV. Peripheral blood smear stained with Leishman-Romanowsky stain showed atypical lymphocytes with pale cytoplasm and nuclei at the periphery with coarse chromatin and multiple nucleoli (Table 1).

The light microscopic examination of the H and E stained tissue section under low power magnification showed a dense infiltrate of monotonous appearing darkly stained round cells, which appeared to be of lymphoid origin, with minimal stroma in the submucosal region. On a higher magnification the tumor cells were homogenous in size and shape with round to oval intensely basophilic nuclei and minimal cytoplasm. They were separated by thin fibrous septae with scattered large pale staining macrophages resembling starry sky pattern. The neoplastic cells showed nuclei with coarse chromatin and several nucleoli indicating a high mitotic index. Microscopically the morphological picture was

Figure 1 Generalized gingival enlargement with prominent swelling in the anterior maxilla.

Table 1 Details of lab investigations

Test	Values
HB	14.1 g/dL
RBC	5.1 million/mm^3
Neutrophils	26
Lymphocytes	41
Eosinophils	4
Monocytes	3
Abnormal cells	26
Platelet count	23000
HIV	Negative
HBs Ag	Negative

RBC: Red blood cell; HIV: Human immunodeficiency virus.

Table 2 Immunohistochemical expression of various markers in the present case

Marker	Expression	Interpretation
LCA	Diffusely positive	Suggestive of lymphoma
Cytokeratin	Negative	Excludes undifferentiated carcinoma
MPO	Negative	Ruled out granulocytic origin
Tdt	Negative	Rules out blast cell origin
CD3	Positive in scattered T cells	Excludes T-lymphocyte predominance
CD20	Focally positive	Indicates mature cell origin
CD10	Positive	Indicative of B-cell origin
CD138	Negative	Excludes plasma cell origin
MIB 1	Positive (almost 100%)	Indicative of aggressiveness

consistent with NHL. Based on the histopathological findings a diagnosis of NHL probably BL was made (Figure 3).

Immunohistochemical (IHC) analysis was performed with a panel of antibodies to confirm the diagnosis (Table 2). A negative cytokeratin staining along with diffuse positivity of LCA confirmed the lymphoid origin. Granulocytic origin was ruled out by MPO negativity. CD3 positivity in scattered cells revealed that the cells were not of T-cell lineage. The origin of B cells was confirmed with CD10 positivity. Tdt was negative which indicated the presence of mature cells and not blast cells. CD 20 was focally positive which confirmed the presence of mature B cells. MIB 1 was > 95% positive which confirmed increased DNA synthesis and increased mitotic activity. Plasma cell neoplasms were ruled out on CD 138 negativity.

The histopathological picture along with IHC findings confirmed the diagnosis of BL.

The patient's condition deteriorated with the platelet count falling below 10000 within few days and he succumbed to the disease.

DISCUSSION

A wide range of etiological factors are responsible for gingival enlargements. They may result from acute or chronic inflammatory changes, systemic diseases such as Wegener's granulomatosis[7] tuberculosis and sarcoidosis or neoplastic enlargements which may clinically mimic inflammatory enlargements[8]. Malignant neoplasms of epithelial origin are more common in gingivobuccal area[9] and are to be primarily considered followed by leukemia[6]. The present case manifested in the form of gingival enlargement with aggressive behavior and poor clinical outcome.

Lymphoma is a malignant neoplasm of lymphocytic cell lines and includes two clinical types namely HL and NHL lymphoma. HL often presents as a nodal disease with predilection for head, neck and mediastinal lymph nodes. NHL is a heterogenous group of neoplasms arising primarily within the lymph nodes but up to 24%-40% cases occur in extra nodal sites[1]. Oral lesions are often a component of disseminated disease process that may involve regional lymph nodes or may at times represent the primary extra nodal form of the disease[10]. Isolated oral lymphoma is extremely rare and oral NHL in Indian sub population is more aggressive compared with western population[11].

BL is an aggressive childhood to early adulthood variant of NHL which is endemic in Africa and is often associated with Epstein-Barr virus (EBV). Majority of the endemic form occurs in children 5 years or lesser[12],

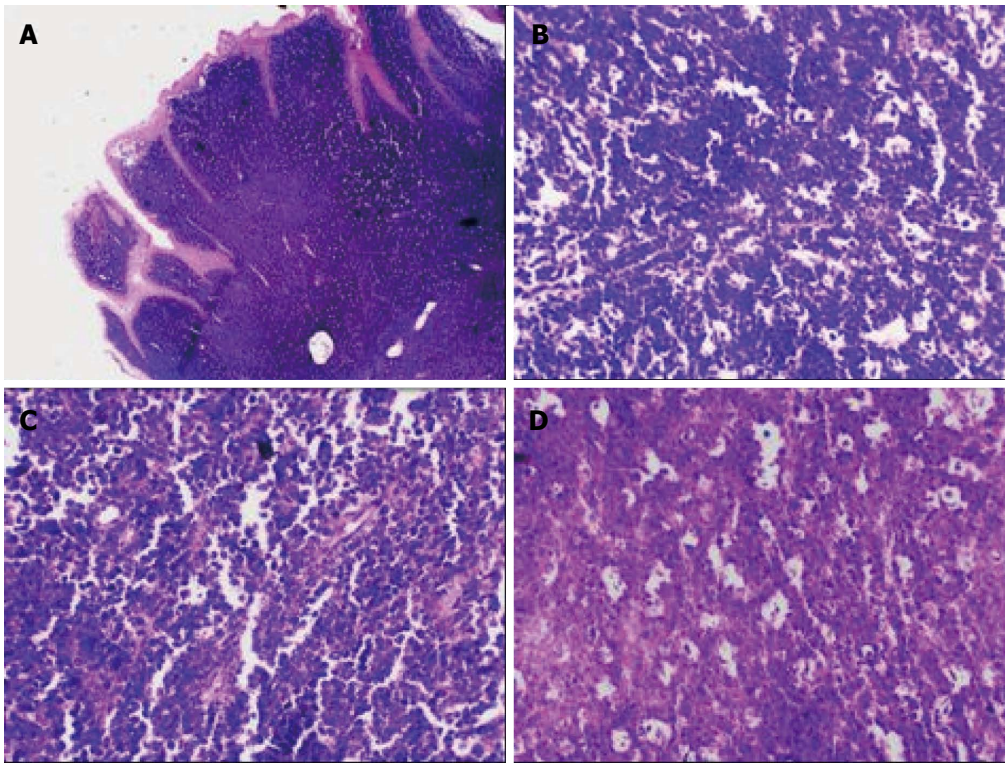

Figure 3 Microscopically the morphological picture. A: Monotonous population of basophilic round cells with minimal stroma beneath the surface epithelium (4 ×); B: Homogenous tumor cells with basophilic nuclei and minimal cytoplasm separated by thin fibrous septa (10 ×); C: Tumor cells showing coarse chromatin and multiple nucleoli indicating high mitotic index (10 ×); D: Macrophages with foamy cytoplasm are seen scattered amongst tumor cells (10 ×).

suggesting a stimulatory effect from the growth factors associated with jaw or tooth development[13]. The sporadic form has no geographic predilection and most commonly develops in adults as an abdominal mass[14]. BL of orofacial region typically occurs in the jaw bones associated with tooth mobility, dental pain and jaw expansion. Sudden and unexpected development of life threatening complications such as airway and abdominal obstruction and acute renal failure has been reported with BL[2]. BL affecting the gingival soft tissue only, has been occasionally reported in the literature while the present article present an unique case with diffuse enlargement involving both maxillary and mandibular gingiva.

BL is classified as a highly aggressive peripheral B cell tumor and demonstrating the highest proliferation rate of any neoplasms in humans, with a potential doubling time of 24 h and a growth fraction of nearly 100%[15]. It is further classified morphologically by WHO into classical BL and two variants namely BL with plasmacytoid differentiation and atypical Burkitt's like lymphoma[16]. All cases of BL show characteristic translocation between IgH locus on either chromosome 14/2/22 and the *c-MYC* gene on chromosome 8. An increase in c-Myc expression results from the translocation. This c-MYC dysregulation seems to be the defining abnormality that eventuates into BL[17].

The microscopic features of typical BL shows tumor cells that are monotonous, intermediate sized with round nuclei containing coarse chromatin, multiple small nucleoli admixed with tingible body macrophages creating starry-sky pattern visible at low power. Mitotic and apoptotic activity are typically a prominent feature. Expression of pan B-cell markers as well as Bcl-6 and CD-10 suggests a germinal centre origin for the tumor cells[16]. Histologically oral BL has to be differentiated from diffuse large B-cell lymphoma (DLBCL) and plasmablastic lymphomas (PBL). DLBCL is predominant variant in oral cavity and this is explained by its proclivity to present at single extra nodal site[18]. The characteristic microscopic feature of PBL is a diffuse sub mucosal proliferation of monomorphic large sized tumor cells with deep ulceration of the overlying mucosa. PBL is characterized by a diagnostic triad of predilection for gingivobuccal complex mucosa, classical plasmablastic morphology with lack of neoplastic plasma cells and a limited histochemical panel including a high Mib-1 index[19].

This paper presents a unique sporadic case of BL in a HIV adult male with the oral lesion limited to the gingival soft tissue only without involvement of the jaw bones. Diffuse involvement of gingiva on both the arches along with rapid growth showed the aggressiveness of the lesion. This lesion has clinical characteristics that mimicked a variety of other aggressive orofacial pathologies including malignant neoplasms and illustrates the inherent difficulty in diagnosis based on the lesion's uncharacteristic clinical appearance. Biopsy and histopathological examination of the tissue with immunohistochemistry was mandatory to arrive at a diagnosis.

Gingival enlargement is a common pathology in

the general population caused by a variety of local and systemic factors. While plaque induced inflammation is the most important cause, enlargement can also be induced by non-neoplastic and neoplastic factors of systemic origin. The clinician can often diagnose the cause of enlargement by careful history, by location and by clinical presentation. It is imperative that the clinician maintain a high degree of suspicion and act promptly in lesions with unusual appearance and behavior. A detailed investigation including biopsy is mandatory to correctly diagnose and treat such lesions. Our case reported some unusual presentation of gingival involvement secondary to malignancy and thus highlights the importance of considering such lesions in the differential diagnosis of gingival enlargements.

COMMENTS

Case characteristics

A 38-year-old male patient reported with a chief complaint of painful swelling in the upper anterior gingiva with difficulty in eating since 6 mo.

Clinical diagnosis

Human immunodeficiency virus associated gingival enlargement was considered as the provisional diagnosis.

Differential diagnosis

Neoplastic gingival enlargement, chronic granulomatous lesion and oral lesions secondary to systemic diseases like leukemia.

Laboratory diagnosis

All lab findings were within normal limits.

Imaging diagnosis

Orthopantamographic examination revealed a generalized horizontal alveolar bone loss without any other relevant changes.

Pathological diagnosis

Burkitt's lymphoma (BL).

Treatment

Patient succumbed to the disease before institution of therapy.

Related reports

BL in an adult immunocompetent individual is less reported in literature and needs to be treated early owing to its aggressive nature.

Term explanation

BL is a malignant neoplasm belonging to group of non-Hodgkin'ss lymphoma with aggressive behavior and poor prognosis.

Experiences and lessons

Oral manifestations of malignant neoplasms such as leukemia and lymphoma should be considered in the differential diagnosis of rapid gingival enlargements and clinical practitioners should be aware of its consequences.

Peer-review

It's a simple case report about oral BL concurrency associated with gingival enlargement. This is a well written case report with a very rare pathology.

Abstract

Neuropathic arthropathy of the shoulder is a rare disorder characterized by joint degeneration, and is associated with loss of sensory innervation. Syringomyelia is a disease in which fluid-containing cavities (syrinxes) form within the spinal cord. Here, we report a case of neuropathic arthropathy of the shoulder secondary to syringomyelia in a 40-year-old woman. X-rays of the left shoulder revealed damage to bone and joint architecture. Blood tests indicated vitamin D deficiency and secondary hyperparathyroidism. Magnetic resonance imaging of the cervical spine showed a large syrinx from the second cervical spine to the second dorsal spine. Although neuropathic arthropathy is uncommon, it should be considered in cases of unexplained pain, discomfort, or limited range of motion of the affected joint. Symptoms related to the affected joint may precede or overshadow neurological deficits. Appropriate radiological examinations and diagnoses are imperative to prevent misdiagnosis or undetected bone and joint disorders.

Key words: Neuropathic arthropathy; Charcot shoulder; Syringomyelia; Magnetic resonance imaging; Vitamin D deficiency

Core tip: Neuropathic arthropathy, also called Charcot shoulder, is a chronic, degenerative condition associated with decreased sensory innervation. Syringomyelia patients typically suffer with shoulder and elbow involvement. Since joint symptoms often appear before other signs,

neurological deficits are often overshadowed, and the condition is misdiagnosed. In cases of unexplained joint pain, discomfort, and limited range of motion, syringomyelia should always be considered even in the absence of detectable neurological features. To prevent misdiagnoses, clinicians should be aware of the clinical and radiological signs of this rare condition. Timely diagnoses are important to avoid unwanted operative procedures that could lead to unsatisfactory outcomes.

Chakraborty PP, Datta S, Ray S, Bhattacharjee R, Chowdhury S. Unilateral neuropathic arthropathy of the shoulder secondary to syringomyelia: Diagnostic challenges. *World J Clin Cases* 2015; 3(12): 1017-1020 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i12/1017.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i12.1017

INTRODUCTION

Neuropathic arthropathy of the shoulder, also called Charcot shoulder, is a chronic, degenerative condition associated with decreased sensory innervation. Patients with diabetes mellitus, syphilis, or syringomyelia are at most risk for this disease[1]. Diabetic patients are most commonly afflicted with foot and ankle disease, while the knee is typically involved in syphilis patients. Syringomyelia patients usually present with pain in the upper limbs, shoulder joint, and elbow[2]. Approximately 6% of patients with neuropathic arthropathy have shoulder joint involvement[3]. Here, we report a case of neuropathic arthropathy of the shoulder secondary to syringomyelia. The case was of particular interest, as it was initially misdiagnosed as a pseudofracture secondary to osteomalacia. Accurate, timely diagnoses are important to avoid operative procedures.

CASE REPORT

A 40-year-old woman visited her family physician with a three-month history of gradually increasing discomfort and restricted movement of the left shoulder. It was not preceded by any trauma. She was found to be non-diabetic, but her serum 25-hydroxy vitamin D level was low (12 ng/mL). She was initially thought to have frozen shoulder and was advised to undergo physiotherapy. However, upon examination of X-ray results and the presence low vitamin D levels, she was then diagnosed with osteomalacia with pseudofracture and was advised to take oral cholecalciferol and undergo physiotherapy. She had no other symptoms related to osteomalacia, such as bone pain, muscle weakness, or difficulty walking.

Due to lack of improvement, the patient was subsequently referred to our facility. Physical examination showed asymmetry of the shoulder joints and drooping of the left shoulder. The shoulder joint was not palpable and the patient had painless restriction of joint movement in all axes. She denied any history of long-term steroid use or other drug use. She had normal menstrual cycles without any history of low trauma fracture elsewhere. She had normal sensations and preserved powers in all the four limbs with normal deep tendon reflexes and downgoing plantars. No muscle wasting, or peripheral nerves thickening were evident. Despite getting a normal neurological examination, we suspected a neuropathic joint.

A thorough look at the radiographs of the left shoulder revealed resorption of the left humeral head and parts of the glenoid cavity, multiple loose bodies, and dislocation of the left shoulder joint (Figure 1). We also obtained blood counts, measured her erythrocyte sedimentation rate, tested for venereal diseases, and measured serum vitamin B12 and serum intact parathormone (iPTH) levels. A skeletal survey and magnetic resonance imaging (MRI) of cervical and thoracic spine were also performed. Besides an elevated iPTH level (120 pg/mL), the rest of the blood and serum results were normal. Skeletal radiographs did not indicate the presence of looser zones, which are common in patients with osteomalacia. However, the MRI of the cervicodorsal spine revealed a hyperintense intramedullary signal change extending from C2 to T2, determined to be a syrinx. The craniovertebral junction appeared normal (Figure 2). Based on the patient's symptoms, the clinical examination, X-ray and MRI findings, we re-diagnosed the patient with neuropathic arthropathy of the shoulder. She was transferred to the physical therapy and rehabilitation department for conservative treatment.

DISCUSSION

The relationship between syringomyelia and neuropathic arthropathy is well described. Syringomyelia is a chronic disease anatomically characterized by the development of a tubular cavitation within the spinal cord. It can be congenital or can be caused by trauma, tumors, degenerative diseases, or infection[4]. The usual manifestations of syringomyelia include dissociated anesthesia in a "cape" distribution, areflexia, weakness, and of upper limb along with neuropathic joints. Less commonly, syringomyelia presents with atypical symptoms (*e.g.*, limb hypertrophy, joint pain, swelling) with or without detectable neurological symptoms[5]. Neuropathic arthropathy is a form of chronic destructive arthropathy that occurs secondary to sensory loss of the involved joint. Twenty-five percent of patients with syringomyelia develop neuropathic arthropathies, 80% of which involve an upper limb[6].

Neuropathic arthropathy of the shoulder is a rare disorder, with very few cases reported in the English literature. A review by Hatzis *et al*[3] found 31 documented cases of neuropathic arthropathy of the shoulder. Although neuropathic arthropathy of the shoulder had varied clinical presentations, shoulder pain and swelling were the most common symptoms. Stiffness and decreased range of movement were the next most frequent symptoms. These more common symptoms often

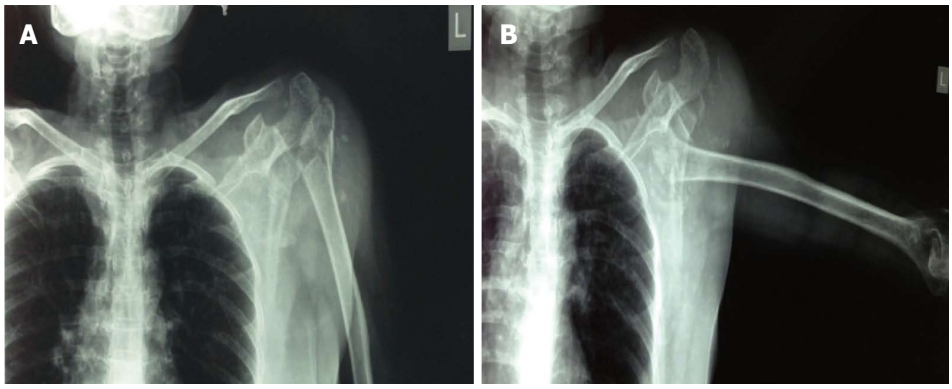

Figure 1 Neuropathic arthropathy of the shoulder in a 40-year-old woman with a syrinx. A: Antero-posterior X-ray of the left shoulder showing concentric bone atrophy of the upper end of the humerus with dislocation of shoulder joint; B: Scapula and clavicle appear to be intact.

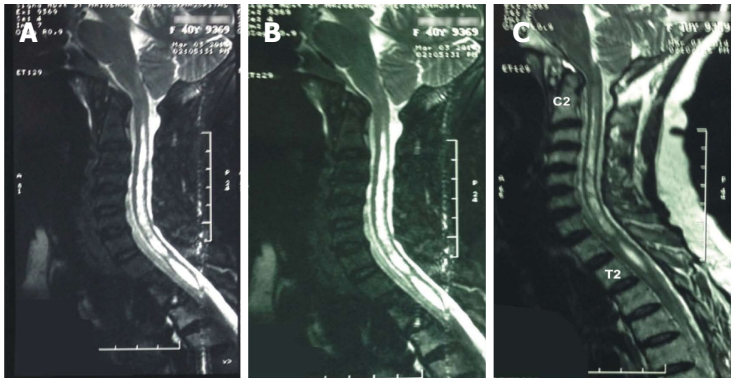

Figure 2 Magnetic resonance imaging images. Sagittal T2 fat suppressed (A and B) and T2-weighted (C) and magnetic resonance imaging images showing a long segment syringohydromyelia through the cervical cord, extending into the upper thoracic region.

precede and overshadow neurological deficits. The patient first visited her family physician with discomfort and restricted movement of shoulder joint, which was suggestive of frozen shoulder.

Neuropathic arthropathy of the shoulder generally progresses slowly, but rapid progression may happen over months or even weeks. The symptoms of neuropathic shoulder may mask the symptoms of syringomyelia, which is often characterized by shoulder instability. Complete dislocation of the neuropathic shoulder may even occur. Since neurological symptoms occur much later than pain or discomfort, patients typically first visit a primary care physician or an orthopedic surgeon[3]. If neuropathic arthropathy of the shoulder is suspected, X-rays and an MRI of the cervical cord should be taken to look for syringomyelia since it is the most common underlying disease.

Low dietary intake of calcium often leads to vitamin D deficiency in the Indian population. In reproductive *vs* post-menopausal age groups, 25-hydroxy vitamin D tests show a deficiency (< 20 ng/mL) in 76% *vs* 16.5% of those measured, or an insufficiency (20-30 ng/mL) in 7.5% *vs* 70%[7]. Vitamin D deficiency can lead to low bone mass, muscle weakness, and an increased risk of osteoporotic fractures. In our patient, the vitamin D deficiency was detected by her primary care physician. She was referred to us with a suspicion that her shoulder pathology was secondary to osteomalacia. Secondary hyperparathyroidism was detected upon further investigation at our clinic based on elevated iPTH levels. Although the presence of low 25-hydroxy vitamin D levels and high iPTH levels made osteomalacia highly likely, a low serum 25-hydroxy vitamin D is a poor indicator of osteomalacia. We therefore performed skeletal radiographs to look for pseudofractures or looser zones, which are common in patients with osteomalacia. These are lucent lines seen perpendicular to cortex which spans the cortex incompletely looser zones occur most commonly in ribs, outer borders of scapulae, and the pubic rami. However, the shoulder radiograph in this case strongly suggested a neuropathic joint. Neuropathic arthropathy of the shoulder leads to rapid, extensive degradation of the proximal humerus and glenoid cavity, and is sometimes destroyed in less than 6 wk[8]. Radiographs of neuropathic arthropathy often show osseous fragmentation and debris. Fractures are lesser-known manifestation of the disorder. The treatment strategy for neuropathic arthropathy is conservative. The prevention of trauma to the joint with proper splinting is the key to treatment. Aspiration of large effusions and splinting prevents further ligamentous laxity[9,10]. Our patient showed satisfactory improvement upon conservative treatment.

The case presented with shoulder-related signs and symptoms. Since a vitamin D deficiency was detected, the patient's physician suspected osteomalacia rather than a neuropathic disorder. Neuropathic arthropathy, although rare, should be considered as the possible

source of unexplained joint pain, discomfort, and limited range of motion. Neuropathic arthropathy is often misdiagnosed, especially that occurring at non-weight-bearing joints. It is commonly misattributed, even with radiographs, to other etiologies such as osteoarthritis, infection, or tumors. Even in the absence of prominent neurological features, syringomyelia should always be considered as the underlying cause of neuropathic arthropathy of the shoulder.

COMMENTS

Case characteristics

A 40-year-old woman presented with stiffness and restricted movement of the left shoulder.

Clinical diagnosis

Neuropathic arthropathy of the shoulder secondary to syringomyelia.

Differential diagnosis

Neuropathic joint, osteonecrosis, and pathological fracture from neoplasms.

Laboratory diagnosis

Blood and serum levels were normal, with the exception of elevated intact parathormone levels (120 pg/mL) and low serum 25-hydroxy vitamin D levels (12 ng/mL).

Imaging diagnosis

X-rays of left shoulder revealed resorption of the left humeral head and parts of the glenoid cavity, multiple loose bodies, and dislocation of the left shoulder joint. Magnetic resonance imaging of the cervicodorsal spine showed a hyperintense intramedullary signal change extending from C2 to T2, indicating the presence of a syrinx.

Treatment

Patient received physical therapy.

Related reports

Neuropathic arthropathy involving the shoulder joint is an uncommon disorder, with less than 70 cases reported in the English literature.

Term explanation

Neuropathic arthropathy represents a spectrum of bone and joint destructive processes associated with neurosensory deficit. Loss of proprioception has been implicated as a causative factor in pathogenesis of the disease.

Experiences and lessons

Even in the absence of prominent neurological features, syringomyelia should always be considered as a differential diagnosis of upper limb neuropathic joints.

Peer-review

This is a good article.
