Approximately a hundred cases of HTTS are previously described, mostly occurring for fingers (24%-47%), toes (25%-43%) or penises (44%)[3]. The typical age of affected children is around 5 years, and fingers are more frequently affected in younger children (up to 1.5 years)[3]. When a toe is affected, this is usually the third or fourth toe[2]. The material causing the strangulation is mostly either nylon or hair (both around 50% of the cases)[2]. However, HTTS in toes is more often caused by hairs[3].

The etiology of HTTS is, as previously mentioned, a hair or thread around a small body part and causing strangulation and sometimes even ischemia or necrosis. The patient can sometimes shed light on the origin of this hair or thread, but in other cases this remains unclear. How a hair can cause such a strangulation is not entirely clear, but one study mentions that that wet hair is longer than dry hair and thus, when drying, a hair tourniquet contracts and thus causes strangulation[3]. With this strangulation, swelling occurs, gradually causing a decrease in arterial blood supply and therefore tissue ischemia and necrosis[2,3].

HTTS diagnosis is easy to make when the clinical picture is recognized. It is however very important that HTTS is not missed, because prolonged HTTS can cause necrosis[3]. Therefore, it is important to always assess capillary refill in such patients[3].

Treatment for HTTS is simple: removal of the strangulating hair or thread. This may be difficult with extensive local swelling, and often surgical incision is required. This incision should be to the bone, to be certain that all the constricting material is dissected[3]. As turned out in this case, after such treatment the symptoms quickly disappear.

COMMENTS

Case characteristics

An 18 mo old girl with a painful swollen third toe was seen at the emergency ward.

Clinical diagnosis

A strangulated third toe was seen, presumably by a hair.

Differential diagnosis

Hair thread tourniquet syndrome is a clinical diagnosis with a very typical representation.

Treatment

Treatment for hair thread tourniquet syndrome consists of incision of the tourniquet.

Related reports

Hair thread tourniquet syndrome usually occurs in little children en generally affects toes, fingers or external genitalia.

Term explanation

Hair thread tourniquet syndrome is abbreviated as hair thread tourniquet syndrome.

Experiences and lessons

Hair thread tourniquet syndrome is a clinical diagnosis and is easily treated when recognized.

Peer-review

This is a nice case and well documented paper about the hair thread tourniquet.

Abstract

Dysbetalipoproteinemia is a rare familial dyslipidemia characterized by approximately equally elevated serum cholesterol and triglyceride levels due to accumulated remnant lipoproteins in apolipoprotein E2/E2 homozygotes. It is associated with an increased risk for premature cardiovascular disease. Thus, making a diagnosis of dysbetalipoproteinemia aids in assessing cardiovascular risk correctly and allows for genetic counseling. However, the diagnostic work-up can be challenging. Diagnosis of dysbetalipoproteinemia should be considered in patients mixed dyslipidemia when the apolipoprotein B concentration is relatively low in relation to the total cholesterol concentration or when there is significant disparity between the calculated low density lipoprotein (LDL) and directly measured LDL cholesterol concentrations. Other indices are also informative in the diagnostic process. We present herein two phenotypically different cases (a 44-year-old man with severe hypertriglyceridemia and a 49-year-old woman with mixed dyslipidemia) of genotypically proven familial dysbetalipoproteinemia and a diagnostic algorithm of the disease.

Key words: Dysbetalipoproteinemia; Chylomicronemia; Hyperlipoproteinemia type Ⅲ; Hypertriglyceridemia

Core tip: Dysbetalipoproteinemia is associated with an increased risk for premature cardiovascular disease and its diagnosis may be challenging since its phenotype may significantly vary when specific environmental, hormonal and genetic factors that affect triglyceride (TG) metabolism co-exist. An algorithm with a number of dysbetalipoproteinemia indices may be helpful for the diagnosis of the disease and roughly equally elevated levels of both total cholesterol (TC) and TG and a low apolipoprotein B to TC ratio seem to comprise the two most helpful indices.

INTRODUCTION

Apolipoprotein E (apoE) in plasma is mainly carried by chylomicrons, very-low-density lipoproteins (VLDL) and high-density lipoproteins (HDL). When associated with these lipoproteins, apoE serves as the ligand for the low density lipoprotein (LDL) receptor and the LDL-receptor related protein on the surface of hepatic cells[1]. In humans, three common apoE isoforms have been described, designated E2, E3, and E4[2,3]. ApoE2 and apoE4 differ from the more frequent apoE3 isoform by a single amino-acid substitution due to a single point mutation, conferring a more acidic or more basic charge to the protein. When compared with the apoE3 isoform, apoE2 has a markedly reduced affinity (< 1%) for the LDL receptor. Only a modest accumulation of cholesterol-enriched lipoprotein remnants of both hepatic and intestinal origin, or β-VLDL is observed in most apoE2/E2 homozygotes, which is not sufficient to cause an elevation of plasma cholesterol and triglyceride (TG) levels above normal. However, in individuals with predisposing genetic, hormonal, or environmental factors, this phenotype is associated with dysbetalipoproteinemia, also known as hyperlipoproteinemia type 3[2,4].

We present herein two phenotypically different cases of genotypically proven familial dysbetalipoproteinemia.

Methods

Blood samples for laboratory tests were obtained after a 12 h overnight fast. All serum laboratory measurements including fasting plasma glucose, creatinine, thyroid hormones, total cholesterol (TC), HDL cholesterol (HDL-C), and TG were determined enzymatically in the laboratory of the University Hospital of Ioannina using an Olympus AU 600 analyzer (Olympus Diagnostica GmbH, Hamburg, Germany). LDL cholesterol (LDL-C) was calculated using the Friedewald equation (provided that TGs were < 350 mg/dL (3.95 mmol/L). Apolipoproteins, serum and urinary proteins were measured with a Behring Nephelometer BN100 with reagents (antibodies and calibrators) from Dade Behring Holding GmbH (Liederbach, Germany). Antinuclear antibodies (MB Laboratories, Sidney, BC, Canada) were assessed by immunofluorescence. A commercial enzyme-linked immunosorbent assay was used to evaluate the levels of anti-extractable nuclear antigen (AESKU Diagnostics, Wendelsheim, Germany), while levels of serum globulins, C3 and C4 fractions of complement and rheumatoid factor were evaluated using nephelometry (Siemens Healthcare Diagnostics, Erlangen, Germany).

VLDL was isolated from plasma by two sequential ultracentrifugations according to the method of Gaw *et al*[5]. In brief, chylomicrons-deficient plasma firstly was prepared by plasma ultracentrifugation in a Beckman SW41 Ti rotor at 20000 rpm for 70 min at 23 ℃. The chylomicrons fraction was carefully removed from the top of the tube and the chylomicrons-deficient fraction was next submitted to ultracentrifugation at density of d = 1.019 g/mL at 45000 rpm for 8 h at 14 ℃. The VLDL fraction floating to the top of the tube was carefully collected.

DNA was extracted from the whole blood specimen according to standard procedures. ApoE genotyping was performed as described by Hixson and Vernier[6]. Polymerase chain reaction (PCR) was used to amplify a 244-bp sequence of the *apoE* gene, including the two polymorphic sites. The PCR product was then digested with the restriction enzyme Hha I and the different genotypes were detected after electrophoresis on 6% NuSieve agarose gel.

CASE REPORT

Case 1

Two years earlier a 44-year-old Caucasian man had received the diagnosis of mixed dyslipidemia based on the following lipid profile; TC: 420 mg/dL, TG: 580 mg/dL, HDL-C: 36 mg/dL. He had no family history of dyslipidemia or established cardiovascular disease, while physical examination was unremarkable. Secondary causes of dyslipidemia were excluded by evaluation of thyroid and renal function, urinary protein excretion, serum protein electrophoresis, erythrocyte sedimentation rate and autoantibodies. A low-fat diet was recommended and patient was given gemfibrozil, 600 mg, twice a day. His lipid profile improved after 2 mo, but he stopped taking the drug and was lost to follow-up. At age 46, the patient had consulted a dermatologist because of the lesions shown at Figure 1 and was referred for serum lipid assessment. He consumed small amount of alcoholic beverages and had stopped smoking 5 years earlier. For the past 6 mo, he experienced symptoms that suggested intermittent claudication. A Doppler ultrasonic study revealed mild stenosis of left femoral artery.

Seen at Figure 1 are the characteristic for dysbetalipoproteinemia tuberous xanthomas over the patient's elbows (they were also present on his knees) and the pathognomonic striated palmar xanthomas, while skin lesions typically associated with chylomicronemia, namely eruptive xanthomas, on his buttocks were also present (Figure 1). Laboratory assessment revealed: fasting plasma glucose: 300 mg/dL, TC: 1055 mg/dL, TG: 2900 mg/dL, HDL-C: 18 mg/dL, VLDL-C: 316 mg/dL, VLDL-TG: 831 mg/dL. The diagnosis of dysbetalipoproteinemia was verified by apoE2/E2 homozygosity genotype.

We suggested the patient to stop fat and alcohol consumption. He received metformin 850 mg twice a day and ciprofibrate 100 mg/d. Four weeks later the patient's skin lesions had regressed significantly and serum laboratory parameters improved (fasting

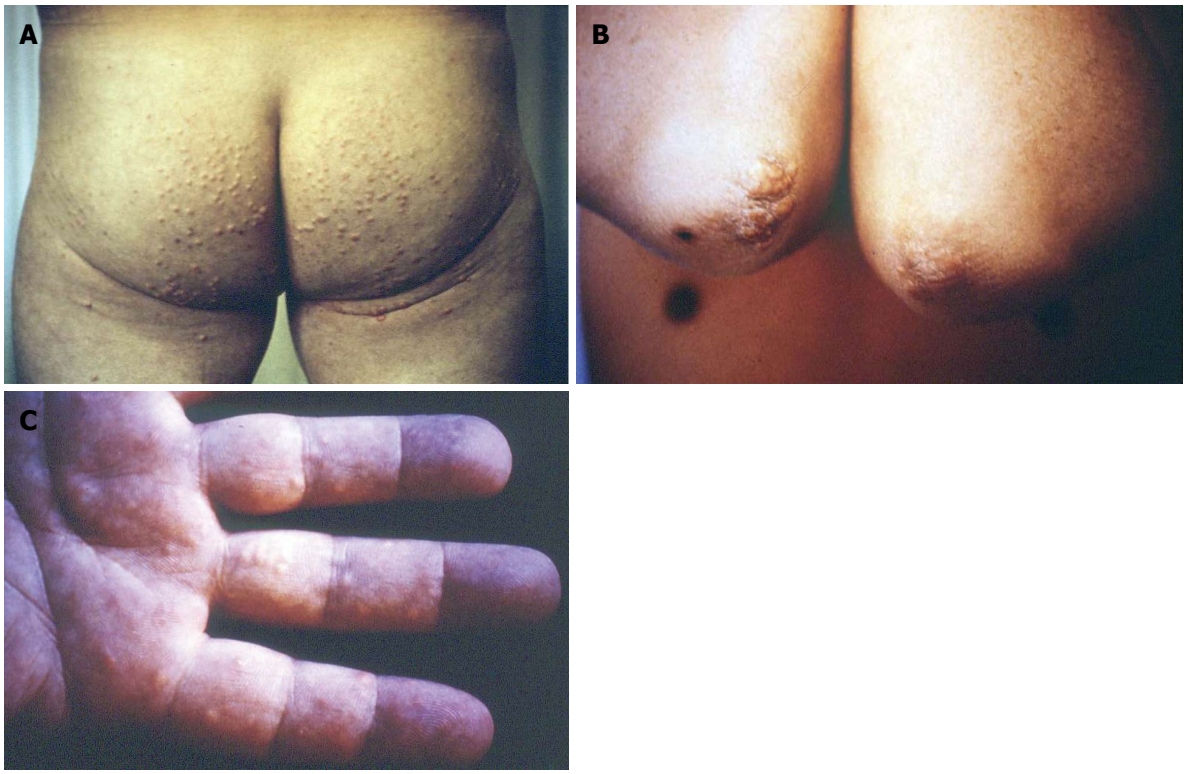

Figure 1 Tuberous xanthomas over the patient's elbows, striated palmar xanthomas and eruptive xanthomas on his buttocks. A: Eruptive xanthomas; B: Tuberous xanthomas; C: Striated palmar xanthomas.

plasma glucose: 150 mg/dL, TC: 412 mg/dL, TG: 754 mg/dL, HDL-C: 27 mg/dL). The dosage of ciprofibrate was increased to 100 mg, twice a day and glimepiride 2 mg/d was added.

Case 2

A 49-year-old Caucasian woman was referred to the Outpatient Lipid and Obesity Clinic of the University Hospital of Ioannina, Greece by her family doctor due to increased TC and TG levels. The patient denied any symptoms indicative of cardiovascular disease but her mother had been diagnosed with peripheral artery disease at the age of 40. In addition the patient had been diagnosed with breast cancer 2 years ago and her body mass index (BMI) was 28 kg/m^2. She was on tamoxifen 20 mg/d and there had been no changes in her medication for the last 11 mo. Clinical examination revealed no pathologic findings, while her electrocardiogram was normal. Treatment naïve lipid profile analysis revealed elevated TC (325 mg/dL), TG (321 mg/dL), LDL-C (214 mg/dL), apoE (147 mg/dL) and lipoprotein a [Lp(a), 47.5 mg/dL] levels, while HDL-C (47 mg/dL), apoA1 (178 mg/dL) and apoB (77 mg/dL) levels were within normal range. Other secondary causes of hyperlipoproteinemia were excluded as in case 1 patient. Dysbetalipoproteinemia was suspected by the equally elevated levels of both TC and TG (TC/TG is approximately 1), before treatment initiation and the low apoB to TC ratio (< 0.33) (Figure 2).We first assessed a number of dysbetalipoproteinemia indices, while the apoE2/E2 homozygosity genotype verified the speculated diagnosis (Table 1, Figure 2).

Patient was advised to switch to a diet low in saturated fats and carbohydrates. She received rosuvastatin 40 mg/d, ezetimibe 10 mg/d and fenofibrate 145 mg/d. Four weeks later patient's lipid profile significantly improved (TC: 238 mg/dL, TG: 160 mg/dL, HDL-C: 50 mg/dL, LDL: 156 mg/dL).

DISCUSSION

Only untreated dysbetalipoproteinemia patients > 30-year-old, like case 1 patient, suffer from diagnostic skin lesions, including tuberous or tuberoeruptive xanthomas on the extensor surfaces of extremities (elbow, knees and buttocks)[7,8]. Striated palmar xanthomas are considered pathognomonic of dysbetalipoproteinemia, but they are not present in all patients (case 2 patient)[8].

Dysbetalipoproteinemia is characterized by increased serum TG and cholesterol rich lipoprotein remnants [mostly intermediate density lipoprotein (IDL) and chylomicron remnants], also known as β-VLDL particles[7,8]. As dysbetalipoproteinemia is associated with increased premature cardiovascular disease demanding aggressive therapeutic management, it is important for the physician to suspect the disease when a mixed dyslipidemia is further characterized by approximately equally elevated levels of both TC and TG (TC is approximately 250-450

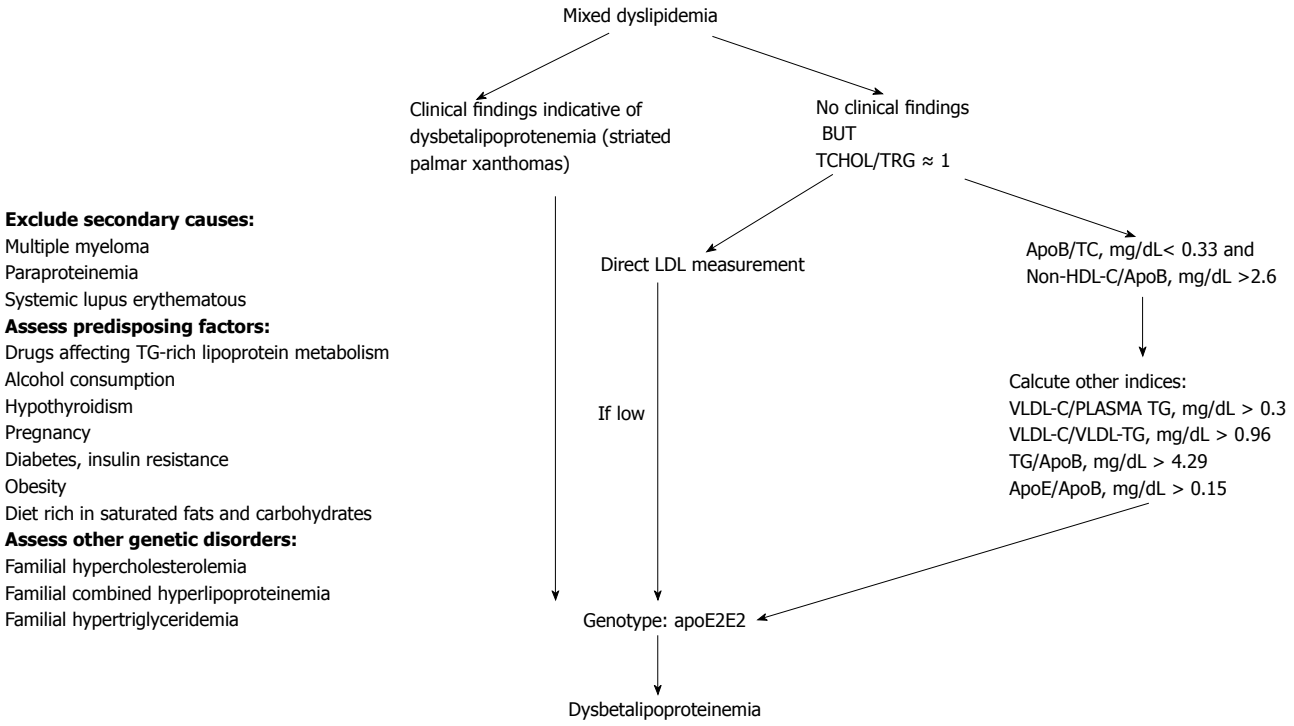

Figure 2 Diagnostic algorithm of dysbetalipoproteinemia. TC: Total cholesterol; TG: Triglycerides; ApoB: Apolipoprotein B; VLDL-C: Very low density lipoprotein cholesterol; VLDL-TG: Very low density lipoprotein triglycerides; ApoE: Apolipoprotein E; Non-HDL-C: Non high density lipoprotein cholesterol.

Table 1 Dysbetalipoproteinemia indices

Index	Patient's 2 values	Indicative for dysbetalipoproteinemia values
TC/TG (mg/dL)	1.01	Approximately 1
ApoB/TC (mg/dL)	0.23	< 0.33
ApoB/non-HDL-C (mg/dL)	0.27	< 0.38
VLDL-C/PLASMA TG (mg/dL)	0.35	> 0.3
VLDL-C/VLDL-TG (mg/dL)	1.06	> 0.96
TG/ApoB (mg/dL)	4.40	> 4.29
ApoE/ApoB (mg/dL)	0.20	> 0.15

TC: Total cholesterol; TG: Triglycerides; ApoB: Apolipoprotein B; VLDL-C: Very low density lipoprotein cholesterol; VLDL-TG: Very low density lipoprotein triglycerides; ApoE: Apolipoprotein E; Non-HDL-C: Non high density lipoprotein cholesterol.

mg/dL, TG is approximately 250-900 mg/dL) and a low apoB to TC ratio (< 0.33) (as it was the case with our second patient)[7,8]. The apoB to TC ratio represents the cholesterol in the circulating lipoproteins, but it does not include the cholesterol that circulates in HDL and other non-apoB-containing lipoproteins[9]. However, the apoB to non-HDL-C ratio was proven to be a less specific dysbetalipoproteinemia index compared with apoB to TC ratio[9]. When available, directly measured LDL-C is lower compared to that of calculated due to impaired conversion of VLDL to LDL[7,8,10]. In addition, an elevated VLDL cholesterol to total TG ratio (> 0.3) is indicative of dysbetalipoproteinemia and was also found in case 2 patient (Table 1)[7,8,10]. However, this ratio should not be used in normolipidemic subjects as they may have elevated ratios. Falsely low ratios, on the other hand, can be found in some dysbetalipoproteinemia patients who additionally have marked chylomicronemia and typical eruptive xanthomas (in the buttocks) as it was with case 1 patient. In this case, patient should be reassessed after several days on a low fat diet. In such cases another point distinguishing dysbetalipoproteinemia from type 5 hyperlipidemia is that the VLDL from a patient with dysbetalipoproteinemia is colored brown, whereas normal VLDL and that from type 2b and type 5 hyperlipidemia is white. Other dysbetalipoproteinemia indices have been also reported including elevated VLDL-C to VLDL-TG (> 0.96) as it represents high levels of cholesterol-enriched VLDL. In addition, elevated apoE to apoB has also been associated with dysbetalipoproteinemia and this index was elevated in our patient (Table 1)[9]. Last, the presence of a broad β band in electrophoresis is diagnostic but it is found in < 50% of cases[11].

Dysbetalipoproteinemia is observed in apoE2 homozygous persons when also a genetic or environmental risk factor for dyslipidemia is also present[7,8]. The disease generally presents after adulthood in men and menopause in women[7,8].

In most cases secondary factors are required for the expression of dysbetalipoproteinemia. These include additional genetic susceptibility variants, or other hormonal or environmental factors, such as obesity, type 2 diabetes, female gender, drugs affecting the metabolism of TG-rich lipoproteins, alcohol consumption or hypothyroidism (Table 2)[8,12]. Of note, case 1 patient was a diabetic man who consumed alcohol, while case 2 patient was an overweight woman who also received tamoxifen, which has been associated with disturbed

Table 2 Factors associated with dysbetalipoproteinemia overt expression

Environmental-hormonal	Genetic	Secondary dysbetalipoproteinemia
Drugs (corticosteroids, tamoxifen, retinoids, antipsychotics)	Familial hypercholesterolemia	Multiple myeloma
Alcohol consumption	Familial combined hypercholesterolemia	Paraproteinemia
Hypothyroidism	Reduced hepatic lipase activity	Systemic lupus erythematous
Pregnancy	Decreased lipoprotein lipase activity	
Diabetes, insulin resistance		
Obesity		
Diet rich in saturated fats and carbohydrates		

TG metabolism. In fact tamoxifen, like estrogens, stimulates the synthesis and secretion from the liver of VLDL, which is the main circulating carrier of TGs, while it decreases VLDL and IDL catabolism as a result of decreasing lipoprotein and hepatic lipase activities. However, the drug can induce only modest elevations in serum TG levels in patients who have a normal lipoprotein metabolism, while it can cause marked hypertriglyceridemia in patients who have a defective TG-rich lipoproteins metabolism[13-15]. Moreover, some patients may possess additional genetic variants or mutations disturbing the metabolic role of apoE[7,8]. On the other hand, less than 5% of dysbetalipoproteinemia patients have dominant mutations in apoE, which *per se* induce mixed dyslipidemia[7,16]. These mutations impair both the chylomicron remnants and IDL particles uptake by liver and the conversion of VLDL and IDL to LDL particles[7]. Of note, patients with dysbetalipoproteinemia show a marked interindividual variation in the serum concentrations of cholesterol and TG, clinically presented as mixed dyslipidemia (case 2 patient) or chylomicromenia (case 1 patient). Furthermore a combination of the apoE2/2 phenotype and additional genetic factors associated with diseases like familial hypercholesterolemia, familial combined hyperlipoproteinemia, or familial hypertriglyceridemia, can determine the expression of dysbetalipoproteinemia[17]. According to the Dutch Lipid Clinic Network criteria proposed by the European Atherosclerosis Society, the diagnosis of familial hypercholesterolemia was not probable in both our patients[18].

Noteworthy, it is important to exclude secondary causes of dysbetalipoproteinemia, including multiple myeloma, paraproteinemia and systemic lupus erythematous can mimic the disease, including the presence of typical xanthomas and the ultracentrifuge findings[19,20]. Thus, a detailed clinical and laboratory assessment is always required.

Dysbetalipoproteinemia patients have increased risk of both coronary artery disease and peripheral vascular disease, even though the LDL-C concentration is low[7,8]. Beta-VLDL is an atherogenic particle that rapidly transforms monocyte-macrophage cells to foam cells; the histologic hallmark of atherosclerosis and xanthomas[21]. Additionally, remnant lipoproteins induce endothelial plasminogen activator inhibitor I expression and activity in cultured aortic endothelial cells contributing to a prothrombotic state[22]. Males with homozygosity for the ApoE2 isoform present with coronary disease at their 4th or 5th decade of their life and there is a predisposition for peripheral vascular disease in these patients[23]. Last, lipoprotein glomerulopathy and pancreatitis in severe hypertriglyceridemic patients with dysbetalipoproteinemia have also been described[24].

Treatment of dysbetalipoproteinemia is the same as for hypertriglyceridemia. Weight loss, diet fat restriction and treatment of secondary factors, such as diabetes and hypothyroidism are important for all dysbetalipoproteinemia patients[7]. In addition, administration of fibrates, statins, omega-3 fatty acids and niacin or their combinations is very effective. However, it has to be underlined that fibrates, with or without statin, seem to comprise the cornerstone of dysbetalipoproteinemia treatment[25].

In conclusion, physician should keep in mind that dysbetalipoproteinemia may present as chylomicronemia when other genetic or environmental causes affecting TG metabolism co-exist. Moreover, dysbetalipoproteinemia has to be suspected in all mixed dyslipidemia cases with equally elevated TC and TG levels (TC/TG = 1) (Figure 2).

COMMENTS

Case characteristics

The two patients presented with dissimilar lipid profile; one presented with extremely high triglycerides (TG) levels and the other presented with equally elevated levels of total cholesterol (TC) and TG.

Clinical diagnosis

The physical signs of the two cases were also dissimilar; one patient presented with tuberous and eruptive xanthomas, while the other patient had no skin lesions.

Differential diagnosis

Type 5 dyslipidemia, chylomicronemia, secondary causes of mixed dyslipidemia and dysbetalipoproteinemia.

Laboratory diagnosis

The first patient had the following lipid profile: TC: 1055 mg/dL, TG: 2900 mg/dL, high density lipoprotein cholesterol: 18 mg/dL, while the second patient had the following lipid profile; TC: 325 mg/dL, TG: 321 mg/dL, low density lipoprotein cholesterol (LDL-C): 214 mg/dL.

Genetic diagnosis

The diagnosis of dysbetalipoproteinemia was verified by Apolipoprotein E2 (apoE2)/E2 homozygosity genotype in both patients.

Treatment

Fibrate with or without statin improved lipid profile in both patients.

Related reports

Dysbetalipoproteinemia is seen in approximately 1 in 10000 people.

Term explanation

Dysbetalipoproteinemia is a rare familial disease characterized by marked elevations of serum cholesterol and triglyceride levels caused by an accumulation of remnant lipoproteins in apolipoprotein E2/E2 homozygotes.

Experiences and lessons

This case report presents the clinical characteristics and lipid profile of dysbetalipoproteinemia and also suggests a diagnostic algorithm. The authors recommend that diagnosis of dysbetalipoproteinemia should be considered in patients mixed dyslipidemia when the apolipoprotein B concentration is relatively low in relation to the total cholesterol concentration or when there is significant disparity between the calculated low LDL-C and directly measured LDL-C concentrations.

Peer-review

This is a nice article that deserves be published.

Abstract

Multiple saccular or giant aneurysms of azygos anterior cerebral artery (AACA) at the distal segments A2-A5 are very rarely reported. Distal anterior cerebral artery (DACA) aneurysms represent approximately 2%-7% of all cerebral aneurysms. We present the case of an Albanian 62-year-old male, admitted at our service after sudden onset of severe headache and vomiting. Computerized tomography (CT) of the head showed hemorrhage in the front of corpus callosum. CT angiography followed by digitally subtracted angiography (DSA) documented a large necked aneurysm with three lobes at the origin of calloso-marginal artery and a single DACA, also known as AACA. A frontal parasagittal craniotomy was performed. Obliteration of the aneurysm was done only by separate clipping of each three lobes at the respective neck. Postoperative DSA demonstrated complete exclusion of the aneurysm and a regular flow of AACA. The patient recovered uneventfully. Despite it is a rare occurrence, an aneurysm of distal segments of anterior cerebral artery A2-A5, concomitant to AACA should be studied with DSA. In the era of embolization, conserving good microsurgical skills is fundamental for dealing with multilobar cerebral aneurysms, associated with rare anatomical variations.

Key words: Azygos; Cerebral; Aneurysm; Clipping

Core tip: This is a detailed description of radiological and surgical findings in a very rare case of trilobed aneurysm of distal anterior cerebral artery. The characteristics of this aneurysm are exposed and its difficult exclusion by separate three clips is argued with a thorough discussion of the literature.

INTRODUCTION

The incidence of true azygos distal anterior cerebral artery (DACA) ranges from 0% to 5%[1,2]. The rarest is the form of unpaired DACA. An azygos artery is better studied through carotid angiography with contralateral compression. In the presented case, there was a trilobed aneurysm of A3 segment in a single or azygos variant of DACA.

CASE REPORT

A 62-year-old man showed up at a local hospital complaining of severe headache with sudden onset. Neurological examination revealed nuchal rigidity but no neurological deficits. Unenhanced computed tomography (CT) of the head revealed a hyperdense lesion in front of the knee of corpus callosum interpreted as hemorrhage with edema of the left frontal lobe (Figure 1).

With the event taking place in 2008, a thorough history was requested. Back to 1990 the patient had been admitted at the same rural hospital after an episode of acute headache and loss of consciousness. A CT of the head at that time had shown same hemorrhage as in recent episode, but the patient had been discharged without any in-depth examinations or treatments (Figure 2).

At present episode the patient was promptly transferred at our neurosurgical facility. The CT angiography revealed A3 aneurysm of DACA. Digitally subtracted angiography (DSA) confirmed a trilobed and a complex broad-necked A3 aneurysm at the origin of the callosomarginal (CM) artery (Figure 3), in presence of azygos anterior cerebral artery (AACA).

Cerebral DSA with contra-lateral carotid artery compression confirmed the presence of AACA. Endovascular option of treatment was not considered and microsurgical clipping of the aneurysm with or without a bypass was planned.

Left frontal parasagittal craniotomy anterior to coronal suture was done in order to control at first the distal tract of CMA. Once identified, the CMA led us to the pericallosal artery proximal to the aneurysm. Then the aneurysm with its three lobes was dissected exposing at first the proximal segment of pericallosal artery, although the interhemispheric approach offers small space. After clearing the adhesions, the broad aneurysm neck and its three lobes were exposed, each of which extended in a different direction (Figure 4).

The neck wall of the aneurysm was sclerotic. Single clip closure of the neck was initially tried, but its hard wall shifted the clip away towards the single pericallosal artery reducing its lumen. Therefore separate clipping was deemed the only possible way to exclude the aneurysm (Figure 5). Uneventful postoperative course followed. Carotid angiography documented preserved flow in the parent artery and complete exclusion of the aneurysm (Figure 6).

DISCUSSION

In 1963 Baptista[2] presented a scale of three groups for the anatomical variations DACA. Years before Wilders coined the term azygos pericallosal artery for the fusion of two A2 arteries. During angiographic and autopsy studies the incidence of this variation is reported from 0.3% to 2%[2-4]. The aneurysms of DACA are seen in 2%-6.7% of the intracranial aneurysms and they are usually saccular, small and single-lobed[2,5-7]. Giant aneurysms of azygos

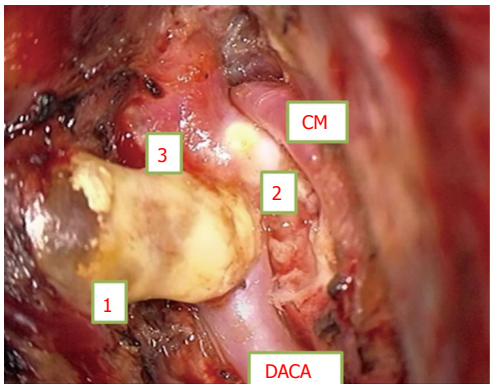

Figure 4 Intraoperative pre-clipping photo. Numbers 1, 2 and 3 refer to respective lobes of the trilobed aneurysm. CM: Calloso-marginal; DACA: Distal anterior cerebral artery/pericallosal artery.

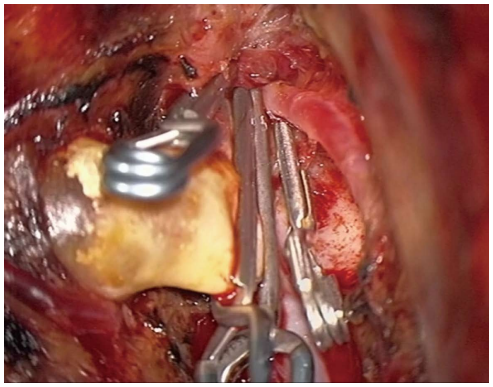

Figure 5 Intraoperative post-clipping photo. Three separate clips exclude the three lobes of the aneurysm.

pericallosal artery and those multi-lobular are extremely rare, and usually situated at the calloso-marginal bifurcation[1,8-12]. Auguste *et al*[13] reported a series of 876 aneurysms surgically treated, with five ACA aneurysms in the presence of an azygos pericallosal artery that represent 0.5% and 1.7% of ACA and ACoA aneurysms of his series. It seems needless to stress the importance of angiography in such cases, not only for a preoperative evidence of the morphology of the aneurysm, but also for the documentation of any variation of AACA, which will influence the surgical technique.

In our reported case preoperative DSA showed a trilobed aneurysm originating from a single neck with different spatial orientation. Single clip closure of the neck was initially tried, but its hard wall shifted the clip away towards the single pericallosal artery reducing its lumen. Therefore we opted for a separate clipping.

The hypothesis of creation of three lobes stands on the blood flow dynamics of the parent artery. The more curved the parent artery, more blood enters the aneurysm.

In case of AACA the blood flow is increased compared with the blood flow of any of the ACAs in a normal anatomical setting. The angled direction of entry and

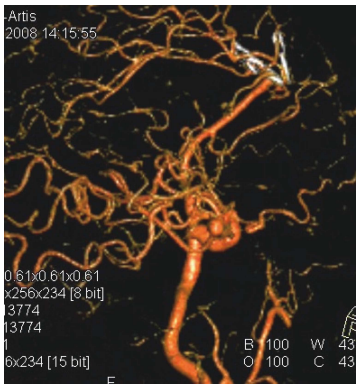

Figure 6 Postoperative digitally subtracted angiography showing preserved blood flow in the pericallosal artery and the exclusion of the aneurysm.

increase of blood flow in the aneurysm space influence the stress over the aneurysm wall. Perioperative morphological study of the single pericallosal artery evidenced the location of the aneurysm at the knee of corpus callosum. At this point the pericallosal artery bends posteriorly. It creates the prerequisite of the scenario mentioned above, that favors aneurysm formation.

In order to explain the origin of such a rare morphology aneurysm, several experimental paradigms are suggested[14]. A larger neck width increases the blood flow rate within the aneurysm. Draining vessels from the aneurysm contribute in the increase of blood flow inside the aneurysm. Both factors increase the pressure on the aneurysm wall and influence multiple lobe formation[14-16].

We suppose that the three lobes in our case were influenced by a change of aneurysm neck and dome, perhaps due to the rupture eighteen years before. We also believe there might be a relationship between the previous supposed rupture of the aneurysm and its rare morphology.

The aneurysm conformation with three lobes, in the background of a very rare anatomical variation of ACA tract, makes our case a clinical rarity. The three lobes of the aneurysm we dealt with are the result of blood flow impact and parent vessel modification after the first hemorrhage, as documented with the CT performed more than a decade prior to the second episode, requiring neurosurgical intervention. We think that vascular neurosurgeons should be prepared to handle such complicated cases.

COMMENTS

Case characteristics

Three lobed azygos anterior cerebral artery (AACA) is an exception. Digitally subtracted angiography (DSA) is the gold standard method of study.

Clinical diagnosis

Repeated episode of subarachnoid hemorrhage was observed in this case.

Differential diagnosis

The differential diagnosis with other type of acute onset of headache was done by computerized tomography scanner.

Laboratory diagnosis

DSA showed AACA aneurysm unsuitable for embolization.

Imaging diagnosis

Surgical clipping was challenged by three lobed shape of the aneurysm, which was excluded only through separate clipping.

Treatment

Excellent surgical skills are necessary for dealing with such rare difficult case.

Peer-review

Interesting case report.

Abstract

This paper reports two cases of long QT syndrome (LQTS) which presented with seizures as their initial feature. Case 1, AB was seen in emergency department with post-partum seizure, discharged and re-presented following cardiac arrest associated with LQTS. Case 2, CD presented initially with tonic-clonic seizure and because of experience with AB, CD was assessed for LQTS which was subsequently confirmed. The legal medicine experience re Dobler v Halverson, which involved a young boy with LQTS, who suffered cardiac arrest without prior diagnosis of LQTS, has reinforced the requirement to seriously consider LQTS as an aetiological factor in first seizure presentations.

Key words: Long QT syndrome; Prolonged QT; Torsades de pointes; Seizure; Epilepsy

Core tip: Long QT syndrome (LQTS), with subsequent cerebral ischemia due to cardiac dysrhythmia, may cause seizures. It is imperative to consider LQTS in patients presenting with first seizure so as to avoid possible brain damage from prolonged cerebral hypoxemia. Failure to recognise LQTS may result in successful suit for negligence if not properly investigated and managed.

Choong H, Hanna I, Beran R. Importance of cardiological evaluation for first seizures. *World J Clin Cases* 2015; 3(4): 381-384 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i4/381.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i4.381

INTRODUCTION

Long QT syndrome (LQTS) represents channelopathies of cardiac potassium/sodium ion channels. Channelopathies may present with seizures and/or risk sudden death because ventricular dysrhythmia known as torsades de pointes (TdP).

CASE REPORT

Case 1 (Year: 2008)

AB was a 26-year-old Asian female, 6 wk post-partum

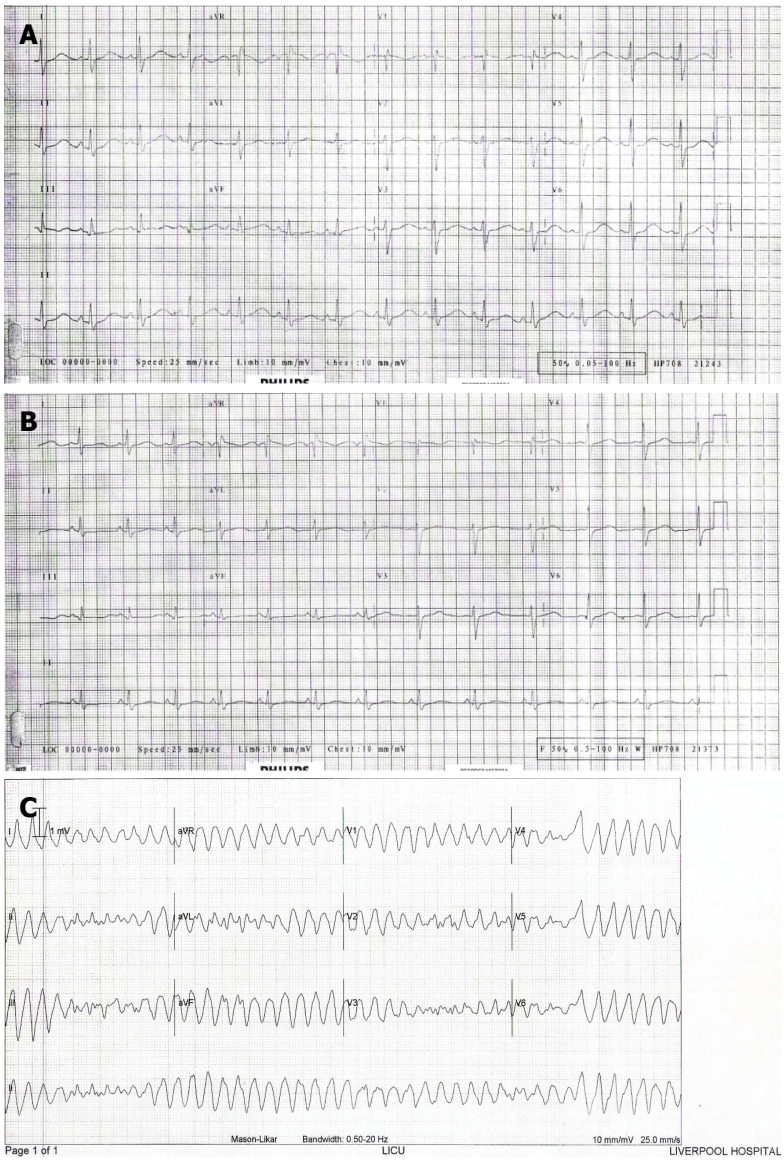

Figure 1 Electrocardiogram of AB. A: Electrocardiogram (ECG) of AB on first presentation showed sinus rhythm, incomplete right bundle branch block (RBBB) and prolonged QTc interval (QTc 526 ms); B: ECG of AB on second presentation showed sinus rhythm, incomplete RBBB and prolonged QTc interval (QTc 505 ms); C: ECG of AB during a syncopal episode on her second admission showed torsades de pointes.

with emergency lower cesarean section at 38 wk into her first pregnancy because of pre-eclampsia and fetal distress. Past medical and family histories were unremarkable and she was not on regular medication.

She had acute "dizziness" when rising from the sitting to standing position, and then collapsed to the floor and was witnessed to be cyanosed. Her husband performed cardiopulmonary resuscitation until the ambulance arrived. Her Glasgow Coma Scale improved with stable vital signs at that time. The paramedics witnessed an episode of generalised tonic-clonic seizure associated with tongue biting that lasted for a few minutes whilst en-route to Liverpool Hospital. In the Emergency Department, she was sedated and intubated because of post-ictal aggression. She was afebrile, blood pressure 127/78 mmHg and pulse rate 70 beats/min. Blood tests were unremarkable with normal computed tomography (CT) pulmonary angiogram, CT brain and CT cerebral venogram. Her electrocardiogram (ECG) showed corrected QT interval (QTc) of 526 ms (Figure 1A), which was above the normal limit for her gender (QTc < 460 ms). She was extubated 24 h later and was back to her normal state. Full neurological examination was unremarkable. No antiepileptic medication was prescribed as this was her first seizure. Electroencephalogram (EEG) and magnetic resonance imaging (MRI) of the brain were organised but she refused to stay in hospital for those investigations and was to be followed by the neurologist.

She was re-admitted the next day after being found unconscious. She was in ventricular fibrillation requiring cardioversion by the paramedics. Her ECG was similar to the previous recording, demonstrating abnormal QTc of 505 ms (Figure 1B) and hence prompting a diagnosis of LQTS. She had further symptomatic polymorphic ventricular tachycardia suggestive of TdP that required cardioversion (Figure 1C). She was subsequently started on beta-blocker therapy and had implantable cardioverter-defibrillator (ICD) for secondary prevention.

Case 2 (Year: 2012)

CD was a 50-year-old Caucasian male with no regular

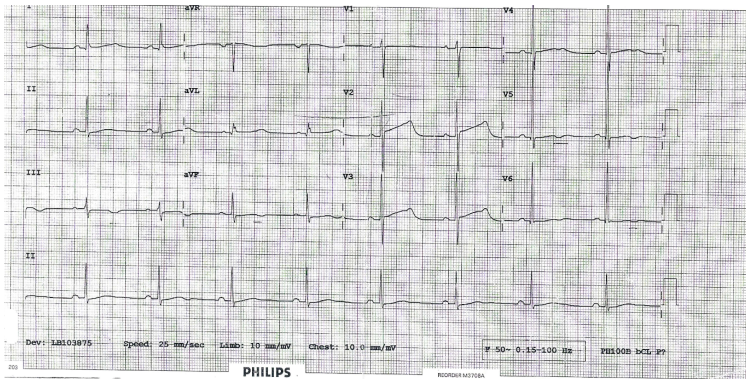

Figure 2 Electrocardiogram of CD showed sinus rhythm and prolonged QTc (QTc 566 ms).

medication. His father died at 57 years old in his sleep.

He presented to Liverpool Hospital with 2 min of witnessed generalised tonic-clonic seizure. This was associated with post-ictal drowsiness but no tongue biting or incontinence. Previously he had three episodes of unconsciousness. The first two were 30 years ago resulting in his being prescribed carbamazepine which he took for a few years but had not taken same for approximately 20 years. He was unable to provide adequate further history nor could he offer more detailed information regarding specific investigations related to those events. Full neurological and cardiological examinations, blood tests, EEG, MRI brain and echo-cardiography were all unremarkable. ECG showed QTc of 566 ms which was above the normal limit for his gender (QTc < 450 ms) (Figure 2) prompting a diagnosis of LQTS. Beta-blocker therapy was commenced. ICD was indicated due to his family history and possible ventricular dysrhythmias that could have accounted for his previous events of loss of consciousness thought possibly to be misdiagnosed as epileptic seizures.

DISCUSSION

Both patients in Cases 1 and 2 presented with generalised convulsive "seizures". AB was initially discharged with conservative management and LQTS was diagnosed on representation. CD was diagnosed because of the experience with AB. This demonstrates that LQTS crosses age, gender and racial boundaries (AB being a young Asian female and CD a middle-aged Caucasian male) demanding a high index of suspicion and consideration of LQTS in all first seizures.

LQTS is a collection of genetically distinct arrhythmogenic disorders resulting in abnormal cardiac potassium and sodium ion channels causing delayed cardiac depolarization[1]. LQTS affects approximately 1 in 2000 people[2,3] and symptomatic cases may present with syncope, seizures or sudden death due to ventricular dysrhythmia known as TdP. These cases are often "erroneously" diagnosed as a primary seizure disorder, having unexplained syncope, or having ill defined "spells"[4,5] which could potentially lead to expensive legal-medicine consequences, such as the Dobler v Halverson case of 2006. This Australian, NSW Court of Appeal, case involved LQTS in a young boy diagnosed by a neurologist as a "faint" without further investigation. Halverson was then managed by his general practitioner (GP), Dr Dobler. Halverson experienced cardiac arrest with severe brain damage and the GP was found negligent for not performing an ECG nor organizing for cardiological assessment.

There is increasing support that seizures, in LQTS, are not solely due to acute cerebral hypoxic-ischemic event secondary to ventricular arrhythmias. It has been proposed that the aetiologies of LQTS and epilepsy may partly overlap *via* a possible link between the cardiac and neural ion channelopathies. It has been demonstrated that patients with LQTS type 2 are more commonly associated with epilepsy, hence supporting the possibility that mutation of *KCNH2* gene responsible for LQTS type 2 may also predispose to seizure activity[5]. Similarly, various case reports and observational studies have suggested that mutation in the *SCN5A* gene, responsible for LQTS type 3, is also associated with epilepsy[6,7]. It follows that initial diagnosis of seizure disorder or epilepsy, with subsequent neurological investigations and antiepileptic treatment, may be inadequate if it does not also include cardiological evaluation. ECG, Holter monitoring and formal cardiological evaluation should become an integral part of a seizure/epilepsy assessment, to identify a subset of patients who also have concomitant LQTS. Failure to do so may predispose the patient to very serious or even fatal consequences and the treating clinician to subsequent personal and legal medicine ramifications.

COMMENTS

Case characteristics

Two cases presenting to hospital after witnessed generalised seizures.

Clinical diagnosis

Both cases had normal physical examination but had prolonged QTc on their electrocardiograms (ECGs), and evidence of torsades de pointes on the ECG for Case 1, prompting the diagnosis of long QT syndrome (LQTS).

Differential diagnosis

Convulsive syncope, secondary to cardiogenic causes; primary or secondary generalised seizure disorder.

Laboratory diagnosis

Both cases had normal routine blood tests, echocardiogram and electro-encephalogram.

Imaging diagnosis

Both cases had normal computed tomography and magnetic resonance

imaging brain.

Treatment

Beta-blocker medication and implantable cardioverter-defibrillator insertion were instigated after the diagnosis of LQTS in both cases.

Related reports

There is a possible link between the cardiac and neural ion channelopathies, hence patients with LQTS may have concurrent primary epilepsy disorder causing seizures rather than solely from the consequences of the ventricular arrhythmias.

Term explanation

TdP refers to Tordes de Pointes which is an uncommon and distinctive form of polymorphic ventricular tachycardia characterized by a gradual change in the amplitude and twisting of the QRS complexes around the isoelectric line; Channelopathies are diseases caused by disturbed function of ion channel subunits or the proteins that regulate them; and *KCNH2* and *SCN5A* are genetic abnormalities found to occur in both inherited epilepsies and LQTS.

Experiences and lessons

Initial diagnosis of seizure disorder or epilepsy, with subsequent neurological investigations and antiepileptic treatment, may be inadequate if it does not also include cardiological evaluation.

Peer-review

The viewpoint of this paper is useful in clinical practice.

Abstract

Authors describe a 53-year-old woman who presented to their diabetes clinic with a three week history of multiple painful and swollen joints. She had been diagnosed with type 2 diabetes 5 years back. On examination, both knee joints and left ankle were swollen. A soft tissue swelling appeared over the medial end of the left clavicle few days later. Rheumatoid arthritis, collagen vascular diseases and other common causes of polyarthritis were ruled out by appropriate investigations. Non steroidal anti-inflammatory drugs failed to give satisfactory pain relief and the arthritis persisted. Conventional cultures of synovial fluid samples including cultures for tuberculosis were negative. Computed tomography showed a space occupying lesion involving the left sternoclavicular joint. Fine needle aspiration from the lesion was performed and acid-fast bacilli were demonstrated in the smear using Ziehl-Neelsen stain. The explanation of her arthritis was therefore tuberculous arthritis in left sternoclavicular joint and reactive arthritis in the rest of the joints. A diagnosis of Poncet's disease was considered in her case. We treated her with standard anti-tuberculosis drugs and the arthritis resolved within a few days. She remained symptom-free at her 2 years' follow-up.

Key words: Poncet's disease; Diabetes; Tuberculous arthritis; Reactive arthritis; Acid-fast bacilli

Core tip: Poncet's disease (PD) is a form of reactive arthritis that develops in patients with active tuberculosis (TB). It is a rare, non-destructive parainfective symmetric polyarthritis. In cases of unexplained atypical arthritis associated with non-articular TB, PD should be considered. PD remains a clinical challenge and is essentially a diagnosis of exclusion and requires a high degree of clinical suspicion. Correct identification of this rare complication of TB is required to avoid delayed initiation of appropriate treatment. The dramatic response of arthritis in PD on starting anti-tubercular treatment substantiates the diagnosis. Further studies are required for better

understanding of the pathogenesis underlying PD.

INTRODUCTION

The association between of diabetes mellitus (DM) and tuberculosis (TB) is becoming more prominent in developing countries where TB remains endemic and the burden of DM is increasing. Atypical presentations are increasingly being recognized in diabetic patients. The diagnosis of joint TB poses a challenge to the clinicians. Although, septic monoarthritis is a well-known complication of tuberculous infection; active TB may be complicated by a sterile reactive arthritis (ReA), known as Poncet's disease (PD), which is not so common and therefore frequently missed. We report here a diabetic patient who initially presented with oligoarthritis, and later on ended with a diagnosis of PD. A review of the literature on diagnostic and therapeutic aspects involved in PD is also included. This case highlights the need for increased awareness among physicians regarding this rare complication of a common disease to avoid delay in diagnosis and starting the appropriate treatment.

CASE REPORT

A 53-year-old lady presented with a three week history of multiple painful and swollen joints. She had been diagnosed with type 2 diabetes in March 2009. Her diabetes was well controlled and she was on insulin and metformin. Her presentation to the clinic had been prompted by her inability to walk in the previous five days. She had been diagnosed with undifferentiated polyarthritis by a family physician. The joint pains started gradually over three weeks involving left ankle and knee joints. Family history for rheumatic or autoimmune diseases was negative. There was no history of mouth ulcers, eye symptoms, skin rash or genito-urinary symptoms. She denied weight loss, coughing, night sweats but mentioned about low grade fever for few weeks.

On examination, she was in pain and was unable to walk. Her blood pressure was 130/80, pulse rate 90 per minute, respiratory rate 24 per minute and a temperature of 36.80 ℃. The patient's ankle and knee joints were swollen and tender on palpation with limitation of movement. A soft, boggy swelling appeared at the medial end of the left clavicle during her hospital stay clinically resembling a cold abscess. She had no erythema nodosum on examination. No adventitious sound was detected on chest auscultation. There was no lymphadenopathy or hepatosplenomegaly. There was no muscle atrophy. She had no signs of peripheral neuropathy. Fundoscopic examination was unremarkable.

Her initial investigation results showed hemoglobin of 11.9 g/dL, a white cell count of 7.6 × 10^9/L, platelets of 130 × 10^9/L and an erythrocyte sedimentation rate (ESR) of 88 mm/h. Urine dipstick showed no white cells, protein was trace. Laboratory tests results for antinuclear antigen, rheumatoid factor and anti-cyclic citrullinated peptide antibodies were negative. The patient was nonreactive for HIV 1 and 2 by ELISA. The radiographs of the both knees and left ankle were normal. The intradermal skin test for tuberculosis reading was 17 mm, which was considered strongly positive. Synovial fluid was aspirated from the left ankle and both knees and analysis revealed leucocytes between 4.0 and 8.2 × 10^9/L, no crystals and the smears were negative for Gram stain. On bacterial culture of the synovial fluid, no growth was found and synovial fluid cultures for TB were also negative. The plausible explanation of her arthritis would therefore be a form of a reactive arthritis. Since no diagnosis could be made, we went for exploring the neck swelling. Computed tomography scan of the neck was performed which showed a space occupying lesion (SOL) around the medial end of clavicle (Figure 1A). Fine needle aspiration from the lesion showed epithelioid cell collection and multinucleated giant cells on the background of necrotic tissue. AFB stain was positive (Figure 1B).

Treatment with non steroidal anti-inflammatory drugs only gives partial relief. Since there was strong evidences suggesting active joint tuberculosis, she was put on four-drug antituberculosis treatment, including rifampicin, isoniazid, pyrazinamide, and ethambutol. Her joint symptoms showed a remarkable improvement within two weeks of initiation of therapy.

Following treatment with standard anti-tubercular treatment, the arthritis had completely resolved in three weeks period. The consistent association of arthritis with presence of active tuberculosis, the lack of evidence of any other known rheumatic disease and the resolution of symptoms on anti-tuberculosis therapy were all consistent with the diagnosis of PD in our patient. She had remained asymptomatic at 2 years' follow-up.

DISCUSSION

PD or tubercular rheumatism is a form of reactive polyarthritis related with active TB in which no myco-bacterial involvement can be found in the affected bones or joints, and there is absence of other detectable causes of polyarthritis[1-3]. TB reactive arthritis was first described by Poncet[4] in 1897 and named after him as PD. PD is considered a ReA, but the clinical presentation of PD is different from the classical pattern of ReA[5]. Unlike ReA,

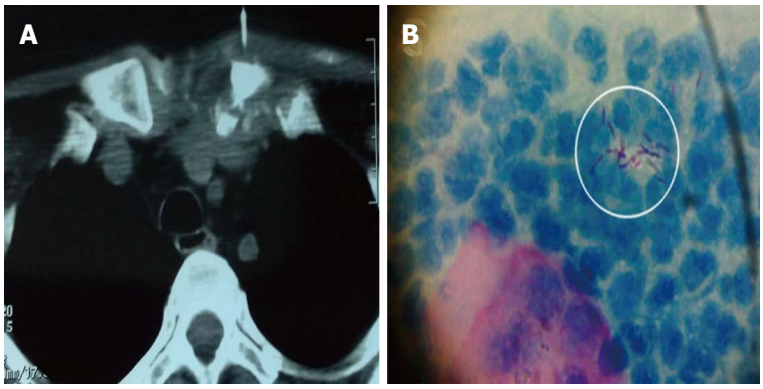

Figure 1 Computed tomography scan of neck showed bone destruction and soft tissue swelling with involvement of articular surfaces of sternoclavicular joint (A); Numerous acid-fast bacilli in the background of necrosis(B) (Ziehl-Neelsen stain, x 1000).

the onset of symptoms in PD prior to the start of arthritis is much longer than only a few weeks, whereas arthritis resolution upon starting of anti-tubercular therapy is generally within a few weeks. Chronic arthritis is not encountered in PD. Although the clinical presentation is somewhat different, the pathogenetic mechanism is considered to be similar. It is thought to occur due to a hypersensitive immune cell mediated response to the tuberculoprotein, resulting in an inflammatory reaction in the joint spaces[2,6]. Due to the rarity of PD despite the frequency of TB, a genetic predisposition has been suggested in the pathogenesis, with links to the HLA DR3 and HLA DR4 haplotypes[7].

Clinically the disease is different to the well recognized TB monoarthritis; a septic mycobacterium infection of a joint leading to its destruction. From the cases previously described, Poncet's arthritis is non-destructive and resolves completely following TB treatment. The arthritis mainly affects the larger joints, with the knee being the most common, followed by the ankle and wrist joints. The axial skeleton tends not to be involved. It is described as a symmetrical polyarthritis but many studies[8] have suggested it to be pauciarticular arthritis, mainly of the larger joints as was the case with our patient. Other common symptoms include lymphadenopathy (mainly cervical and axillary), grumbling fevers (which may be present many weeks prior to developing the arthritis) and skin changes; classically erythema nodosum[9]. In the review of 50 cases report on PD by Kroot *et al*[1] erythema nodosum was present only in 6% of the patients.

The diagnosis is usually one of exclusion and should be considered in all patients with a symmetrical arthritis in TB prevalent regions. Extra-pulmonary TB, particularly lymph node TB, is traditionally thought to be the main culprit[10,11]. The complete resolution of rheumatic symptoms on anti-tuberculosis therapy further confirms the diagnosis. Resolution of the arthritis of PD with anti-tubercular drugs ranged from a week to few months.

To conclude, active tuberculosis needs to be considered in the differential diagnosis of patients presenting with fever and polyarthritis of unclear cause, particularly in regions where the prevalence of tuberculosis is high. The diagnosis of this clinical entity remains a clinical challenge and demands a high index of suspicion. Since not all clinicians are aware of PD, this entity is probably underdiagnosed.

COMMENTS

Case characteristics

A 53-year-old diabetic woman presented with multiple painful and swollen joints.

Clinical diagnosis

The patient's ankle and knee joints were swollen and tender on palpation with limitation of movement. A soft, boggy swelling appeared at the medial end of the left clavicle during her hospital stay clinically resembling a cold abscess.

Differential diagnosis

Septic arthritis, reactive arthritis, rheumatoid arthritis.

Laboratory diagnosis

Her investigation results showed hemoglobin of 11.9 g/dL, a white cell count of 7.6 × 10^9/L, platelets of 130 × 10^9/L and an erythrocyte sedimentation rate of 88 mm/h. Results for antinuclear antigen, rheumatoid factor and anti-cyclic citrullinated peptide antibodies were negative. The intradermal skin test for tuberculosis reading was 17 mm, which is considered a positive test.

Imaging diagnosis

The radiographs of the both knees and left ankle were normal. Computed tomography scan of the neck showed a space occupying lesion (SOL) around the medial end of clavicle.

Pathological diagnosis

Fine needle aspiration from supraclavicular SOL/of the left supraclavicular node showed epithelioid cell collection and multinucleated giant cells on the background of necrotic tissue. AFB stain was positive.

Treatment

The patient was put on four drug anti-tuberculosis (TB) therapy since the evidence was strongly suggestive of active joint tuberculosis.

Related reports

Reviewing the literature, more than 50 case reports were found. In most reports "Poncet's disease" was described as an aseptic polyarthritis, presumably reactive arthritis arthritis developing in the presence of active TB elsewhere.

Term explanation

Poncet's disease is a reactive polyarthritis associated with active TB in which no mycobacterial involvement can be found in the affected bones or joints.

Experiences and lessons

The diagnosis of Poncet's disease remains clinical and is established on excluding other potential causes of arthritis in a patient with active tuberculosis. In cases with unexplained atypical arthritis and non-articular TB, Poncet's disease should be considered.

Peer-review

It is a case report describing Poncet's disease which goes unnoticed and underdiagnosed. The manuscript is scientifically sound and based on the discovery of facts. Data presented are duly supported by appropriate figures.

Abstract

Malignant peripheral nerve sheath tumor (MPNST) with rhabdomyoblastic differentiation is called as malignant triton tumor (MTT). It is highly aggressive soft tissue tumor with higher local recurrence rate. MTT has poor prognosis than MPNST. MTT seems to be more aggressive in patients with neurofibromatosis (NF-1). We herein, reporting an interesting case of 55 years male with multiple neurofibromas all over the body since 30 years and multiple café-au-lait spots, diagnosed as NF-1. Since 6 years, he had an enlarged mass in left thigh. Wide excision of mass was done. On histopathological examination revealed the diagnosis of MTT and diagnosis of which was confirmed on immunohistochemistry.

Key words: Malignant triton tumor; Neurofibromatosis-1; Desmin; S-100 protein

Core tip: Meticulous histopathological examination along with immunohistochemistry is the mainstay to arrive at such rare histological diagnosis. The surgical pathologist should keep in mind such rare entity while dealing with such kind of patients.

Shete S, Bolde S, Pandit G, Matkari P, Ingle SB. Unusual histological variant of malignant peripheral nerve sheath tumor with rhabdomyoblastic differentiation. *World J Clin Cases* 2015; 3(4): 389-392 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i4/389.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i4.389

INTRODUCTION

Malignant peripheral nerve sheath tumor (MPNST) is an unusual type of soft tissue sarcomas. It accounts for about 5%-10% of all soft tissue sarcomas [1]. Amongst them malignant triton tumor (MTT) constitutes about 5% of all MPNSTs[2]. MTT is a subtype of MPNST that

has real diagnostic challenge for surgical pathologists with regard to its cell of origin and its relatively aggressive course. It is comprised of malignant Schwann cells coexisting with characteristic malignant rhabdomyoblasts[3]. It occurs in two forms, one is sporadic form and the other is neurofibromatosis type 1 (NF-1) associated form. Majority of the reported cases are of later variety. Immunohistochemically the rhabdomyoblastic elements are typically positive for skeletal muscle markers such as desmin, myoglobin or muscle actin. MTT has a poorer prognosis than MPNST[3]. This poor outcome is mainly attributed to the high frequency of grade Ⅲ histology in this sarcoma[4].

CASE REPORT

A 55-year-old male patient presented with multiple swellings all over the body ranging from 1-3 cm since 30 years (Figure 1). These nodules were histopathologically reported as neurofibromas. A subcutaneous nodule in left thigh was enlarged to attain a present size of 8 cm × 4 cm × 3 cm. He had café-au-lait spots on the trunk ranging from 0.5-1.8 mm. On family history, patient's mother, sister and brother had similar complaints. So he was diagnosed as a case of NF-1. Ultrasonography was suggestive of neoplastic lesion mostly soft tissue sarcoma.

Fine needle aspiration cytology was done and reported as malignant soft tissue tumor with possibilities of malignant fibrous histiocytoma and rhabdomyosarcoma (Figure 2A). Complete resection of the mass was done and the specimen was sent for histopathological evaluation.

On, gross examination showed a mass of 8 cm × 4 cm × 3 cm in size, covered with skin. Cut surface was soft, pale grey in colour with areas of necrosis.

Histopathological examination showed dense areas of malignant spindle shaped cells with oval nuclei with prominent mitoses, marked nuclear pleomorphism along with foci of necrosis. Many nuclei were bizarre and hyperchromatic. Alternating with hypercellular Antoni A areas, there were hypocellular myxoid areascalled as- Antoni B areas. Thick walled congested blood vessels were found. Interspersed within it are seen many Scattered round cells with abundant eosinophilic cytoplasm with atypical nuclei, which were recognized as rhabdomyoblasts (Figure 2B).

The surgical cut margins margins were free of tumor invasion. On Immunohistochemical evaluation, spindle cells showed focal S-100 positivity (Figure 3A) and cells with deeply eosinophilic cytoplasm (rhabdomyoblasts) showed positivity for Desmin (Figure 3B).

After histopathological confirmation patient was under treatment with radiotherapy and doing well without any recurrence on follow up since last 6 mo till date.

DISCUSSION

Peripheral nerve malignant lesions are displaying

Figure 1 Photograph showing multiple neurofibromas, present all over the body.

differentiation towards Schwann cells, perineural cells, fibroblasts are labelled as MPNST. This term now replacing the earlier terminologies malignant schwannoma, neurofibrosarcoma and neurogenic sarcoma[1]. The diagnostic criteria for NF-1, is presence of two or more of the following signs[1]: (1) Six or more cafe-au-lait macules; (2) Two or more neurofibromas of any type or one plexiform neurofibroma; (3) Freckling in the axillary or inguinal region; (4) Optic Glioma; (5) Two or more Lisch nodules; (6) Osseous Lesion; and (7) First degree relative (parent, sibling, offspring) with NF-1.

MPNST constitutes 5%-10% of all soft tissue sarcomas, about one fourth to one half occur in the setting of neurofibromatosis[1]. Patients with NF-1 have propensity to transform in to sarcoma after a prolonged latent period (10-20 years)[5]. Our patient was diagnosed as having NF-1 and after long latency period of 30 years, he developed MPSNT with rhabdomyoblastic differentiation. MPNST can also arise spontaneously without association of NF-1[4].

MTT is a rare tumor arising from peripheral nerves. It is an autosomal dominant disorder. It has a strong association with neurofibromatosis (type 1). The common sites of occurrence are head, neck, extremities and trunk[4]. The symptoms are mainly attributed to mass effect giving rise to neurological signs and symptoms[4].

In 1973 Woodnelf *et al*[6] proposed the classification of MTT by establishing three criteria for diagnosis: (1) Tumor with peripheral nerve involvement in a patient with NF-1; (2) Majority of the cells in the tumor are Schwann cells; and (3) Presence of Rhabdomyoblasts[6].

Our patient had NF-1 and histology showed all the above mentioned criteria. The pathognomic feature of this tumor is the presence of rhabdomyoblasts. The number of rhabdomyoblasts varies from area to area in the same tumor. They are having abundant eosinophilic cytoplasm. Desmin is demonstrated in the rhabdomyoblasts.

The histogenesis of this unusual tumor is discussed by Masson. He postulated that both cell lines have similar origin, *i.e.*, from less well differentiated neural crest cells[1,7] . The strong relation between neural

Inset shows rhabdomyoblastic differentiation (400 ×).

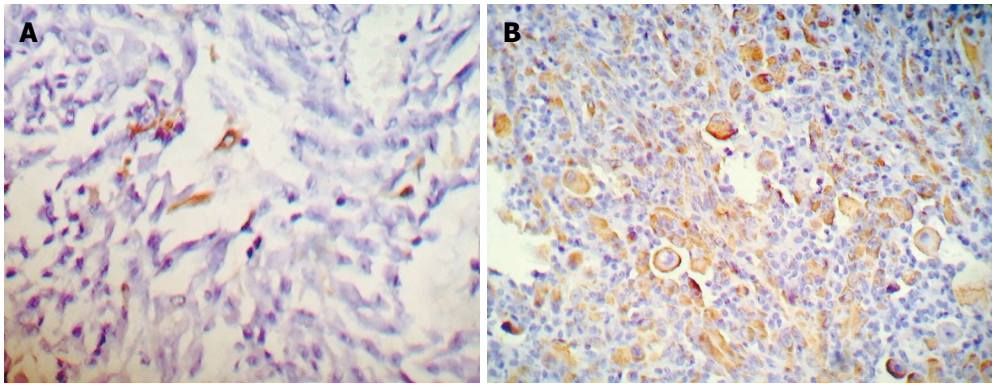

Figure 3 Immunohistochemistry. A: Immunohistochemistry showing focal S100 positivity in spindle cells; B: Immunohistochemistry showing Desmin positivity in rhabdomyoblasts.

tissues and rhabdomyoblastic differentiation has been reported as the development of skeletal muscle differentiation within other neural tumors such as Ocular Medulloblastoma[8], Ganglioneuroblastoma[9,10]. The five years survival rate for MTT is only 11% in contrast to 39% for MPNST[11]. MTT is significantly worse than the usual MPNST. The aggressiveness of MTT is attributed to high grade (grade Ⅲ) nuclear features with high proliferative capacity[4]. Radical excision followed by high dose radiotherapy is the conventional treatment for this unusual tumor[3].

MTT is an uncommon sarcoma which is having high propensity of local recurrence and distant metastases. Histopathologically, the diagnosis of MPNST with mesenchymal differentiation is difficult. So meticulous histopathological examination and immunohistochemical demonstration of neural markers and skeletal muscle markers help to hit the correct diagnosis. Early diagnosis, complete resection of the tumor followed by radiotherapy can help to increase survival of the patient.

COMMENTS

Case characteristics

A 55-year-old male patient presented with multiple swellings all over the body ranging from 1-3 cm since 30 years.

Clinical diagnosis

Multiple neurofibromas.

Differential diagnosis

Neurofibromas, fibrosarcoma, malignant peripheral nerve sheath tumor (MPNST).

Laboratory diagnosis

Fine needle aspiration cytology, histopathology with Immunohistochemistry showing Desmin positivity in rhabdomyoblasts.

Imaging diagnosis

Ultrasonography was suggestive of neoplastic lesion soft tissue sarcoma.

Pathological diagnosis

An unusual histological variant of MPNST with rhabdomyoblastic differentiation.

Experiences and lessons

Careful histological examination along with clinical work up is important to arrive at such unusual diagnosis.

Peer-review

Good overview of the diagnostic challenges in the correct interpretation of this rare tumor.

Abstract

Epithelial-to-mesenchymal transition (EMT) represents conversion of an epithelial cell in an elongated cell with mesenchymal phenotype, which can occur in physiologic and pathologic processes such as embryogenesis (type 1 EMT), wound healing and/or fibrosis (type 2 EMT) and malignant tumors (type 3 EMT). The proliferation rate, metastasizing and recurrence capacity, as also the individualized response at chemotherapics, in both epithelial and mesenchymal malignant tumors is known to be influenced by reversible switch between EMT and mesenchymal-to-epithelial transition (MET). Although much research work has already been done in these fields, the specific molecular pathways of EMT, relating to the tumor type and tumor localization, are yet to be elucidated. In this paper, based on the literature and personal experience of the authors, an update in the field of EMT *vs* MET in epithelial and mesenchymal tumors is presented. The authors tried to present the latest data about the particularities of these processes, and also of the so-called endothelial-to-mesenchymal transition, based on tumor location. The EMT-angiogenesis link is discussed as a possible valuable parameter for clinical follow-up and targeted therapeutic oncologic management. The paper begins with presentation of the basic aspects of EMT, its classification and assessment possibilities, and concludes with prognostic and therapeutic perspectives. The particularities of EMT and MET in gastric and colorectal carcinomas, pancreatic cancer, hepatocellular and cholangiocarcinomas, and lung, breast and prostate cancers, respectively in sarcomas and gastrointestinal stromal tumors are presented in detail.

Key words: Gastrointestinal stromal tumor; Carcinoma; Gastrointestinal cancer; Hepatic cancer; Sarcoma

Core tip: This review, based on the personal experience of gastrointestinal pathologists, which correlates with literature data, is intended to provide an up-date in the field of epithelial-mesenchymal transition and mesenchymal-epithelial transition in epithelial and mesenchymal-malignant tumors, respectively. The molecular mechanism of these processes and their possible role in tumor progression, metastasis and therapy are presented in detail.

Gurzu S, Turdean S, Kovecsi A, Contac AO, Jung I. Epithelial-mesenchymal, mesenchymal-epithelial, and endothelial-mesenchymal transitions in malignant tumors: An update. *World J Clin Cases* 2015; 3(5): 393-404 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i5/393.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i5.393

INTRODUCTION

Because of paucity of data on biological behavior of epithelial and mesenchymal malignant tumors, the process of metastasis is still so poorly understood that it is difficult to block it therapeutically. In recent years, one of the newest described mechanisms that seems to contribute to migratory and invasive properties of tumor cells is the epithelial-mesenchymal transition (EMT)[1-3]. Till now, it is known to be implicated in carcinomas and in some mesenchymal tumors, such as sarcomas and gastrointestinal stromal tumors (GIST)[1-21]. However, the molecular mechanisms underlying EMT and distant metastasis remain somewhat unclear.

In this review we intend to present the main characteristics of EMT in a logical manner, beginning with the basic molecular mechanisms and possibilities of its quantification on histological slides. Then, the particularities of EMT in several carcinomas and sarcomas are explored and a future perspective synthesized.

BASIC INFORMATION ABOUT EMT

Definition of EMT

EMT represents conversion of an epithelial cell in an elongated cell with mesenchymal phenotype, which can occur in physiologic and pathologic processes[22]. Being influenced by several biochemical mechanisms, EMT involves mainly loss of cell polarity, dissolution of cell membrane, disintegration of cytokeratin filaments and desmosomes, and migration of the newly formed cells that have a mesenchymal phenotype[23,24]. Besides increase in migratory capacity, cell resistance to apoptosis also increases with associated cytoskeletal disorders and excessive deposits of extracellular matrix components[23-25].

Classification of EMT

Based on the pathogenetic role, three types of EMT are described. Type 1 EMT, involved in embryogenesis and organ development, mainly designed to generate the primary mesenchyme[23,26]. The first report on type 1 EMT in vertebrata embryogenesis was published in 1995[22].

Type 2 EMT is involved in non-neoplastic processes and genesis, and recruitment of fibroblasts in chronic inflammation-related tissue repair, wound healing, tissue regeneration and fibrosis[23-27].

Type 3 EMT represents cytoskeleton disorders that result from dissolution of cell-cell adhesion, cell scattering and loss of apical-basal cell polarity in malignant tumors[1,2,23,28].

EMT and endothelial-to-mesenchymal transition in non-neoplastic lesions

Type 1 EMT plays important roles in embryo implantation, embryogenesis and organ development[23,26]. At the same time, the reverse mesenchymal-to-epithelial transition (MET) is necessary to generate a secondary epithelium of kidney and other organs[23,24]. The secondary epithelia can remain in this status or can be re-differentiated into several structures such as fibroblasts, connective tissue, astrocytes, adipocytes chondrocytes, osteoblasts, and muscle cells[23,24]. The EMT-to-MET switch is mediated by several genes such as paired box2 (*Pax2*), Wilms tumor1 (*Wt1)*, and *Bmp7*[23]. In the embryonic heart, during formation of the atrioventricular/endocardial cushion, EMT is induced during somitogenesis by the HGF (hepatocyte growth factor) and its c-Met/Crk proteins, secreted by mesenchymal cells[23-25]. EMT is mandatory for the formation of epicardium-derived progenitor cells and their migration in the sub-epicardial space and it is mediated by several factors, such as transforming growth factor-β 1 (TGF-β1) and myocardin[29].

Type 2 EMT was described not only in physiologic repairing processes but also in renal, pulmonary, and hepatic fibrosis and even in pathogenesis of fistulae in Crohn's disease[23-27]. In renal fibrosis, about 35% of fibroblasts originate from tubular epithelial cells, which are detached and mobilized through a damaged basement membrane, and they are responsible for specific lesions such as chronic glomerulonephritis, diabetic nephropathy, lupus nephritis, and Alport syndrome[24]. The other fibroblasts are recruited from bone marrow (15%) and renal stroma (50%)[24]. In cardiac fibrosis, TGF-β1-mediated genesis of fibroblast from damaged vessels-endothelial cells, known as endothelial-to-mesenchymal transition (EndMT), was suggested as the predominant event, as it is involved in cardiac embryogenesis too[25]. In renal fibrosis, it is observed that the EMT-related fibroblasts are SMA-positive myofibroblasts; it is suggested that a combined EMT-EndMT is the key event of any fibrosis[24].

Because TGF-β action and EndMT are experimentally

inhibited and E-cadherin expression is restored in epithelial cells by bone morphogenetic protein 7 (BMP-7), it is supposed that systemic administration of this protein may delay progression of cardiac fibrosis and prevent chronic rejection of transplanted heart[25], besides delaying renal failure[24]. Rapamycin may also ameliorate the amount of fibrotic tissue by blocking the mTOR signaling[30].

EMT in malignant tumors (type 3 EMT)

In malignant tumors, EMT-related invasion and migration of tumor cells in blood flow is associated with poor prognosis, high metastatic rate, and low disease-free survival time[1-21]. In cancer cell lines, EMT is considered when the cells gradually change from epithelial to migratory elongated spindle-like mesenchymal cells with fibroblastic morphology; expression of epithelial markers decreases as tumor cells progressively display the mesenchymal markers[1,2]. Gaining mesenchymal signature facilitates detachment of tumor cells, accompanied by proteolytic digestion of basement membrane, vascular invasion (intravasation), and migration of circulating tumor cells to distant sites[2,3,24].

As not much is known about the cytoskeleton of detached and circulating tumor cells, it is supposed that EMT produces detyrosination of some proteins, such as α-tubulin (storage of Glu-tubulin)[28]. This process, a vimentin-dependent one, induces formation of tubulin microtentacles (microtubules-based membrane protrusions), which are distinct from the well-known actin-based prolongations (lamelipodia, filopodia) and confer on the circulating tumor cells with mesenchymal phenotype the capacity of attachment at the endothelial layers and further extravasation at distant sites[28]. Moreover, Glu-tubulin increases the intravascular life of tumor cells, from 3-5 min to about 16 h, favoring cell extravasation[28,31].

At the same time, in distant metastatic tissue, a reverse MET can be acquired (EMT-MET switching) according to the metastatic microenvironment; regaining of epithelial features allows re-proliferation of tumor cells in these secondary-formed tumor clusters in lung and liver metastases, but not in bone metastatic tissue[2,3,15,18]. It is also worth mentioning that, in primary tumors, in parallel with EMT, the transformed tumor cells acquire a stem cell pattern or activate multidrug-resistant stem cells, and the converted mesenchymal cells that did not migrate in the blood flow are responsible for local recurrence, probably due to a reverse MET in the primary tumor, besides metastatic sites[18,32].

EMT MARKER PROTEINS

Literature describes several markers, which are involved in EMT. During EMT, E-cadherin expression is reduced to near-zero level, E-cadherin-to-N-cadherin (Neural cadherin) switch is installed and other EMT-related markers [vimentin, fibronectin, smooth muscle actin (SMA), desmin, Sox, SNAIL1/SNAIL, SNAIL2/SLUG, Axl, zinc finger E-box-binding homeobox 1 (ZEB1), Notch-1, v-ets erythroblastosis virus E26 oncogene homologue 1 (ETS1), fms-related tyrosine kinase 1 (FLT1), V-set and immunoglobulin domain-containing protein 1 (VSIG), stromelysin-3, Twist, FOXC2, HOXB7, ACTA2, platelet derived growth factor (PDGF), *etc.*] are overexpressed[4,11,32], predominantly at the invasive front[23]. Other epithelial cell-cell adhesion molecules such as claudins (types 3, 4, and 7), α-catenin, γ-catenin, occludin, desmoplakin and plakoglobin are also down-regulated in cells with mesenchymal signature[5,11,32]. Immunohistochemically, E-cadherin and catenins mark the cell membrane; N-cadherin, vimentin, and PDGF present a predominant cytoplasmic expression; Notch-1 and ZEB1 mark the nuclei, whereas SNAIL, SLUG, and Twist mark the cytoplasm, as well as the nuclei of the tumor cells.

It is important to note that some of the transformed cells present only mesenchymal phenotype, whereas other tumor cells display a dual epithelial-mesenchymal expression[32], also known as an amphicrine pattern[33]. As regards the stem cells with malignant potential, it is still unclear if they are identical to the cells with mesenchymal signature, or they represent two distinct cell types; they are marked by both mesenchymal markers and stem cell markers such as CD44 and ALDH (aldehyde dehydrogenase)[34].

SLUG is a zinc-finger transcription inhibitory protein, a member of the SNAIL family (SNAIL 1 and 2) that is primarily described in the neural crest and embryonic mesodermal cells; it also plays roles in type 1 and type 3 EMT[32-36]. SNAIL 1/SNAIL is a transcriptional hypoxia-activated protein that interacts with Wnt- and also with serine/threonine kinase receptor signalling pathways; the tumor cells' invasiveness and resistance to apoptosis are influenced by its overexpression in both tumor cells and stromal fibroblast[32,37]. SNAIL 2/SLUG is involved in cancer progression and suppresses E-cadherin, desmoplakin, and keratin-18 expression, but the exact mechanism is not known; it is supposed to interfere with the Wnt/GSK3β/β-Trcp1 pathway[4].

Vimentin is a mesenchymal marker that can be acquired during EMT but its expression is low and most difficult to be quantified, as compared with other EMT markers that indicate a mesenchymal-like phenotype[1].

The receptor tyrosine kinase Axl is an EMT marker whose mRNA expression is strongly correlated with vimentin. It is involved in EMT of breast, and pancreatic and lung cancers and is expressed more in mesenchymal than in epithelial lines[6-8].

Dismantling of epithelial cell membrane and remodeling of extracellular matrix are also influenced by matrix metalloproteinases (MMP-2, MMP-3, and MMP-9) that act as proteolytic enzymes and may link the EMT with increased invasion and metastasis, and shortened survival time in almost all types of human

cancer[23,24,38].

VSIG, also known as radioiodinated cell surface A33 antigen or glycoprotein A34, is a single-pass 387 amino acid membrane protein involved in cell-cell adhesion[39].

Cathepsin family (*e.g.,* Cathepsin Z located at 20q13.3, Cathepsin X, *etc*.) is also considered to be involved in EMT and to contribute to tumor metastasis through down-regulation of E-cadherin, α-catenin, and β-catenin, and up-regulation of vimentin, fibronectin, MMP-2, MMP-3, and MMP-9[38].

MOLECULAR FACTORS INVOLVED IN EMT

In the last few years, several research works were carried out to understand the mechanism of EMT in both carcinomas and mesenchymal tumors, but data are elusive.

As regards DNA, the next-generation sequencing-based methods proved that the genome-wide DNA methylation reprogramming is not involved in EMT; the progressive EMT and genetic disorders are rather related to altered histone modifications[1,9] and epigenetic mechanisms[11]. Recently, it is suggested that a 76-gene EMT-signature is involved in the metastatic process and that it influences the therapeutical answer of tumor cells[7], but the results are still confusing.

E-cadherin's transcriptional down-regulation is one of the key factors of EMT but other factors, such TGF-β also play important roles in these processes[1,9]. It is worth noting that there are no deletions or mutations of *E-cadherin* gene, but only epigenetic down-regulation or transcriptional silencing which allows its further re-expression in primary or metastatic tumors[18]. E-cadherin is codified by the *CDH1* gene; it interferes with other EMT-related genes, such as vimentin, fibronectin 1 *(FN1), CDH2* (which codifies the protein N-cadherin), *ZEB1* (target of SNAIL), *ZEB2/SIP1*, *K-ras, integrin, Notch,* and *Axl* (a tyrosine kinase inhibitor)[7]. The cancer cell lines with epithelial phenotype are characterized by overexpression of other genes such as *claudins 4* and *7, MUC1, RAB25, SPINT2,* and *ERBB2*[7]. However, some of these molecular markers (SNAIL 1/2, ZEB 1/2, E47) are direct inhibitors of the transcription of *E-cadherin* gene, whereas Twist, Goosecoid, FoxC2, and E2.2 are indirect E-cadherin inhibitors[11,16,17]. At the same time, SNAIL 1/2, ZEB1/2, and Twist are activated by TGF-β, a cytokine, secreted by mesenchymal stromal and inflammatory cells, whereas N-cadherin is activated by Twist[32,40]. If we take into account that TGF-β also induces renal EMT, besides mobility of endothelial cells, followed by EndMT and subsequent renal and cardiac fibrosis[24,25], and regulation of matrix accumulation[32], then we can suppose that stromal fibrosis is generated by an interaction between EMT and EndMT. Moreover, TGF-β is a tumor suppressor in early-stage carcinomas but induces tumor cells' proliferation, migration, and metastases, in advanced stages[32].

Epidermal growth factor (EGF) is a mitogenic factor involved in tumor proliferation and aggressiveness, through its receptor, EGFR. Although *EGFR* and *K-ras* genes' status are used as indicators for targeted therapy with anti-EGFR drugs of several tumors, such as pulmonary and colorectal cancers, the origin of this factor or its prognostic role is not firmly proved. As regards the role of this pathway in EMT, it seems that the Ras-activated/SNAIL/SLUG pathway interacts with FoxC2 and the phosphatidylinositol 3'-kinase (PI3K)/Akt/mTOR axis, at least in the case of colorectal cancer[40].

One of the newest factors found as pivotal regulators of EMT and as negative regulators of E-cadherin are the post-transcriptional gene regulators microRNAs (miRs): miR-21, miR-26b, miR-29c, miR-31, miR-124, miR-212, and the five members of the miR-200 family (miR-200a, 200b, 200c, 141, and 429) with their most prominent gene targets *ZEB1* and *ZEB2* (also known as *SIP1* and *SFHX1B*)[2,10,11,17,18,21,40]. Their overexpression is believed to inhibit EMT in human carcinoma cells and to decrease tumor cell proliferation and migration in the blood flow[2,10,11,17,18,21]. EMT-related interaction of miR-200 family with *p53* gene is also assumed[19].

Their elective affinities for specific types of cancer cell lines are described below.

EMT, ENDMT AND ANGIOGENESIS

The data available on the link between EMT and angiogenesis is so scattered that it does not elucidate if the link is any possible important therapeutic implications. For example, the MMP family members (MMP-2, MMP-3, and MMP-9), which are released by fibroblasts and macrophages, are known to influence both EMT and angiogenesis[23,38], though not proved to mediate the interaction among these two processes. At the same time, EMT, activated *via* SNAIL/Twist, is responsible for the attachment of tumor cells to the activated endothelial cells *via* α-tubulin detyronisation[28]. The transcription factor Twist, a target gene of SNAIL, is reportedly implicated in embryogenesis (EMT type 1), but its hypoxia-activated over-expression is also proved in several human carcinomas[41]. However, its role in carcinogenesis and metastasis is not well defined. In experimental models, Twist inhibition does not decrease tumor cell proliferation rate, but reduces circulating tumor cells significantly[28]. In cancer tissues its expression is increased at the invasion front[41]. Based on these observations, it is supposed that Twist increases direct invasion of tumor cells in the surrounding tissues, and cell penetration inside the endothelial layer, but does not influence tumor growth[28,41]. As a therapeutic target, its inhibition may decrease the rate of metastasis.

Because the endothelium of pre-existing mature vessels, involved in angiogenesis of both epithelial

and mesenchymal tumors, is activated by CD105 (endoglin)[42,43], new studies are necessary to prove if the Twist-attached endothelial cells are also CD105 positive or other mechanism is involved in this attachment.

Most recently, a possible TGF-β1 mediated-EndMT of intratumor endothelial cells is reported[44]. It relates to the cases in which the intratumor endothelial cells lose the cell-cell junction and immunoexpression of CD31 and gain positivity for mesenchymal markers such as α-SMA (smooth-muscle actin)[44]. It is important to note that the endothelial cell-specific miR-302c is proved to inhibit this EndMT, but decreases the tumor cell motility[44]. In previous researches, our team observed inconstant positivity of Kaposi sarcoma cells[42] and gastric tumor cells for the endothelial marker CD105 (Gurzu *et al*[42], personal communication), which could indicate even a possible epithelial-to-endothelial transition or an incidental positivity of epithelial cells with mesenchymal signature.

A relationship between inflammation, angiogenesis and EMT is suggested by COX-2-mediated EMT, which is stimulated by TGF-β through a PGE2-dependent mechanisms[23,35], and also by an MMP-related signaling[23].

Other arguments that favor a link between angiogenesis and EMT-mediated metastasis are that, on the one hand, the endothelial cell-secreted factors, such as EGF, increase cell mobility and inhibit apoptosis, whereas, on the other hand, the EGF-related EMT is more prominent in the perivascular area, but the intraluminal tumor cells exhibit an epithelial phenotype[45]. It is important to prove that the involved vessels present CD105-positive activated endothelium. EGF seems to also induce a stem-like phenotype of EMT-transformed tumor cells (in both intra- and perivascular tumor cells) and SNAIL positivity through PI3k-Akt pathway, whereas down-regulation of EGF in endothelial cells decreases tumor growth rate and the immunoexpression of stem cell markers[45]. The data suggests that antiangiogenic therapy should be based on inhibition of tumor cells from secreting pro-angiogenic substances such as vascular endothelial growth factor-A (VEGF-A), and of the activated endothelial cells to synthesize pro-angiogenic/pro-stem/pro-EMT substances such EGF[45].

EMT IN GASTROINTESTINAL CARCINOMAS

EMT in gastric carcinoma

Fewer than 50% of GC cells express E-cadherin, and SLUG cytoplasmic positivity is reported in about 30% of the cases[36]. Most of the E-cadherin negative cases are hereditary[46] or acquired diffuse/poorly-cohesive gastric carcinomas (GCs)[47]. The 5-year survival rate is strongly related to E-cadherin expression, which is 88.6% in positive cases and 63.5% in cases with loss of E-cadherin expression[36]. As regards SLUG immunoexpression, the 5-year survival rate is about 78% in negative cases and only 54.3% in SLUG positive-GCs[36].

Independent of the histologic type, E-cadherin negative/SLUG positive-GCs are associated with higher risk for lymph node and distant metastases, as compared to the E-cadherin positive/SLUG negative-GCs[36]. The reverse correlation of E-cadherin/SLUG is observed in only 75.5% of GCs, while the other cases present double positivity for E-cadherin and SLUG[36]. In E-cadherin positive-GCs, association of SLUG positivity induces a lower survival rate, as compared to SLUG negative cases (92% *vs* 46.7%)[36].

In Chinese patients, the cell-cell adhesion molecule VSIG is also reduced in GC samples, as compared with paired gastric mucosa, whose decreased levels are proved with PCR, western-blot and IHC examinations[38]. Using IHC methods, total loss of VSIG was found in more than 50% of the cases, especially in GCs with distant metastases, and decreased levels in 46% of them, which are strongly correlated with the overall survival rate and disease-free survival[38].

Cathepsin X expression was detected in *Helicobacter pylori*-infected normal gastric mucosa, which was 3-12 fold up-regulated in 68% of metastatic GCs with EMT, especially in the cases with an intestinal type architecture[38,48].

Twist is especially overexpressed in diffuse type GCs and is correlated with N-cadherin expression; both of them are down-regulated in intestinal type-GC, as compared to paired normal gastric mucosa[49]. N-cadherin is expressed in chief and parietal cells of the normal mucosa. Based on these observations, it was suggested that E-cadherin-to-N-cadherin/Twist switch is specific for carcinogenesis of diffuse type GC, whereas intestinal-type GC is more related to TGF-β-dependent ZEB2 (SIP1) up-regulation/SNAIL weak down-regulation/E-cadherin loss[49]. At the same time, release of TGF-β, which activates the EMT-inductors SMAD 2/3 and PI3K/Akt signaling, is caused by extreme hypoxia[50].

Among the miR-200 family members, miR-141 is reported to have been down-regulated in about 80% of primary GCs, as compared with matched normal gastric mucosa and also in several human gastric cancer cell lines[11,18]. Its overexpression inhibits proliferation of GC cells, but decreased level of miR-141 favors occurrence of distant metastases[18].

As regards the therapeutic approaches, EMT may induce in GCs a Wnt/β-catenin signaling-dependent resistance to adriamycin, which can be reverted by therapy with the proton pump inhibitor pantoprazole[51].

EMT in colorectal carcinoma

In advanced-stage colorectal carcinomas (CRCs), a predominant-epithelial phenotype was reported from the center of primary tumor, and mesenchymal features in the cells from the invasion front[11,20]. As regards SLUG expression, its positivity induced in CRC cells an EMT-related aggressive behavior, but no relation could be proved between E-cadherin and SLUG expression[36,52]. Aggressivity was also induced

by SLUG overexpression in fibroblasts of the tumor stroma[37].

Increased E-cadherin and decreased vimentin-expression were noted in liver metastases, as compared with the primary tumor[11]. This immunophenotype, which indicates an EMT in primary tumor, predominantly in the invasive areas, and a reverse MET in hepatic metastases, seems to be related to altered functions of miRNAs such as miR-21[40], miR-29c[2], miR-31[40], miR-212[10], and some members of miR-200 family[11].

The miR-21 and miR-31 are particularly considered related to the TGF-β-pathway, because of their being targeted by the T lymphoma and metastasis gene 1 (*TLAM1*); their down-regulation increases CRC cells motility and invasion[40].

The miR-29c is down-regulated in primary CRC tumor cells with high invasive potential and re-expressed in hepatic metastases[2]. In CRCs lines, miR-29c decreased the proliferation, migration and metastatic potential of tumor cells, negatively regulated the Wnt/β-catenin signaling pathway and inhibited EMT *via* PI3K/AKT and GSK-3β/β-catenin signaling[2,40]. Immunohistochemical examinations showed increased nuclear β-catenin expression, loss of E-cadherin, up-regulation of T-cell factor/lymphoid enhancing factor transcriptional activity, and increased cell migration and invasiveness in miR-29c knockdown CRC cells, whereas overexpression of miR-29c induced a nuclear-to-cytoplasmic shift of β-catenin[2]. In matched liver metastastases foci, elevated levels of miR-29c induced MET[2]. In CRC, the two target genes of miR-29c and EMT-MET switch are the protein tyrosine phosphatase type IVA 1 and guanine nucleotide binding protein alpha13[2].

Overexpression of miR-212 seems to be responsible for inhibition of CRC cells proliferation; besides, by delaying their migration in blood flow, it becomes protective for both hepatic and lung metastases[10]. On the other hand, low level of miR-212 associates with overexpression of manganese superoxide dismutase, which mediates the EMT of CRC cell lines and induces a more aggressive tumor phenotype and a shorter survival rate of patients diagnosed with CRC[10].

In metastatic CRC of miR-200 family members, the miR-141 and miR-200c, mapped to chromosome 12, were found to be overexpressed in liver metastatic tissue, as compared with primary tumor cells[11]. Owing to gradually decreasing expression of miR-200c in tumor cells, as compared to adjacent normal colonic mucosa, and also in the tumor invasion front, it was found that this molecular factor, which is re-expressed in liver metastases, induces cell proliferation but suppresses cell invasion and migration[11]. On the other hand, high level of miR-200c/141 promoter region in CRC cell lines is associated with epithelial signature, resulting in up-regulation of E-cadherin, down-regulation of vimentin expression, and lower risk for distant metastases[11].

The other two members of miR-200 family, miR-200b and miR-429, which are mapped to chromosome 1, do not influence the EMT in CRC cell lines; miR-200b, but not miR-429, is down-regulated in liver metastatic tissue, as compared with primary tumor cells[11]. However, the most significant member of miR-200 family, involved in EMT and metastatic process of CRC, is miR-200c, which exerts negative regulation of its gene targets *ZEB1, ETS1* and *FLT1*[11]. Although the miR-200 family interacts with *p53* gene in other cancer cell lines[19], no correlation between mi-R200c and p53 was found in CRC[11].

Based on the above-mentioned expression of mi-RNAs, the most recent studies suggest that these molecular factors may serve as potential diagnostic markers and targets for therapeutic strategies in patients with metastatic CRC[2,10,11]. Further *in vivo* studies are necessary to confirm this supposition and to emphasize the relationship between mi-RNAs and other genes such as *p53* and mismatch repair (*MMR*) genes.

As regards the circulated CRC cells, it was proved that, inside the blood vessels, disruption of actin filaments increased cell adhesion, whereas destabilizing cytoskeletal microtubules prevented cell attachment and tumor intravasation at the junctions located between endothelial cells[28,53].

EMT IN PANCREATIC CANCER

In pancreatic cancer cells, EMT is induced by several molecular factors, such as the receptor tyrosine kinase *AXL*[7,8], loss of FOXA1/A2 expression[17], and dysregulation of miR-200 family[17], but this event is not so frequent as the other carcinomas are[17,54]. Moreover, loss of E-cadherin expression, a result of *E-cadherin* gene methylation, is correlated with histological grade of differentiation, which is noticed in about one quarter of well-differentiated ductal adenocarcinomas, half of the poorly-differentiated ones and few or none of the non-cohesive (undifferentiated and signet ring cell carcinomas) cases[17,55]. In chemoresistant well/moderately-differentiated pancreatic adenocarcinomas, E-cadherin loss and a membrane-to-cytoplasm shift of β-catenin expression pattern were noticed in the non-cohesive foci[17,55]. N-cadherin does not mark the normal acinar, ductal, and pancreatic islets; it is expressed in more than 50% of pancreatic carcinomas and is more intense in infiltrating cells from the invasive tumor front, independent of the tumor stage[56]. As regards the other IHC markers that indicate a mesenchymal-like phenotype of the epithelial tumor cells, SLUG was reportedly expressed in half percent of the cases, while SNAIL 1 marked 75% of pancreatic carcinomas. SNAIL 1 presents predominant positivity in the ductal cells of the tumor center and in undifferentiated carcinomas, as compared with the more cohesive carcinomas, whereas SLUG is more intense in the invasive front[56]. Moreover, 50% of the pancreatic carcinoma cells present double positivity for SNAIL and E-cadherin[56]. Twist is negative in 97% of pancreatic carcinomas and its expression is

10-fold higher after exposure of pancreatic cell lines to hypoxia for 48 h[56].

Hypomethylation and overexpression in pancreatic carcinomas cells and elevated serum levels of miR-200a and miR-200b are associated with retention of E-cadherin expression, as also with epigenetic silencing through methylation of *ZEB2 (SIP1)* gene[11,17]. As SIP1 expression is absent in most of the pancreatic cancers, it seems that E-cadherin dysregulation is rather related more to miR-200a and miR-200b than to *SIP1* gene[17]. The serum levels of these miR-factors were noticed to be elevated in patients with chronic pancreatitis, as compared with healthy controls[17]; they can be used as a screening parameter to identify patients with chronic pancreatitis and high risk for ductal adenocarcinoma.

EMT IN HEPATIC CANCER

EMT in hepatocellular carcinoma

The EMT-angiogenesis-stem cell-like phenotype crosstalk is supposed as a key factor of hepatocellular carcinoma (HCC), based on the fact that the number of tumor-associated macrophages, which secrete TGF-β and are involved in angiogenesis, is directly correlated with the number of activated stem cells, as well with EMT-dependent tumor cells invasiveness[57]. Just as other carcinomas do, TGF-β induces EMT through E-cadherin down-regulation and up-regulation of several factors, including twist, N-cadherin, and SNAIL[58].

Cathepsin Z was also reported to be up-regulated and involved in EMT and metastasis of about 43% of HCCs; its increased level was correlated with high serum level of α-fetoprotein and also with poorer 5-year and 3-year survivals[38].

Down-regulation of miR-124 and miR-26b was reported in HCC cells, in cases with a more aggressive behavior, whereas their overexpression suppressed tumor cell proliferation, inhibited EMT and prevented cytoskeletal disorders through blocking formation of stress fibres, filopodia and lamellipodia[21,58]. In HCC, the two target oncogenes, negatively regulated by miR-124 are ROCK2 and EZH2[21].

As regards the therapy, the advanced-stage HCC is currently treated with the multityrosine kinase and angiogenesis inhibitor, sorafenib. Because MET is also involved in metastatic behavior of HCC, the new MET-inhibitor, Tivantinib (ARQ 197), is being tested in the ongoing trials, as a second-line therapy of HCC[59].

EMT in cholangiocarcinoma

Based on the scanty data available, it is believed that the EMT in cholangiocarcinomas is regulated mainly by the transcription factors ZEB2 and S100A4, which are modulated by TNF-α (tumor necrosis factor)[60]. TNF-α also stimulates TGF-β activity[60] which in turn activates other EMT-inducers, such Twist, N-cadherin, and vimentin[61]. Just as other carcinomas do, EMT induces a high rate of metastasis and a short overall survival rate[60], and thus help in blocking TGF-β by BMP-7[61].

EMT IN LUNG CANCER

Lung cancer is one of the tumors that is known for rapid progression accompanied by a large number of genetic and epigenetic changes[1,7]. EMT is identified in about 23% of non-small cell lung cancer (NSCLC) lines and in one third of the patients with metastatic lung cancer. Based on the histology of the cell lines, the squamous pattern associates with a mesenchymal phenotype in about 50% of lines; adenocarcinomas are characterized mostly by epithelial phenotype, and the other patterns (neuroendocrine, large cell carcinoma) by only mesenchymal signatures[7]. Although it was experimentally proved that DNA methylation is not involved in EMT of lung cancer cell lines, after transition, the expression of some DNA-related enzymes, such as methyltransferases 1, 3a, and 3b, and ten eleven translocation (TET1), were significantly altered and some histone methylation was changed[1].

In A549 lung cancer cell lines, during TGF-β-dependent EMT, miRNA relative expression of E-cadherin was progressively lost and the most significant overexpression was attributed to N-cadherin, followed by SNAIL 1 and vimentin[1]. Maximum level of N-cadherin was observed after 96 h of incubation, with significantly increasing levels from 24 to 96 h[1]. SNAIL 1 becomes significantly expressed after 4-12 h of incubation, followed by progressive overexpression in the next 24-96 h; its level is quite low compared to that of N-cadherin[1]. The overexpression of vimentin does not differ significantly at 12, 24, and 96 h. Moreover, its level is maintained at a constant value, which is similar to the levels of SNAIL 1 and N-cadherin, quantified at 10-12 h of incubation[1]. In NSCLCs, SNAIL 1 and vimentin's expressions are reversely correlated with the miR-30a level[62].

In contrast, another experimental study proved that 76 genes were involved in EMT, the main ones being *CDH1* and *vimentin,* followed by several EMT transcription factors such as *FN1, MMP2* (matrix metalloprotease-2), and *ZEB1*; the gene *CDH2* was identified inconstantly and was not included in the EMT molecular signature[7]. In mesenchymal cells from NSCLC lines, *K-ras* mutation, loss of *STK11 (LKB1)*, and *SMARCA4* mutations/deletions are more frequent than in epithelial lines; the last ones rather show CDKN2A and CDKN2B loss[7].

In lung cancer cell lines, EMT also induces down-regulation of some histones methylation, such as DNMT1, DNMT3a, DNMT3b, H3K4me3, H3K9me2, TET2, and TET3, and up-regulation of TET1, and H3K36me3[1].

As regards the prognosis, retention of the epithelial phenotype, proved by E-cadherin positivity in the tumor cells, was associated with longer time to progression

and a longer survival, independent of the mutation status of the *EGFR* (epidermal growth factor receptor) gene[7,12]. *EGFR* wild type/*K-ras*-wild type molecular profile seems to indicate a less aggressive NSCLC[7].

EMT as the therapeutic target in lung cancer

Patients with *EGFR*-mutated NSCLCs showed significant improved outcome after having been introduced to anti-EGFR drugs, such as erlotinib (Tarceva)[12] and gefitinib[13]. However, the *EGFR* wild type and *K-ras* mutated NSCLCs are resistant to EGFR inhibitors, and the data about the effect of these targeted drugs on *EGFR* wild type/*K-ras*-wild type patients is scanty[7].

In NSCLC cell lines, EMT was proved to induce resistance to erlotinib, whereas resistance to Akt/mTOR and PI3K/Akt1 pathway inhibitors was seen in both EGFR wild-type and mutated tumors with mesenchymal signature[7]. However, the mesenchymally-transformed cells are not pan-resistant; they are sensitive to sorafenib and the commonly used chemotherapics such as cisplatin, gemcitabine, vinorelbine, pemetrexed, docetaxel, paclitaxel, and platinum-doublets[7].

On the one hand, retention of the epithelial phenotype (high E-cadherin and low vimentin/fibronectin) is associated with erlotinib sensitivity, even in wild-type *EGFR* and wild-type *K-ras* NSCLCs[7,14]. It was then suggested that E-cadherin's diffuse positivity could be used as an indicator of erlotinib/gefitinib sensitivity, especially in wild-type cases[12]. On the other hand, in culture cell lines with mesenchymal signatures, which are insensitive to anti-EGFR drug gefitinib, restoration of the epithelial phenotype could induce re-sensitivity to this drug[7,13].

The level of the receptor tyrosine kinase Axl increases in mesenchymal NSCLC lines, because the cells, having a dose-dependent synergistic effect with erlotinib, are sensitive to the Axl inhibitor SGI-7079; the maximum synergy level was obtained at high concentrations for both erlotinib and SGI-7079[7].

Based on the foregoing data, a 76-gene EMT signature (including the genes *CDH1, CDH2, vimentin,* and *FN1*) was experimentally designed to predict 8-wk disease control in NSCLC-patients treated with erlotinib, independent of their molecular profile[7]. However, the exact underlying biological mechanism is not fully understood and hence deserves further investigation.

EMT IN BREAST CANCER

EMT in breast[4] is dependent on reducing mi-RNA expression of E-cadherin, which is related to *CDH1* promoter methylation, but not to mutational inactivation[9]. Just as the other carcinomas are, E-cadherin is re-expressed in hepatic metastatic tissues[11], and local recurrence may be dependent on the EMT-MET switch in the primary tumor[32].

Claudins (types 1, 3, 4, and 7) were described to be down-regulated in certain types of breast cancer, such as fibromatosis-like metaplastic carcinoma, a low-grade *EGFR* (exons 18, 19, 20, and 21) wild-type basal-like spindle cell carcinoma with predominant HER-2 and hormone receptors negativity, diffuse positivity for basal keratins and focal vimentin and E-cadherin expression[5]. Fibroblastic-like phenotype of breast carcinoma cells (with negative or low E-cadherin expression), intense angiogenesis (indicated by overexpression of VEGF-A) and chromosome instability can also be induced by twist, *via* Wnt/β-catenin[32,63].

SNAIL 1, known to induce invasiveness in several human cancers, seems to be a hypoxia-protective factor for breast tumor cells, *via* β-catenin activation, which regulates expression of HIF-1 (hypoxia-inducible factor 1)-dependent genes, besides being an inductor of hormone-resistance[32,63]. Based on these facts, it is suggested that SNAIL 1 may be used as an indicator of response of breast cancer to antiangiogenic therapy[64].

Twist expression was proved to be up-regulated in tandem with tubulin detyrosination, in both invasive ductal[28] and lobular-type adenocarcinomas[41], at the invasion front[28,41]. This interaction, which is mainly twist-dependent, seems to promote penetration of tumor cells through the endothelial cell layer, endothelial engagement and, probably, consecutive angiogenesis that favors metastasis[28].

EMT is also induced by the receptor tyrosine kinase *AXL*[6,7], Pyk2 and TGF-β *via* SNAIL 1/2 and ZEB 1/2[32], and it seems to have particular pathways in triple negative breast cancers[32].

As regards miRNA, the miR-200 family-mostly miR-200a/b/c, miR-141, and miR-429-is considered to influence EMT of breast cancer cells with inhibition of the E-cadherin repressors ZEB 1/2[32,65]. An interaction between *p53* gene and miR-200c is also defined in breast cancer cell lines[19]. The miR-21s also influences the EMT phenomenon *via* tumor suppressor gene PTEN and AKT/ERK1/2 axis[32,66]. Besides down-regulation of cyclin-dependent kinase (CDK8), β-catenin targeted-miR-26b is the other reported negative prognostic factor in breast cancer[58,67].

EMT is reported to be involved in breast cancer resistance to tamoxifen; the most down-regulated factor is the methaderin-targeted miR-375[68], whereas miR-519a is up-regulated in tamoxifen-resistant breast cancer cell lines with mesenchymal-like signature[69]. Re-expression of miR-375 and inhibition of miR-519a might serve as potential therapeutic approaches for estrogen receptor-positive breast carcinomas[68,69]. It was also experimentally proved that some contraceptive pills, such as centchroman, may be used to inhibit EMT and to play a dose-dependent antiapoptotic and antiproliferative role in human breast cancer cells, *via* down-regulation of HER2/ERK1/2/MMP-9 signaling[70].

EMT IN PROSTATIC CANCER

Prostatic carcinomas have a predilection for bone metastases, the metastatic cascade being also related

to EMT that is linked with stem cell signature of the prostatic carcinoma cells[15]. Although vimentin and ZEB 1 contribute to EMT, the most involved marker that plays a role in bone metastasis seems to be Notch-1[15].

In liver metastases, prostate carcinoma cells are bound to hepatocytes in an E-cadherin-dependent manner[18]. In primary tumor tissues, EMT is characterized by activation of EGFR and subsequent down-regulation of E-cadherin, whereas, in liver metastases, down-regulation of EGFR signaling induces re-expression of E-cadherin and cell-cell adhesion[18]. In bone metastatic tissue, E-cadherin remains down-regulated and Notch-1 is up-regulated[15].

EMT AND MET IN MESENCHYMAL TUMORS

EMT and MET in sarcomas

Inhibiting MET is one of the therapeutic goals currently being tested in human sarcomas. However, because of the aberrant expression of the EMT markers noticed in many mesenchymal tumors, most of the researchers believe that EMT is involved in grade of recurrence, metastasis rate and overall survival rate[71-75]. To our knowledge, it is more about MET than EMT, but the molecular aspects are neither well explored nor well defined.

In chondrosarcomas, CXCR4 and survivin were tested as candidates for molecule-targeted therapy, and they were found expressed in more than 80% of chondrosarcomas. Besides inducing SNAIL and N-cadherin up-regulation, they are directly correlated with recurrence rate, *via* MEK/ERK and PI3K/AKT signaling[73].

In osteosarcoma cell lines, HIF-1α-mediated hypoxia induces increased level of E-cadherin and decreased vimentin expression. This aberrant pattern is associated with a higher proliferation rate and increased invasivity of the osteosarcoma cells that can be inhibited by resveratrol[74], which has an antiangiogenic effect due to increased nitric oxide production in endothelial cells[76].

In neuroblastomas, several EMT pathways are up-regulated; EMT induces not only aggressiveness but also chemoresistance to doxorubicin[75].

EMT and MET in gastrointestinal stromal tumors

Although they are mesenchymal tumors, one third of GIST cells are proved to express not only the mesenchymal markers such as vimentin and SNAIL, but also as being positive for the cell-cell adhesion molecule E-cadherin and AE1/AE3 keratin[71,72]. Moreover, SNAIL-positive/E-cadherin negative GISTs, independent of vimentin expression, presented a higher risk for distant metastases[71] and keratin/E-cadherin positive-cases were predominantly vimentin/N-cadherin negative[72]. Based on these facts, it is supposed that both EMT and the reverse MET processes are involved in GISTs metastasis.

The post-transcriptional factor miR-137, which is targeted by Twist1, enhances the epithelial cell morphology and it serves as an apoptosis inductor, decreasing GIST cell motility[72]. In conclusion, miR-137 induced-EMT seems to indicate a lower risk for distant metastases and hence may be used as a potential therapeutic tool.

SUMMARY AND FUTURE PERSPECTIVES

Although the literature provides several new insights into EMT of tumor cells, supplementary molecular exploration is necessary for therapeutical reducing the rate of metastasis. The literature review shows that several factors are indeed involved in EMT, most of them having prognostic and/or predictive value. However, the features relating specifically to organ-related carcinomas need further elucidation, because most papers dealing with this subject contain no specific and valuable data.

If EMT is indeed involved in the resistance of tumor cells to specific drugs, such as anti-EGFR substances, tamoxifen, and classic chemotherapics, identification of transition pathways could be of immense help in evolving an appropriate targeted therapy for both carcinomas and malignant mesenchymal tumors, including GISTs.

Additional studies of complex molecular profiling are necessary to elucidate the particularities of EMT in terms of histological type and localization of the tumor and angiogenesis-EMT interaction. Complex studies should also take into account not only cases with E-cadherin loss, but also the particularities of those cases, which show focally decreased expression and aberrant immunohistochemical pattern. We believe that, in the near future, the particularities of EMT will be a very useful parameter for proper clinical follow-up, individualized therapy and a more refined molecular classification of malignant tumors.

Abstract

Coronal shear fractures of the distal humerus are rare, complex fractures that can be technically challenging to manage. They usually result from a low-energy fall and direct compression of the distal humerus by the radial head in a hyper-extended or semi-flexed elbow or from spontaneous reduction of a posterolateral subluxation or dislocation. Due to the small number of soft tissue attachments at this site, almost all of these fractures are displaced. The incidence of distal humeral coronal shear fractures is higher among women because of the higher rate of osteoporosis in women and the difference in carrying angle between men and women. Distal humeral coronal shear fractures may occur in isolation, may be part of a complex elbow injury, or may be associated with injuries proximal or distal to the elbow. An associated lateral collateral ligament injury is seen in up to 40% and an associated radial head fracture is seen in up to 30% of these fractures. Given the complex nature of distal humeral coronal shear fractures, there is preference for operative management. Operative fixation leads to stable anatomic reduction, restores articular congruity, and allows initiation of early range-of-motion movements in the majority of cases. Several surgical exposure and fixation techniques are available to reconstruct the articular surface following distal humeral coronal shear fractures. The lateral extensile approach and fixation with countersunk headless compression screws placed in an anterior-to-posterior fashion are commonly used. We have found a two-incision approach (direct anterior and lateral) that results in less soft tissue dissection and better outcomes than the lateral extensile approach in our experience. Stiffness, pain, articular incongruity, arthritis, and ulnohumeral instability may result if reduction is non-anatomic or if fixation fails.

Key words: Coronal; Shear; Fractures; Distal; Humerus; Management; Approach; Two-incision

Core tip: Coronal shear fractures of the distal humerus are rare, complex fractures that can be technically challenging to manage. Distal humeral coronal shear fractures may occur in isolation, may be part of a complex elbow injury, or may be associated with injuries proximal or distal to the

elbow. This article aims to summarize the classification, evaluation, management (including surgical approaches, techniques, and post-operative care), and complications of these complex fractures as well as give recommendations on the management.

INTRODUCTION

Coronal shear fractures of the distal humerus are rare, complex fractures that can be technically challenging to manage[1-3]. They usually result from a low-energy fall and direct compression of the distal humerus by the radial head in a hyper-extended or semi-flexed elbow or from spontaneous reduction of a posterolateral subluxation or dislocation[2,4,5]. Due to the small number of soft tissue attachments at this site, almost all of these fractures are displaced[2]. The incidence of distal humeral coronal shear fractures is higher among women because of the higher rate of osteoporosis in women and the difference in carrying angle between men and women[2,6-11]. Distal humeral coronal shear fractures may occur in isolation, may be part of a complex elbow injury, or may be associated with injuries proximal or distal to the elbow[2,6-10]. An associated lateral collateral ligament injury is seen in up to 40% and an associated radial head fracture is seen in up to 30% of these fractures[2,9,12]. Stable internal fixation restores articular congruity and allows initiation of early range-of-motion movements in the majority of cases[1-3]. Several surgical exposure and fixation techniques are available to reconstruct the articular surface following distal humeral coronal shear fractures. A lateral extensile approach and fixation utilizing countersunk headless compression screws placed in an anterior-to-posterior fashion are commonly used[1-3,7-10]. Stiffness, pain, articular incongruity, arthritis, and ulnohumeral instability may result if reduction is non-anatomic or if fixation fails[3]. We present several methods including a two incision method technique utilizing a direct lateral approach combined with a direct anterior approach. This paper aims to review the literature regarding distal humeral coronal shear fractures and to discuss approach and treatment techniques for these difficult fractures. The search algorithm and search criteria included any original and review articles on the topic of distal humeral coronal shear fractures.

CLASSIFICATION

Bryan and morrey classification

The most common classification of capitellar fractures is the expanded Bryan and Morrey's types Ⅰ-Ⅳ. Type Ⅰ (Hahn-Steinthal) consists of a large fragment of trabecular bone of the articular surface of capitellum and with little to no extension into the lateral trochlea. The type Ⅱ (Kocher-Lorenz) fracture is limited to the cartilaginous articular surface of the capitellum that may include a small fragment of subchondral bone. Type Ⅲ (Broberg-Morrey, Grantham) is a comminuted/compression fracture of the capitellum[13]. Type Ⅳ fracture, later described by McKee, is a shear fracture of the distal end of the humerus that extends in the coronal plane across the capitellum to include most of the lateral trochlear ridge and the lateral half of the trochlea[14].

Dubberley classification

More recent attempts at distal humeral fracture classifications have attempted to characterize capitellar fractures in a manner meant to direct surgical management and potentially predict outcome of injuries. Dubberley *et al*[9] classified capitellar fractures into three types. Type 1 involving primarily the capitellum with or without lateral trochlear ridge, described as a coronal shear fracture equivalent to Hahn-Steinthal. Type 2 is a fracture of capitellum and trochlea in a single piece where the fracture extends in the coronal plane across the capitellum to include most of the lateral trochlear ridge and the lateral half of the trochlea-essentially McKee's-described type Ⅳ Bryan and Morrey fracture. Lastly, type 3 involves fractures of both the capitellum and the trochlea as separate fragments. The fractures are further subdivided into type (A) or (B) depending on absence or presence of posterior condylar comminution, respectively[2,3,9].

Ring classification

Ring *et al*[8] also proposed a five-type system of capitellar fracture classification based on noted injury patterns given that isolated coronal shear fractures were described as rare[2,3,8]. The five types progressively include more distal humeral involvement beginning with Type 1, a coronal shear fracture comprised of single articular fragment that includes the capitellum and the lateral portion of the trochlea. Type 2 includes an associated fracture of the lateral epicondyle. Type 3 involves a further impaction of the metaphyseal bone behind the capitellum in the distal and posterior aspect of the lateral column. Type 4 adds a fracture of the posterior aspect of the trochlea. Finally, type 5 includes a fracture of the medial epicondyle[8].

Evaluation

Evaluation of a patient with a distal humeral coronal shear fracture involves clinical assessment and radiography[1]. A radiographic elbow trauma series consisting of AP, lateral, and radiocapitellar views as well as radiographic images of the wrist and forearm should be obtained requisitely[3]. The double-arc sign on lateral X-ray (Figure 1) of the elbow is pathognomonic of a fracture with substantial

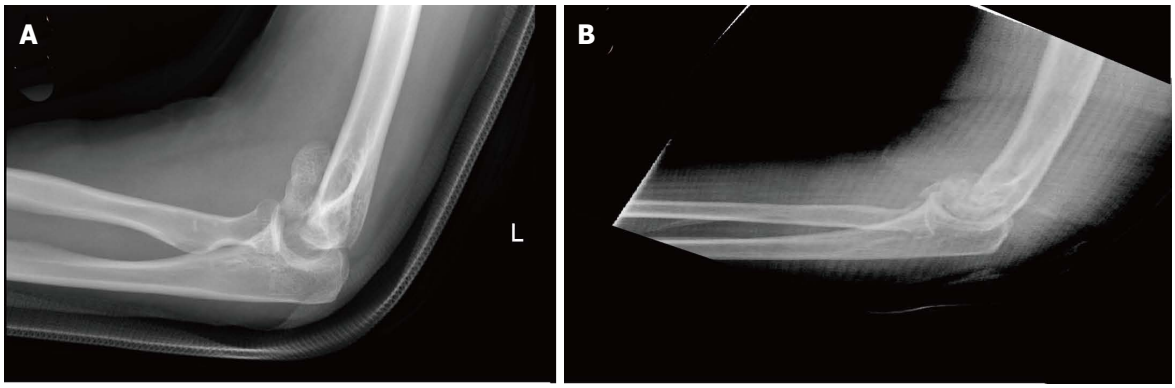

Figure 1 Lateral elbow X-ray of a two patients with distal humeral coronal shear fractures. A: Distal humeral coronal shear fracture-lateral view; B: The double-arc sign is seen, which signifies a McKee's type IV fracture in the Bryan and Morrey classification (involvement of both the capitellum and trochlea).

extension into the trochlea (McKee's type Ⅳ fracture in the Bryan and Morrey classification)[1,2,14]. However, X-rays only have a 66% sensitivity and a negative predictive value of only 63%-67% for detecting fractures beyond the capitellum[1,2,4]. For this reason, a preoperative CT scan of the elbow is recommended to better define the fracture and associated injuries and to guide operative planning[1,2,4,7,14,15]. A thorough neurovascular exam of the upper extremity, assessment of the forearm compartments, and a secondary musculoskeletal survey should always be performed in these patients[3]. Pain and guarding will limit assessment of elbow stability in the office setting or emergency department. As a result, thorough elbow assessment should be conducted at the time of surgical intervention under anesthesia[3]. In general, obtaining imaging of a joint above and below the level of injury will usually reveal bony injuries, but soft tissue injuries require a high index of suspicion and physical examination. This includes palpation of the entire extremity with particular focus on the distal radial ulnar joint and rotator cuff[3,16]. Follow-up examination and MRI scanning may be needed particularly of the shoulder[16].

Non-surgical treatment

Non-surgical management of coronal shear fractures of the distal humerus is reserved only for patients not medically fit for surgery. Otherwise, it is not recommended to treat these fractures non-surgically. Non-operative treatment would involve closed reduction with prolonged immobilization. Such measures often lead to suboptimal results and complications such as chronic pain, mechanical symptoms, and instability[1-3].

Surgical treatment

The goal of surgery is to restore articular congruity and obtain stable fixation, allowing for early range-of-motion to minimize the sequelae associated with non-op treatment: arthritis, pain, stiffness, and instability[2]. Surgical options include open reduction and internal fixation (ORIF), excision, total elbow arthroplasty, and arthroscopic reduction and fixation[2]. These types of surgical treatment and their indications are discussed individually below.

ORIF

ORIF results in good to excellent outcomes [measured by the Mayo Elbow Performance Score (MEPS)] in the majority of patients with coronal shear fractures of the distal humerus[1,2]. Based on many studies, the mean flexion-extension arcs after ORIF of a distal humeral coronal shear fracture range from 96° to 132°[1,3,6-9,17]. Superior results with ORIF are attributed to the fact that it allows anatomic reduction with stable fixation and thus initiation of early range-of-motion exercises[1].

ORIF involves opening the skin *via* a particular surgical approach (discussed in a separate section) to visualize and subsequently fix the fracture. There is currently no consensus on the optimal method of fixation for coronal shear fractures of the distal humerus. Countersunk headless compression screws (along with plate supplementation on the lateral column in cases of comminution extending beyond the articular surface) have been used with success[1,2,7,8,10]. Ruchelsman *et al*[3] recommend placing two screws in a divergent fashion for a Ring's type Ⅰ fracture to ensure rotational control, with sufficient screw spread to avoid iatrogenic fracture of the capitellum. Ring's Type Ⅱ and Ⅲ fractures (posteroinferior/lateral metaphyseal comminution and/or trochlear extension) often require supplemental fixation[3,7-9,18]. This can be accomplished using minifragment Synthes screws (West Chester, PA), threaded K-wires, and bioabsorbable pins for osteochondral capitellum and trochlea fractures < 5 mm, and pelvic reconstruction, precontoured or locking plates to buttress the lateral column in cases of extensive posterolateral comminution[3,8,9,18]. A biomechanical analysis by Elkowitz *et al*[19] has shown that placing headless compression screws in an anterior-to-posterior fashion is superior to placing cancellous screws in a posterior-to-anterior fashion. A follow-up study showed that Acutrak headless compression screws (Acumed, Hillsboro, OR) offered more stability than Herbert screws (Zimmer, Warsaw, IN) when placed

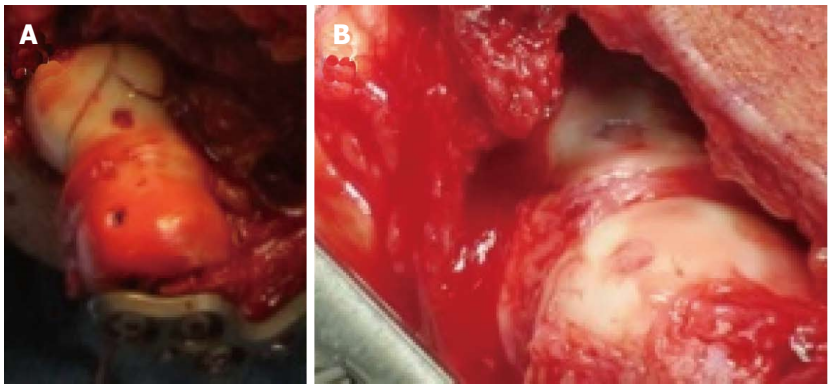

Figure 2 Headless compression screws. A: Holes left by headless screws in the articular surface. This patient later returned to surgery for a contracture release; B: At that time screw holes are shown to be covered with fibrocartilage.

in an anterior to posterior fashion[20]. Placing screws anterior-to-posterior is advantageous because it avoids disruption of the posterior soft tissues and allows better preservation of blood supply[1,21]. Sen *et al*[22] described placing screws in a lateral to anterior fashion to avoid posterior stripping, in addition to an anterior antiglide plate for the capitellum. When posterior comminution is present, supplemental fixation with bone graft might be necessary[2,7-9]. A recent study by Lee *et al*[23] found no significant difference in terms of clinical outcomes and complication rates between orthogonal and parallel plating methods for distal humeral fractures. However, the authors of the study state that orthogonal plating may be preferred in coronal shear fractures (where the posterior-to-anterior fixation can provide additional stability to the intra-articular fractures). Additional studies are needed to explore the association between plating methods and specific fracture patterns.

Our preferred method is to use headless compression screws placed in an anterior-to-posterior fashion with or without a lateral plate for the fixation of coronal shear fractures. There is a Grade C recommendation for this method[1]. Figure 2 shows the appearance of holes created by headless compression screws right after (Figure 2A) and several months after (Figure 2B) insertion.

Excision

Capitellar excision is another option in the treatment of distal humeral coronal shear fractures. This method is associated with complications such as substantial elbow instability, particularly when there is ligamentous injury or the trochlea is involved[1-3]. Grantham *et al*[24] and Mancini *et al*[25] reported poor clinical outcomes and valgus instability plus distal radioulnar joint subluxation, respectively, following capitellar excision. Excision remains an option for small, unfixable fractures, but ORIF should be utilized instead whenever possible[2].

Total elbow arthroplasty

Total elbow arthroplasty is a good option in select elderly patients with fractures deemed unrepairable (Figure 3)[2,26-29]. This is particularly relevant to patients with pre-existing arthritis of the elbow[1,30,31]. McKee *et al*[28] conducted a prospective, randomized, multicenter study in which they compared ORIF with total elbow arthroplasty in forty patients over the age of sixty-five years with displaced, comminuted, intra-articular fractures of the distal humerus. They reported better functional outcomes at two years post-operatively in the group with total elbow arthroplasty based on MEPS and DASH scores. Furthermore, five out of twenty patients (25%) in the ORIF group had to undergo intra-operative conversion to total elbow arthroplasty due to extensive comminution and an inability to achieve stable fixation.

When acute total elbow arthroplasty is anticipated or being considered, it is critical to avoid the olecranon osteotomy operative approach (discussed in a separate section). This approach compromises fixation of the olecranon component and is contraindicated for total elbow arthroplasty[1,28]. Reichel *et al*[29] reported a case in which an ORIF had to be immediately converted to a total elbow arthroplasty following an olecranon osteotomy.

Overall, there is fair evidence that acute total elbow arthroplasty is the preferred treatment for elderly patients (> 65 years of age) with a displaced, comminuted, intra-articular distal humeral coronal shear fracture that is not amenable to stable internal fixation. This gets a grade B recommendation[1].

Arthroscopic reduction and fixation

A case report by Hardy *et al*[32] described arthroscopic-assisted reduction and screw-fixation of a type Ⅰ Hahn-Steinthal capitellum fracture using one viewing portal and two instrumentation portals. According to many authors, arthroscopic reduction and fixation techniques for coronal shear fractures of the distal humerus should be reserved only for simple fractures without comminution (such as type Ⅰ in the Dubberley or Bryan and Morrey classification)[2,32-35].

Postoperative care

After surgical intervention, the patient is put in a long-arm posterior plaster splint or compressive dressing if rigid fixation has been achieved. The patient is usually

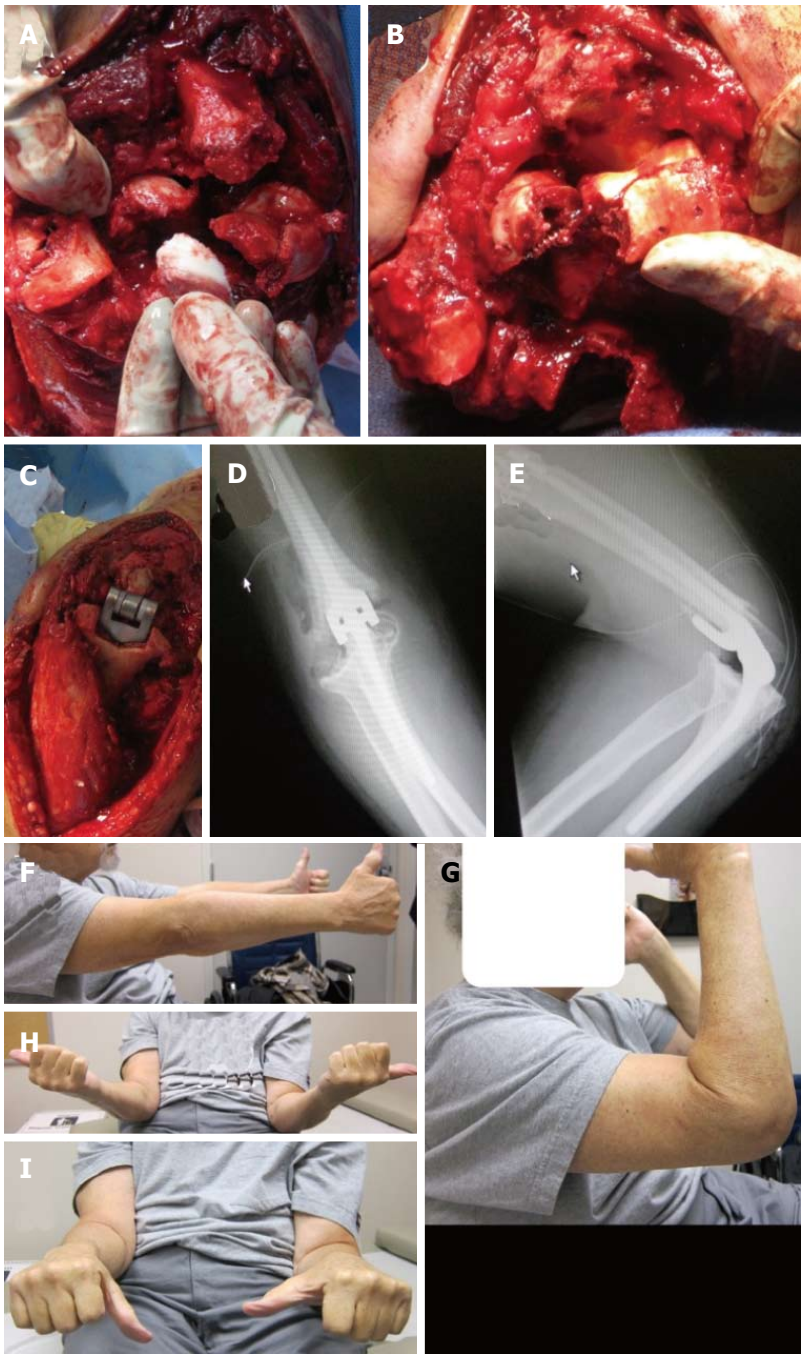

Figure 3 Total elbow arthroplasty. A-E: A non-reconstructible coronal shear fracture in an elderly patient. A total elbow arthroplasty was performed in this patient; F-H: Postoperative range of motion.

seen for his/her first post-operative office visit between seven and ten days post-operatively. The splint and/or compressive dressing are usually removed at this visit. Active and active-assisted range of motion of the elbow and forearm along with formal therapy is also initiated after the first office visit[3].

If the fixation achieved intra-operatively is suboptimal, the patient may be put in a functional brace[3]. If there is concomitant ligamentous or functionally equivalent osseous injuries, then mobilization in pronation is established for lateral-sided injuries and mobilization in supination is established for medial-sided injuries[3,36,37]. When clinical and radiographic evidence of fracture union is evident, strengthening exercises can be initiated[3].

When there is concern about the stability of fixation, delayed or protected mobilization with a hinged elbow brace or cast may be necessary. A hinged brace with gradual reduction of the extension block allows maintenance of radial head congruity with the reduced capitellum. When flexion contracture occurs in the early post-operative period, extension thermoplastic splinting is used[3]. Gelinas *et al*[38] showed that turn-buckle splinting is effective in regaining ulnohumeral motion. If ulnohumeral motion remains poor and there is flexion contracture present, a contracture release can be performed[3].

SURGICAL APPROACHES

Lateral extensile approach

The operative treatment described in majority of publications is performed through the extended lateral Kocher approach. Most authors advocate the extended lateral Kocher approach for fractures without significant posterior comminution or medial column damage[8,10,39].

In the extended lateral approach, the patient is positioned supine and the arm is controlled with a tourniquet. An incision is made from the lateral supracondylar ridge extending over the lateral epicondyle to 2-5 cm distal to the radial head. The common extensor origin is elevated anteriorly. The lateral ulnar collateral ligament (LUCL) should only be elevated if necessary to obtain sufficient exposure of the fracture[8,9,12,14,40-42]. In our practice, we have abandoned elevating the LUCL and place any plates we may use directly over the ligament. If there is an associated fracture of the lateral epicondyle, the fragment should be retracted with the disrupted LUCL[8,43]. In such cases, place a suture through the LUCL; this allows reattachment through holes drilled in the lateral epicondyle after fracture fixation[14]. We commonly suture the LUCL directly over the plate if the ligament is torn or has been elevated.

The incision is then extended between the biceps and triceps proximally and between the anconeus and extensor carpi ulnaris distally. The forearm is then pronated to protect the posterior interosseus nerve (PIN) and the common extensor origin is elevated to create a soft tissue flap. This flap constitutes the vascular supply of the posterior distal humerus and capitellum[12]. The anterior joint capsule can now be elevated and retracted to expose the capitellum and trochlea[14]. The lateral extensile approach is seen in Figure 4 (the 2nd row pictures of both columns). Anterior retractors over the radial neck increase risk of injury to the PIN and should be avoided[12].

Intraoperative difficulty achieving anatomic reduction often signifies posterior comminution of the lateral column not apparent on radiographs. In such cases, and with known posterior comminution, the distal lateral triceps should be reflected from the olecranon to allow the elbow to hinge open, exposing the posterior lateral column[8]. Additionally, some authors elected to use a supplemental posterior midline incision in cases when the medial trochlea could not be visualized well with the extended lateral approach alone[8,42].

Posterior approach and olecranon osteotomy

The posterior approach with an olecranon osteotomy can be used when an articular fracture extends to the medial epicondyle and when there is significant posterior comminution or medial column damage[8,10,17,39]. Additionally, a posterior approach without osteotomy is recommended if future procedures or arthroplasty is anticipated[10]. Dubberley *et al*[9] recommend a posterior approach for all coronal shear fractures with an olecranon osteotomy for some type 2 fractures, and most type 3 fractures.

In the olecranon osteotomy approach, the patient is positioned in the lateral decubitus position with the arm over a bolster and controlled with a tourniquet. A posterior midline incision is made and a single or multiple intermuscular planes are developed to access the capitellum. Lateral planes described in the literature include the Boyd, Kocher, and Kaplan exposures[9,44-46]. Patients with Dubberly type 1 fractures-coronal shear fractures of capitellum and a part of lateral trochlear ridge-can be managed without disruption of the LUCL, a second medial plane, or an olecranon osteotomy[9].

Dubberly type 2 fractures-single fragment fractures of the capitellum that extend into the trochlear groove-often require a second intermuscular exposure through a medial flexor pronator split in order to access the medial trochlea. If reduction remains difficult, it is necessary to disrupt the LUCL allowing the joint to hinge open on the medial collateral ligament. The LUCL should be repaired after fixation using drill holes and a locking suture technique. However, the LUCL should be preserved whenever possible to avoid the risk of instability following repair[9,43].

An alternative to LUCL disruption is an olecranon osteotomy. Dubberly type 3 fractures-comminuted shear fractures of the capitellum and trochlea-often require olecranon osteotomy. After elevation of fasciocutaneous flaps, the ulnar nerve is identified and protected. Then, a chevron osteotomy is created over the olecranon through the bare area. An oscillating saw is used to cut two thirds of thickness of bone and the remaining attachment is carefully separated using an osteotome[8]. We typically place sponge in the ulnohumeral joint and saw directly to the sponge to minimize the kerf of bone removed. This exposes the anterior articular fragments for fixation. The olecranon fragment can be repaired after fracture fixation with two Kirschner wires directed anteriorly to the distal coronoid process and one 18 gauge or two 22 gauge figure of eight tension band wires[8]. Alternatively, the olecranon fragment can be repaired with plate and screw fixation[9].

In studies published to date there are no significant differences in outcomes between the extended lateral approach and the posterior midline approach[3,12,14,17,39]. Given that an olecranon osteotomy creates increased risk of non-union and symptomatic hardware, the procedure is only used for large and or comminuted fractures[9,17].

Anterolateral approach

A few authors advocate for an anterolateral approach because it exposes the capitellum and the trochlea without disruption of the LUCL or an olecranon osteotomy[47,48]. One advocate of this approach recommends an extended lateral approach for isolated fractures of the capitellum and an anterolateral approach for fractures with involvement of the trochlea[47].

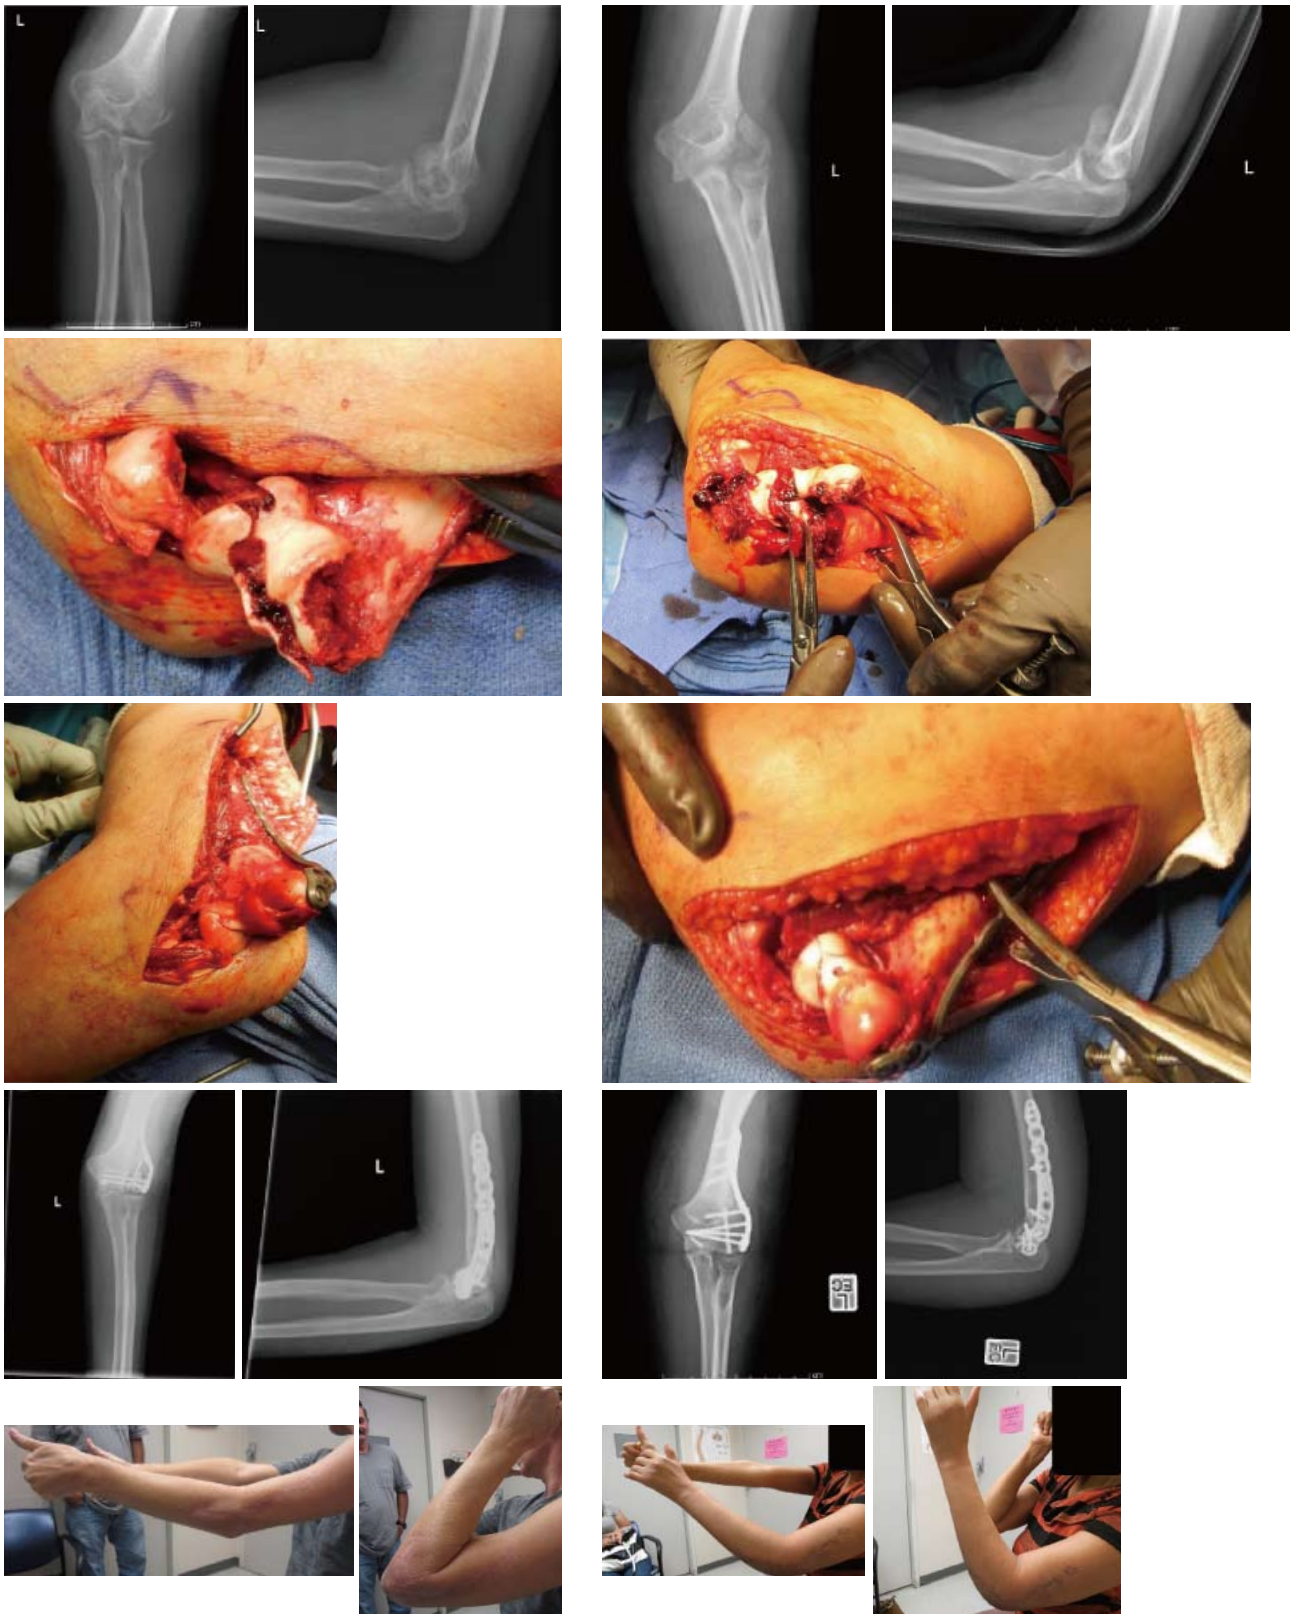

Figure 4 Comparison of outcomes following lateral extensile approach open reduction and internal fixation. Pictures in the left column represent a 52 years old female who fell from a 2 feet wall. Pictures in the right column represent a 45 years old female who fell from a standing height. As can be seen in the first two rows of pictures in each column, both these patients sustained similar Dubberley type 3b fractures. The third and fourth rows in each column shows that good reduction and fixation was achieved intra-operatively in both patients. The last row in each column show maximum range of motion in each patient. The patient in the left column achieved a reasonable outcome, while the patient in the right column had severe stiffness and range of motion deficit which required an operative contracture release. Both patients underwent open reduction and internal fixation of their fractures using the lateral extensile approach for which the lateral collateral ligament was divided. Secondary to poor results, we have abandoned this method and now universally use the technique shown in Figure 4 or utilize olecranon osteotomy.

In this procedure the patient is positioned supine and the arm is controlled with a tourniquet. An incision is made 7 cm proximal to the flexion crease of the elbow between the biceps and brachioradialis and extended along the lateral border of the biceps. At the elbow the incision curves laterally to avoid scarring perpendicular to the flexion crease. The incision continues along the medial border of the brachioradialis 7 cm distal to the flexion crease. The radial nerve is identified and retracted laterally with the brachioradialis. The biceps is reflected medially exposing the anterior joint capsule which is incised vertically. Flexion exposes the capitellum for fracture fixation[47].

Malki *et al*[48] propose a more limited anterolateral exposure with an additional posterolateral stab incision for isolated capitellar fractures. In this approach, an incision is made over the lateral epicondyle and the anterior lateral joint capsule is incised longitudinally. This exposed fracture is manually reduced. Next, a threaded guide wire is inserted radially and directed perpendicular to the fracture. An additional stab incision on the posterior lateral elbow allows for fixation radially and posteriorly. A second wire is advanced parallel to the first wire through this incision until it nearly elevates the articular cartilage. A cannulated drill bit and tap are advanced over the wires and a short cannulated screw is inserted over the wire for definitive fixation[48].

Arthroscopic

There have been four cases reported on arthroscopic repair of coronal shear fractures of the distal humerus: three Dubberly type 1A fractures and one type 3A fracture[32,34,35]. Advocates of arthroscopic fixation report less soft tissue injury and decreased risk of devascularization, infection, and elbow contracture compared to ORIF[32,35]. However, the type 3A fracture that underwent arthroscopic repair developed avascular necrosis at one-year follow up[34]. It has been demonstrated that arthroscopy is a technically difficult but feasible approach for fixation of single fragment coronal shear fractures of the capitellum without comminution or significant involvement of the trochlea[32,34,35]. Given the limited evidence, authors advocate for judicious use of arthroscopic fixation for coronal shear fractures of the distal humerus[34]. It is not possible to perform an adequate comparison of the arthroscopic approach to the extended lateral or the anterolateral approach because there are so few cases in the literature.

In the procedure, the patient is placed in lateral decubitus position, the elbow is flexed to 90 degrees and controlled with a tourniquet. Three incisions are made on the lateral elbow: one for a fluid control system to distend the joint, a second for instrumentation, and a third for the arthroscope. The joint is lavaged and fracture site cleaned with a shaver. The fracture fragment is reduced with a punch and held in place with a K wire prior to fixation with cannulated screws advanced through the articular cartilage[32]. Alternatively, the fracture can be reduced using a K wire and definitively fixed with screws advanced over guide pins perpendicular to the fracture[34,35].

Two incision technique (lateral and anterior approach)

In order to minimize the total soft tissue dissection we have developed a two-incision technique (Figure 5). Of note, we prefer to use a headlight during this procedure. A lateral incision is made over the supracondylar ridge extending distal over the suspected extensor digitorum communis (EDC) tendon. Full thickness fascio-cutaneous flaps are raised. The dissection proceeds in between EDC and extensor carpi radialis brevis (ECRB). The supinator is then elevated off the radial head/neck junction sharply retaining the annular ligament and anterior capsule below undisturbed. A sharp capsulotomy is performed along the lateral distal humerus, stopping at the annular ligament [anterior to the lateral collateral ligament (LCL) insertion], just enough to visualize the fracture. If the capsule is tight and we cannot see the fracture, we divide the annular ligament anterior to the radial portion of the LCL (which lies directly beneath the EDC tendinous origin) to improve our visualization of the fracture[49].

We take great care not to dissect or elevate the LCL. If the fracture is comminuted, there is frequently a shell of bone attached to the LCL. Even in such cases, we do not elevate the LCL but rather apply plate fixation directly over it. Large capitellar fracture fragments are then fixed with headless compression screws. Small, comminuted fragments (usually posterior) are excised if present. We then view the medial extent of the fracture through this lateral incision. At this time, we make an anterior approach as previously described for fixing coronoid fractures[50] but with a more limited dissection to the distal humerus[50,51].

An incision of approximately 3 cm is made beginning at the elbow crease. Dissection proceeds between biceps and the neurovascular bundle. A finger is used to palpate the trochear fracture fragments (typically larger fragments). The brachialis is split at the level of the trochlear fragments through the anterior approach. A longitudinal capsulectomy is then made and the fracture's trochlear fragments are reduced under direct visualization and fixed with headless compression screws. The reduction can be provisionally fixed with several 0.054 K-wires and confirmed through both the lateral and anterior approach prior to placing the headless compression screws. Lateral comminution is addressed by applying a buttress plate directly over the LCL if needed. Fractured fragments are stressed manually and visualized throughout range of motion for stability.

Grades of recommendation for the evaluation, treatment, and post-op care of coronal shear fractures of the distal humerus

The following recommendations for care are adapted from a 2011 review article by Nauth *et al*[1], who

conducted a thorough literature search on the topic of distal humeral fractures: (1) Grade C recommendation for the use of CT scanning in the assessment of coronal shear fractures; (2) Grade C recommendation for ORIF of all displaced coronal shear fractures in patients for whom surgery is suitable; (3) Grade C recommendation for the use of a lateral extensile approach for the fixation of the majority of coronal shear fractures; (4) Grade C recommendation for the use of headless compression screws placed in an anterior-to-posterior fashion for the fixation of coronal shear fractures; (5) Grade B recommendation for acute total elbow arthroplasty in patients > 65 years of age with displaced, comminuted, intra-articular distal humeral fractures not amenable to stable internal fixation; and (6) Grade B recommendation for initiation of early range-of-motion exercises (within 2 wk) following ORIF of distal humeral coronal shear fractures.

Grades of recommendation: (1) A = Good evidence from Level-Ⅰ studies with consistent findings; (2) B = Fair evidence from Level-Ⅱ or Ⅲ studies with consistent findings; (3) C = Poor-quality evidence from Level-Ⅳ or Ⅴ studies with consistent findings; and (4) Ⅰ = Insufficient or conflicting evidence[1,52].

Outcomes

Good to excellent outcomes have been reported for the majority of patients who have undergone ORIF following a distal humeral coronal shear fracture. Outcomes are particularly good when the fracture is isolated to the radiocapitellar compartment[2,3,6-10,12]. One can expect mean pronosupination arcs of 156° to 180°, flexion-extension arcs of 96° to 141°, and flexion contractures of 10° to 28° for these fractures after ORIF[2,6-8,12,14,17,47]. Figure 5 shows one of our patients who achieved excellent outcomes in terms of range-of-motion following ORIF of a distal humeral coronal shear fracture. Of note, we utilized the two-incision technique described above for this patient.

Fractures with significant medial extension or comminution don't do as well, with non-unions occurring in the worse fracture subtype[2,6,9-11,14,47,53]. Dubberley *et al*[9] conducted a cohort study (n = 28) which found significantly inferior functional elbow evaluation scores (based on the American Shoulder and Elbow Surgeons function score and Mayo Elbow Performance Index) with Dubberley type Ⅱ (medial trochlear extension) and Dubberley type Ⅲ (capitellum-trochlea comminution) fractures compared to type Ⅰ fractures[9]. In another study by Ruchelsman *et al*[3,7], patients with McKee type Ⅳ fractures had significantly reduced terminal flexion and net ulnohumeral arc and larger flexion contracture compared to patients with type Ⅰ fractures at two years post-operatively[3,7]. The differences in outcome between the different fracture types may be due to increased severity of injury and/or to the extended surgical approach needed to facilitate exposure in the worse fracture types[3].

Satisfactory clinical and functional outcomes have been reported by some authors following ORIF of McKee's type Ⅳ fractures[3,7,10,11,14,47]. Despite a mean postoperative flexion contracture of 14.5° to 17.5°, a functional arc of ulnohumeral motion is achieved in most of these patients[3,7,14,47].

In a subcohort analysis of 16 patients with distal humeral coronal shear fractures, 5 out of 16 had a concomitant radial head fractures (Mason type Ⅰ and type Ⅱ)[7]. At a mean of 27 mo postoperatively, 2/5 had excellent outcomes, 2/5 had good outcomes, and 1/5 had a fair outcome (based on Mayo Elbow Performance Index). However, compared to the 11 remaining patients with an isolated capitellum and trochlea fracture, patients with concomitant ipsilateral radial head fractures had greater loss of terminal flexion and extension and reduced ulnohumeral arc of motion[3,7]. However, since the sample size in this study was very small, statistical significance cannot be reached and larger cohort studies are needed to compare outcomes of fractures with concomitant radial head fracture with those of isolated capitellum and trochlea fractures following ORIF[3].

A study by *Guitton et al*[6] found good to excellent outcomes in 13 out of 14 (93%) patients at long-term follow-up (median of 17 years) following operative fixation of distal humeral coronal shear fractures. This study shows that outcomes following ORIF are durable[2].

Complications

Complications following ORIF of distal humeral coronal shear fractures in the early post-operative period include stiffness, pain, loss of fixation, instability, infection, neurologic complications (*i.e.*, ulnar neuritis), and hardware complications[3]. Arthritis, malunion, nonunion, avascular necrosis and heterotopic ossification represent complications that can arise later. Overall, complications other than stiffness are rare[2].

Dubberley *et al*[9] found 7 out of 17 patients status post ORIF for Dubberley type Ⅱ or Ⅲ fractures who had elbow contracture with less than functional ulnohumeral motion. Figure 4 compares two patients with similar fractures, one of whom had a good outcome while the other developed severe stiffness and range of motion deficits status post ORIF. It is more important to maintain articular congruity than it is to prevent flexion contracture. The latter, a complication sometimes seen following ORIF of coronal shear fractures of the distal humerus, can be later addressed with contracture release[2]. In a series by Ring *et al*[8], 8 out of 21 patients required a contraction release. There was a mean increase of 42° in ulnohumeral motion following the release. In this same series, two patients who had undergone ORIF through an extended lateral approach developed ulnar neuropathy which required decompression

Figure 5 Two-incision approach. A case demonstrating the two incision approach (lateral and medial). A: The lateral collateral ligament is not reflected (the plate is placed directly on top of it). Stable fixation of the capitellar fragment could not be obtained with headless compression screws and a one-third tubular plate was added for stability; B: Flexion demonstrates a mild amount of impingement, which was not symptomatic postoperatively; C: Anterior view demonstrates trochlear fracture line. Even though two incisions are used there is less soft tissue dissection overall than required in other approaches; D-G: Approximate 6 wk follow-up range of motion in this patient.

and transposition. According to Ruchelsman *et al*[3], olecranon osteotomies have been associated with rare hardware complications (such as impingement of hardware in the radiocapitellar joint) which may necessitate screw removal.

Mild to moderate degenerative changes have been

reported in patients having undergone ORIF for distal humeral fractures[3,7,9]. Of 14 fractures treated with ORIF, only seven had Broberg and Morrey radiographic grade Ⅰ or Ⅱ arthritis and two had grade Ⅲ arthritis at a median 17-year follow-up[2,6,8,9].

In a series by Brouwer *et al*[53], 8 out of 18 (44%) patients with Dubberley type ⅢB fractures developed radiographic nonunion while none (0 out of 12) with Dubberley type ⅡA or ⅡB fractures developed nonunion. Of the 8 that developed nonunion, two had infections and were thus considered as failures. The remaining six had good to excellent results in half and fair results in the other half. There was no difference in range of motion compared to the patients who achieved union[2,53]. Dubberley *et al*[9] reported two patients status post ORIF for a type Ⅲ fracture that developed nonunion and had to be converted to total elbow arthroplasty. Total elbow arthroplasty is a salvage option for nonunion/malunion as well as for severe symptomatic post-traumatic arthrosis, articular osteonecrosis, and elbow instability[3].

In a recent study by Lee *et al*[23], only five out of sixty-seven patients with distal humeral fractures developed some degree of heterotopic ossification following ORIF. However, of these patients, only one developed a functional deficit (this patient had suffered from a high trauma injury and had a delayed operation). Overall, clinically significant heterotopic ossification is uncommon and there is insufficient evidence to recommend a prophylactic regimen against this complication[1-3].

CONCLUSION

The aim of this paper was to review the literature on the topic of distal humeral coronal shear fractures and to present several approach and treatment techniques.

Coronal shear fractures of the distal humerus represent significant articular injuries and are usually more complex than suggested by radiographic imaging. CT scans are therefore highly recommended for preoperative assessment of these fractures and treatment planning. The fracture pattern and extent of articular involvement dictate method of surgical exposure and internal fixation technique used for treatment. Open reduction internal fixation through lateral extensile exposures or posterior exposures using variable-pitch, headless compression screws is the treatment of choice for simple fracture types, leading to good to excellent outcomes in the majority of cases. Additional extensile exposures, LUCL disruption, olecranon osteotomy, bone grafting, and supplemental fixation using minifragment screws, column plating, and/or bioabsorbable implants may be required for more complex fracture types. We have found a two-incision approach (lateral and direct anterior) results in less soft tissue dissection and damage than the extensile approaches. Coronal shear fractures with substantial medial extension and posterior comminution generally have worse outcomes. The most common complication following ORIF of these fractures is stiffness (flexion contracture). It should be noted that the literature on distal humeral coronal shear fractures is comprised mainly of level-Ⅲ and Ⅳ studies. Consequently, more prospective, multicenter, large-scale trials are needed to assist surgical decision-making in the future. Furthermore, longer-term data are needed to fully evaluate the incidence and severity of rare complications such as arthritis, osteonecrosis, and heterotopic ossification following these fractures.

Abstract

Timely diagnosis and control of cardiovascular risk factors is a priority objective for adequate primary and secondary prevention of acute stroke. Hypertension, atrial fibrillation and diabetes mellitus are the most common risk factors for acute cerebrovascular events, although novel risk factors, such as sleep-disordered breathing, inflammatory markers or carotid intima-media thickness have been identified. However, the cardiovascular risk factors profile differs according to the different subtypes of ischemic stroke. Atrial fibrillation and ischemic heart disease are more frequent in patients with cardioembolic infarction, hypertension and diabetes in patients with lacunar stroke, and vascular peripheral disease, hypertension, diabetes, previous transient ischemic attack and chronic obstructive pulmonary disease in patients with atherothrombotic infarction. This review aims to present updated data on risk factors for acute ischemic stroke as well as to describe the usefulness of new and emerging vascular risk factors in stroke patients.

Key words: Cardiovascular risk factors; Hypertension; Atrial fibrillation; Diabetes mellitus; Ischemic stroke; Transient ischemic attack; Sleep apnea

Core tip: Prevention of acute stroke by controlling cardiovascular risk factors is a health care priority worldwide for a number of reasons, particularly due to the increasing occurrence of acute cardiovascular events in progressively older segments of the population, the high morbidity and mortality of some stroke subtypes and the economic burden associated to care of acute stroke patients. The frequency of the different cardiovascular risk factors is not equal for all subjects diagnosed of first-ever stroke. For this reason, it is necessary to know the most common profiles of vascular risk factors associated with each individual type of stroke in order to improve primary and secondary stroke prevention strategies. The role of new risk factors, such as sleep-disordered breathing or complex atheromatosis of the aortic arch merits further investigation.

INTRODUCTION

Cerebrovascular diseases are the first cause of mortality in women and the second cause of death in men in industrialized countries[1-3]. Stroke is the main reason of functional disability. Neurological sequelae are present in 90% of stroke patients, one third of which will not be able to resume daily life activities at the same level than before stroke[1,2]. Cerebrovascular diseases are also an important cause of cognitive impairment and dementia[3]. The high frequency of stroke is illustrated by the cumulative incidence per 100000 persons-year that in Catalonia in 2002 and in the population over 24 years of age was of 218 new cases among males and 127 among females[4]. Therefore, to recognize cardiovascular risk factors and to treat them appropriately is the key to establish primary preventive strategies in non-stroke patients or secondary preventive measures to avoid recurrence in stroke victims.

The etiology of stroke is multifactorial, and therapeutic actions focused on vascular risk factors, particularly in secondary stroke prevention have been shown to reduce the risk of recurrent stroke, as well as the risk of any other coronary or peripheral vascular episode[4,5].

Risk factors for stroke are usually divided into non-modifiable (age, sex, ethnicity, low weight at birth, inherited diseases) and modifiable (hypertension, diabetes mellitus, heart diseases, smoking, dyslipidemia, alcohol abuse, obesity, metabolic syndrome, use of oral contraceptive drugs, hormone treatment in postmenopausal women, clinically silent carotid stenosis, peripheral artery disease, drug abuse, migraine, and other)[3-5].

NON-MODIFIABLE RISK FACTORS

Age, gender, ethnicity/race, low birth weight, family history of stroke and genetics/heredity[6]. In relation to age, in 2006, it was found that 93% of subjects who had suffered a stroke in Spain were older than 64 years of age[7]. Age is a continuous risk factor for the occurrence of stroke and dementia, with a two-fold increase in the incidence and prevalence rates for each successive 5 years after age 65 years. On the other hand, men show a higher incidence of cerebral vascular disease than women. With regard to ethnicity/race[8,9], it has been demonstrated that black patients have a higher incidence of stroke *vs* white patients. Intracranial atherosclerotic disease is more frequent in patients of Asian. Birth weight is inversely associated with coronary heart disease and stroke[9]. The underlying mechanisms of this association are poorly understood but might be related with genetic or nutritional factors[1].

Family history of stroke in a first-degree relative also increases the likelihood of suffering from an acute cerebrovascular event even after adjusting for other vascular risk factors. This increased risk may be due to different mechanisms, including inherited predisposition for stroke risk factors, genetic transmission of susceptibility to stroke, familial-related lifestyle, cultural and environmental factors, and interactions between genes and environmental factors[10].

Different genetic disorders have been associated with stroke. Rare monogenic disorders can cause stroke[11], such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL), cerebral amyloid angiopathy, moyamoya syndrome, Fabry disease, Ehlers-Danlos syndrome type Ⅳ, Marfan syndrome, Sneddon syndrome, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS) and coagulopathies. However, as with other complex traits, the genetic etiology of common stroke is likely to be polygenic and more related to genetic influences on well-documented risk factors, such as hypertension, dyslipidemia, cardiopathy or diabetes[12,13]. Cerebrovascular events have also been related to polymorphisms of genes that regulates clotting factors, angiotensin-converting enzyme, nitric oxygen synthetase and phosphodiesterase 4D among other[10].

A meta-analysis of genome-wide association studies (the METASTROKE collaboration) identified genetic variants specific to the different stroke subtypes[14]. This study highlights the importance of detailed stroke subtyping in order to maximize success of genetic studies in ischemic stroke and to establish whether different genetic pathophysiological mechanisms seem to be associated with different stroke subtypes.

MODIFIABLE RISK FACTORS

Modifiable risk factors for ischemic stroke are well known. Appropriate treatment of these risk factors has been associated with a reduction of stroke. This allows the implementation of measures for primary or secondary stroke prevention.

Hypertension

Hypertension together with age are leading risk factors for silent or symptomatic cerebrovascular disease[15-17]. High blood pressure multiplies the risk for stroke as much as 4-fold. Both factors are also related to the probability of suffering some degree of cognitive impairment[4]. The risk of cerebral hemorrhage in hypertensive patients is 3.9 times higher than in non-hypertensive individuals. In aneurysmal subarachnoid hemorrhage the relative risk is 2.8 higher[18-22]. The diagnosis and control of hypertension one of the main strategies for primary and secondary prevention of stroke[22-24]. The effect of chronic hypertension on cerebral vessels and tissue (microhemorhages, silent infarctions, white matter lesions and atrophy) also supports a physiopathological mechanism for the association between hypertension and cognitive

Table 1 Distribution by age groups of demographic and cardiovascular risk factors in 2704 consecutive patients with cerebral infarction collected from the "Sagrat Cor Hospital of Barcelona Stroke Registry"[7] *n* (%)

Previous cerebral hemorrhage	38 (9.8)	20 (2.9)	7 (0.7)	1 (0.2)

Data expressed as frequencies and percentages in parenthesis. COPD: Chronic obstructive pulmonary disease; BMI: Body mass index.

impairment[25-29]. As shown in Table 1, according to data of 2704 patients with first-ever ischemic stroke collected from the Sagrat Cor of Barcelona Stroke Registry, hypertension was the main risk factor in the different age groups[7].

Diabetes mellitus

Dyslipidemia, hypertension and obesity are atherogenic risk factors frequently found in type 2 diabetes patients[4,5]. Also, diabetes is an independent risk factor of ischemic stroke of atherothrombotic cause. The influence of diabetes upon increasing the stroke risk is higher in women than in men[30]. Diabetes is the main risk factor following hypertension of cerebral small vessel disease and has been identified as a significant independent variable of symptomatic recurrence in patients with first-ever cerebral infarction of the lacunar type[31,32]. The combination of hypercholesterolemia and hypertension increases the frequency of vascular complications in patients with diabetes.

Heart diseases

Heart diseases are the second cause of acute cerebrovascular events and are diagnosed in one third of patients with stroke[33,34]. Atrial fibrillation (AF) and atrial flutter are the most important and modifiable risk factor, frequently associated with cardioembolic stroke. Cardioembolic infarction is the most severe stroke subtype due to the very low percentage of symptom-free patients at hospital discharge, the non-negligible risk of early recurrent embolic events and the high mortality in the acute stroke phase (27% in the Sagrat Cor of Barcelona Stroke Registry)[33-36]. The prevalence of AF increases with age. It has been shown that 5% of subjects older than 70 years have AF (the mean age of patients with AF is 75 years), and about one fourth of acute strokes in very old patients (> 80 years) are also caused by AF[37,38]. Future embolism is also more frequent in patients with underlying comorbid heart diseases, such as AF and stenosis of the mitral valve. The risk of stroke is 3 to 4 times higher in the absence of organic heart disease or risk factors (lone atrial fibrillation). On the other hand, AF associated to hypertensive heart disease is the most common cardiogenic source of cerebral embolization in industrialized countries[33]. Similar rates of cardioembolism for paroxysmal and chronic AF have been reported, so that preventive therapy should not be different for patients with paroxysmal AF and those with chronic AF[33]. In patients without history of transient ischemic attack (TIA) or stroke, AF carries a risk of stroke of 2%-4% per year. Cardiac emboli arising from cardiac chambers are often large and hence especially likely to cause severe stroke, disability and death[33].

A number of cardiac conditions are potential sources of embolism, such as dilated myocardiopathy, heart valve disease (mechanical prosthetic valve, mitral rheumatic stenosis, infectious endocarditis, marantic endocarditis), left ventricular hypertrophy, atrial myxoma and congenital heart diseases (such as patent foramen ovale, atrial septal aneurysm and ventricular septal defects). Acute coronary syndromes are minor causes of cardioembolism. There is an inverse correlation between ejection fraction of the left ventricle and the incidence of ischemic stroke[33-39].

Cigarette smoking

Cigarette smoking is an independent predictor of cerebrovascular disease in both men and women[40]. Smokers have a relative risk of ischemic stroke of 1.92

times higher as compared to non-smokers. Smoking increases the risk of thrombus formation in narrow arterial vessels and contribute to enhance atherosclerotic plaque burden. Also, smoking increases blood viscosity, fibrinogen and platelet aggregation, and decreases high-density lipoprotein (HDL) cholesterol, which causes direct damage to endothelium and an increase in blood pressure[40-42]. A meta-analysis of 19 prospective studies has shown an association of smoking with dementia and cognitive decline[43]. Finally, there is growing acceptance that passive cigarette smoke increases the risk of stroke[44].

Dyslipidemia

Plasma lipids and lipoproteins [total colesterol, triglycerides, low-density lipoprotein (LDL) cholesterol, HDL cholesterol and lipoprotein (a)] have an influence on the risk of cerebral infarction, but the relationships between dyslipidemia and stroke have not been consistently elucidated[9]. Data from prospective studies in male patients have shown that in the presence of total serum cholesterol values > 240 to 270 mg/dL, there is an increase in the rates of ischemic stroke[45].

In general, the risk of ischemic stroke in both genders is clearly related with dyslipidemia. In men, low HDL levels is a risk factor for cerebral ischemia but data in women are inconclusive. Because high levels of LDL are clearly related with a higher cardiovascular risk, adequate control of LDL cholesterol is recommended (*e.g.,* National Cholesterol Education Program Ⅲ guidelines) in subjects without history of cerebrovascular accident[46].

High triglyceride levels are a component of the metabolic syndrome. In a study of 11117 patients with coronary heart disease, cerebral infarctions were significantly associated with high serum levels of triglycerides and low levels of HDL cholesterol[9].

Alcohol abuse

Chronic heavy alcohol consumption (> 60 g/d) is associated with an increase in the relative risk of stroke [risk ratio (RR) of 1.69 in cerebral ischemia and RR = 2.18 in cerebral haemorrhage][44]. Ethanol is a direct neurotoxin and chronic ethanol abuse causes different neurodegenerative processes, including dementia[47,48]. However, light-to-moderate alcohol consumption (20-30 g/d, equivalent to 1 or 2 drinks per day) is associated with a lower risk of stroke, white matter disease and clinically silent cerebral infarcts[3,44].

Overweight and obesity: Adiposity

Obesity is defined as an increase above 25% of the theoretical body weight according to age and sex. The term "adiposity" refers to the amount of adipose (fat) tissue in the body, and can be considered more precise than "obesity" which is mainly one of the ways to measure adiposity. Adiposity is an energy imbalance between energy intake (calories) and energy expenditure (physical activity and metabolic processes); however, the ideal or normal threshold for adiposity has not been established. Increase in fat tissue is associated with a higher risk of insulin resistance, diabetes, hypertension, dyslipidemia, vascular diseases and other conditions. Persons with a body mass index (BMI) of < 18.5 kg/m^2 are classified as being underweight, between 18.5 and 25.9 kg/m^2 as healthy weight range, between 26 and 29.9 kg/m^2 as overweight and ⩾ 30 kg/m^2 as being obese[49]. Abdominal obesity is commonly measured by either the waist-to-hip ratio or waist circumference and appears to be a more sensitive measure of adiposity and vascular risk. Clinically, abdominal obesity is defined by a waist circumference > 102 cm in men and 88 in women[50]. Weight and abdominal fat reduction is associated with a lowering in blood pressure, and may thereby reduce the risk of stroke. Moreover, there is evidence linking the continuum of adiposity, hyperinsulinemia, and diabetes with dementia[51].

Metabolic syndrome

Metabolic syndrome is defined as te presence of three or more of the following: (1) abdominal obesity as determined by waist circumference > 102 cm and > 88 cm for women; (2) triglycerides ⩾ 150 mg/dL; (3) HDL cholesterol < 40 mg/dL for men and < 50 mg/dL for women; (4) systolic blood pressure ⩾ 130 mm Hg and diastolic blood pressure ⩾ 85 mmHg; and (5) fasting glucose ⩾ 110 mg/dL[52,53]. Hyperinsulinemia/insulin resistance is an important marker of the metabolic syndrome. The metabolic syndrome is a predictor of coronary heart disease, cardiovascular disease (which includes coronary heart disease and stroke) and all-cause mortality. Also, the risk of stroke is higher for patients presenting some of the diseases included in the metabolic syndrome[9].

Asymptomatic carotid stenosis

Approximately between 5% and 10% of men and women over 65 years had > 50% and 1% > 80% asymptomatic carotid stenosis[3], which has been also identified as a risk for stroke[9] and an important clinical feature of underlying ischemic heart disease.

Peripheral vascular disease

Epidemiological studies have shown that patients with intermittent claudication have a high risk of premature death due to ischemic heart disease and stroke. Also, individuals with peripheral vascular disease are at a higher stroke risk[9,54]. History of intermittent claudication, peripheral vascular disease or coronary heart disease in a patient with cerebral infarction indicates the presence of clinically generalized atherosclerosis, according to which the diagnosis of cerebral ischemia of atherothrombotic cause is highly probable.

Postmenopausal hormone therapy

Postmenopausal hormone therapy (estrogen with or without a progestin) should not be used for primary

prevention of ischemic stroke because, paradoxically, the risk of stroke is increased.

The increased risk for vascular outcomes should be taken into account when hormone replacement therapy is used for other indications[9,45].

Oral contraceptive use

The risk of stroke associated with low-dose oral contraceptives (containing low doses of estrogens) in women without additional risk factors (*e.g.,* cigarette smoking or history of thromboembolic episodes) appears low[45]. Women taking oral contraceptives older than 35 years, active smokers, with hypertension, diabetes, migraine headache or history of thromboembolism are at higher risk of stroke[9,45].

Drug abuse

Drug abuse (mainly heroin, cocaine, amphetamins) has been also identified as a risk factor for stroke through different mechanisms, including blood pressure, hematologic, hemostatic and vasculitic-type changes, as well as increased platelet aggregation and blood viscosity[3,9,45].

Migraine

Migraine has been marginally associated with stroke risk in young women but in persons over 60 years an association between stroke and migraine has not been documented[55]. The risk of stroke has been related to underlying pathophysiological mechanisms of migraine (with aura), such as reduced blood flow particularly in the posterior circulation[9]. In young adults, stroke and migraine may be linked by paradoxical embolism through a patent foramen ovale. Patients with migraine also show an increase in platelet–leukocyte aggregation and platelet activation, increasing the risk of emboli formation and suggesting a link at cellular level between stroke and migraine[55,56].

LESS WELL-DOCUMENTED VASCULAR RISK FACTORS

The causal role of these factors in stroke patients remains inconclusive and futher studies are needed to clarify the contribution of each of these factors to the overall stroke risk.

Increase of the apoB/apoA1 ratio

Plasma levels of apolipoprotein B (apoB) is an indicator of very-low density (VLDL) and LDL lipoproteins with proatherogenic properties because each VLDL and LDL particle contains a molecule of apoB. It seems that plasma concentration of apoB is the highest lipid predictor of ischemic heart disease. In patients with TIA, an increase in the apoB/apoA1 ratio would product stroke more strongly (HR = 2.9) than other lipid values, such as apoB (HR = 2.3), total cholesterol (HR = 1.8), LDL cholesterol (HR = 1.5), LDL/HDL ratio (HR = 1.3) and apoA1 (HR = 1.2)[9,45].

Sedentarism

A sedentary lifestyle is associated with an increase in the risk of stroke. Regular physical activity has well-established benefits for reducing the risk of cardiovascular disease, premature death and stroke[9]. The excellent review of Hankey[45] of potential new risk factors for ischemic stroke includes data of a meta-analysis of 23 studies and shows that subjects with high physical activity as compared to those with low physical activity had a lower stroke risk (RR = 0.79). Also, in another study, a reduction in the risk of stroke was reported in relation to moderate physical activity at leisure time (RR = 0.87) and active daily activity $\geqslant$ 30 min daily (cycling/walking to work). The protective effect of physical activity may be partly mediated through its role in reducing blood pressure and controlling other risk factors for cardiovascular disease, diabetes and increased body weight. It has been also related to a reduction of plasma fibrinogen and platelet activity, with increases of both tissue plasminogen activator and HDL cholesterol[3,45].

Insufficient daily fruit and vegetable intake

A meta-analysis of 17 cohort studies showed that risk of stroke decreased by 11% for each additional portion per day of fruit, by 5% for fruit and vegetables, and by 3% for vegetables[3,45]. A higher sodium intake increases the risk of stroke, whereas a higher consumption of potassium was associated with a reduction in the risk of stroke, probably due to the blood pressure lowering effect and mitigation of sodium effects on pressor responsiveness[9,45]. In Asian populations, diets characterized by consumption of cholesterol and saturated fats, as well as low consumption of animal-related proteins have been associated with an increased stroke[9,45].

Psychosocial stress

The risk of stroke is also increased in the presence of stressful live events, including depression[44].

Sleep-related breathing disorders

The presence of sleep apnea is also a risk factor for stroke. Sleep apnea may increase the risk of stroke by leading to or worsening hypertension or ischemic heart disease. Sleep apnea causes reductions in cerebral blood flow, altered cerebral autoregulation, impaired endothelial function, accelerated atherogenesis, hypercoagulability, inflammation and paradoxical embolism in patients with patent foramen ovale. In patients with advanced sleep-disordered breathing, cardiac arrhythmias, atrioventricular block and atrial fibrillation appear when the oxyhemoglobin saturation falls to < 65%. Sleep apnea as a risk factor for

cerebrovascular events is usually underdiagnosed[57-59].

Inflammatory markers

There is increasing evidence of the relevance of inflammation as a physiopathological mechanism of atherothrombotic stroke.

Leukocyte and monocyte counts: In the CAPRIE trial (Clopidogrel *vs* Aspirin in Patients at Risk of Ischemic Events) patients with a history of peripheral arterial disease, stroke, or myocardial infarction or who had a leukocyte count in the highest quartile at baseline showed a higher adjusted risk of recurrent ischemic events compared with those in the lowest quartile (RR = 1.42)[45]. Monocyte count has been shown to be an independent predictor of future atherosclerotic plaque formation in the carotid artery in subjects without preexisting carotid atherosclerosis[3,60].

C-reactive protein: In apparently healthy individuals, high-sensitive C-reactive protein, acute-phase reactant and biological marker of inflammation, has been shown to be an independent risk factor for death of vascular cause, stroke and myocardial infarction[45].

Other biomarkers: An increase in the levels of other inflammatory biomarkers, among which, tumor necrosis factor (TNF) and interleukin 2 (IL-2) are also related to subclinical carotid disease[45]. Inflammatory cells in the atherosclerotic plaque are involved in the release of substances (matrix metallopeptidases) causing rupture of the plaque by instability of the fibrotic layer[45]. An increase of inflammatory mediators have been shown in atherosclerotic plaques in symptomatic as compared to asymptomatic patients[3,45].

Infection

It has been shown that recent infection (within 1 wk) can be a risk factor for stroke and coronary-related complications[3]. This may be partly related to generalized activation of circulating leukocytes, enhancing the tendency for thrombosis at the site of atherosclerotic plaque. Moreover, *Chlamydia pneumonia* DNA or *C. pneumonia* antigen, have been identified in 40% of atherosclerotic plaques[3,45].

Periodontal disease related to seeding of the bloodstream with Gram-negative organisms has been associated with carotid atherosclerosis and the risk of stroke[45]. However, antibiotic treatment has been unsuccessful in the prevention of severe cardiovascular events, at least in patients with established coronary heart disease.

Cytomegalovirus, herpes virus and *Mycoplasma pneumoniae* infection increase the risk of stroke by various mechanisms, particularly by increasing inflammatory mediators, facilitating the coagulation cascade and enhancing expression of adhesion molecules on vascular endothelial cells[3,45].

Helicobacter pylori have also been identified in human atherosclerotic plaque.

These data support the concept of "infectious burden", according to which prolonged exposure to multiple microorganisms during the life period may contribute to the development and activation of the atherosclerotic plaque[9,45].

Fibrinogen

In a meta-analysis of thres prospective studies, patient with fibrinogen concentrations above the median value showed an increased risk of stroke (HR = 1.34) in comparison with patients with serum fibrinogen values below the median, particularly in patients with non-lacunar syndromes (HR = 1.42)[45].

Other biological factors

Hemocysteine: It has been consistently shown a positive and independent association between total plasma hemocysteine and atherosclerotic disease, risk of silent and symptomatic stroke and cognitive decline[45,61]. Also, *MTHFR TT* genotype confers a significantly greater mean hemocysteine levels and greater risk for stroke (OR = 1.26) than carriers of the *MTHFR CC* genotype. Although a standard definition of hyperhomocysteinemia is lacking, it seems that fasting plasma concentrations > 16 μmol/L may be considered indicative of hyperhomocysteinemia[3,55]. Ongoing randomized controlled clinical trials continue to assess the efficacy of homocysteine-lowering treatment for decreasing the risk of ischemic stroke.

Elevated lipoprotein (a): Lipoprotein (a) [Lp(a)] complex has proatherogenic and prothrombotic properties and has been shown to be a risk factor for coronary heart disease[45]. Lp(a) enhances arterial cholesterol deposition, thereby promoting atherogenesis[3,45]. There is an increasing evidence suggesting that high Lp(a) levels may induce cerebral ischemia but findings have not been completely consistent[45].

Lipoprotein-associated phospholipase A_2: High concentrations of Lp-PLA_2 are associated with an increased risk of cardiovascular events, independent of other risk factors, and potentially may increase the stroke risk[45].

Hypercoagulability: Venous thrombosis (but not cerebral infarction) is associated with thrombophilias (hereditary) or acquired hypercoagulable states[45]. Anti-phospholipid antibodies (aPL) is most frequently the cause of arterial thrombosis IgG and IgM anti-cardiolipin antibody and lupus anticoagulant are useful tests to detect aPL. Young women with cerebral infarction have a higher prevalence of aPL.

Therefore, primarily young women who have a history of thrombotic events and meet the laboratory criteria for antiphospholipid syndrome might benefit

from the administration of moderate-intensity warfarin or other antithrombotic therapies as primary or secondary prevention strategies[3,45]. On the other hand, a relationship between stroke and other hereditary hypercoagulable states (protein S or antithrombin Ⅲ, protein C deficiency, *etc.*) has not been reported in most case-control studies[45].

Albuminuria: An increased risk of stroke, death of vascular cause, myocardial infarction and renal dysfunction has been documented in patients with microalbuminuria or proteinuria (30-300 mg/d and > 1 g/d, respectively)[45].

Cystatin C: Cystatin C is a serum marker of renal function that has been shown to be a predictor of stroke, myocardial infarction and vascular death, even stronger in elderly subjects than is creatinine[3,45].

EMERGING VASCULAR RISK FACTORS

Asymptomatic vascular disease

Asymptomatic vascular disease is the first consequence of the impact of uncontrolled progression of cardiovascular risk factors on systemic or cerebral arteria vessels of the organism. Asymptomatic vascular disorders may be viewed as subclinical arterial markers related to cardiovascular risk factors, and are predictors of stroke, myocardial infarction and vascular death in the mid- and long-term. Mild carotid stenosis, carotid intima-media thickness and atheroma of the aortic arch, as well as carotid artery distensibility and endothelial reactivity of the brachial artery have been reported as potential causes of asymptomatic vascular disease[3,44].

Complex atheromatosis of the aortic arch is a risk factor of embolism. There is a significant relationship between atheromatous plaques in the aortic arch and cerebral ischemia, particularly in the presence of protruding plaques ⩾ 4 mm in thick. Morphologically complex plaques (aortic atherosclerotic debris) is considered a high risk embolic source (increased stroke risk by 1.7)[3,44,62-64].

Clinically silent cerebral ischemia

Modern neuroimaging techniques allow the detection of clinically silent cerebral ischemia in the form of white matter hyperintensities, cerebral infarcts, cerebral atrophy or microbleeds, which may be considered stroke risk factors[45]. Most lacunar infarctions are asymptomatic and magnetic resonance imaging (MRI) studies reveal the presence of lacunes in approximately 20%-28% of individuals older than 65 years. Silent lacunar infarction is a risk factor of new infarctions of the lacunar type and cognitive impairment[65-69]. Also, symptomatic progression of lacunar disease has been demonstrated given that at 3 years, between 10% and 50% of patients will show new silent lacunar infarcts in MRI studies. Progression of leukoaraiosis is documented in 40% of patients with lacunar infarct. Therefore, clinically silent small vessel cerebral disease is a stroke risk factor that should be taken into account given the independent role as significant predictor of both symptomatic vascular recurrence and cognitive impairment[70,71].

Other factors

Proteomic risk markers, history of TIA, previous cerebral infarction or primary intracerebral hemorrhage, chronic obstructive pulmonary disease (COPD), chronic liver disease and use of oral anticoagulants are other risk factor for stroke.

RISK FACTORS IN THE DIFFERENT ISCHEMIC STROKE SUBTYPES

Studies of data collected from hospital-based stroke registries have shown that the different etiological stroke subtypes present clearly differentiated cardiovascular risk profiles. In this respect, in the Sagrat-Cor of Barcelona Stroke Registry, clear differences between cerebral infarcts and spontaneous intracerebral hemorrhages were observed[72]. Main risk factors in patients with cerebral infarction are hypertension (54.1%), atrial fibrillation (29.3%) and diabetes (22.6%), whereas in patients with hemorrhagic stroke, the frequency of hypertension was higher (61.3) but the occurrence of atrial fibrillation (15.3%) and diabetes (14.7%) was lower[72] (Table 2). These differences were statistically significant and were consistent with data reported in other studies[73-78]. Also, it should be noted that risk factors in stroke patients present a characteristic profile according to the patient's age, with a high percentage of patients with atrial fibrillation and other heart conditions in the oldest old group (⩾ 85 years) (Table 1).

Moreover, each subtype of ischemic stroke exhibits a distinct vascular risk profile[7] (Table 3). When a logistic regression analysis was performed (Table 4)[7], the risk profile for the subtype of atherothrombotic infarction is characterized by the presence of peripheral vascular disease (OR = 2.28), which is a clear and well-known indicator of generalized atherosclerosis, together with hypertension (OR = 1.84) and diabetes mellitus (OR = 1.66), which are major risk factors traditionally related to cardiovascular and cerebrovascular morbidity of large artery atherosclerosis[36,79]. Other risk factors include history of TIA (OR = 1.50), which should be considered a true neurological emergency due to the early risk of subsequent neurological deterioration (cerebral ischemia)[80], COPD (OR = 1.40), -a clinical entity associated with cigarette smoking and recurrent infection episodes, which may cause an acquired subclinical hypercoagulable status-, previous cerebral infarction (OR = 1.40), the presence of which is associated with an increased risk of recurrent cerebral

Table 2 Comparison of demographic data, risk factors, neuroimaging findings and early outcome between stroke patients with intracerebral hemorrhage and cerebral infarctions ("Sagrat Cor Hospital of Barcelona Stroke Registry" period 1986-2004)[72] *n* (%)

Variable	Intracerebral hemorrhage (*n* = 380)	Cerebral infarction (*n* = 2082)
Age, yr, mean (SD)	72.51 (12.55)	74.97 (12.21)
Age, yr		
< 65	83 (21.8)	329 (15.8)
65-74	112 (29.5)	521 (25.0)
75-84	120 (31.6)	808 (38.8)
⩾ 85	65 (17.1)	424 (20.4)
Gender		
Males	199 (52.4)	987 (47.4)
Females	171 (47.6)	1095 (52.6)
Lacunar syndromes	36 (9.5)	554 (31.4)
Hypertension	233 (61.3)	1126 (54.1)
Diabetes mellitus	56 (14.7)	471 (22.6)
Atrial fibrillation	58 (15.3)	609 (29.3)
COPD	29 (7.6)	166 (8.0)
Magnetic resonance imaging	95 (25)	656 (31.5)
Respiratory events	45 (11.8)	183 (8.8)
Symptom-free at discharge	23 (6.1)	382 (18.3)
In-hospital mortality	107 (28.2)	249 (12.0)
Transfer to a convalescence/rehabilitation unit	64 (16.8)	243 (11.7)
Length of stay, median (IQR)	15 (8-26)	12 (8-20)

Data expressed as frequencies and percentages in parentheses unless otherwise stated. COPD: Chronic obstructive pulmonary disease; IQR: Interquartile range (25^{th}-75^{th} percentile).

Table 3 Cardiovascular risk factors in 2704 consecutive patients with cerebral infarction collected from the "Sagrat Cor Hospital of Barcelona Stroke Registry" according to the different stroke subtypes[7] *n* (%)

Variables	Atherothrombotic (*n* = 770)	Lacunar (*n* = 773)	Cardioembolic (*n* = 763)	Undetermined cause (*n* = 324)	Unusual cause (*n* = 114)
Hypertension	509 (66.1)[b]	525 (71.6)[b]	377 (49.4)[b]	59 (18.2)[b]	31 (27.2)[b]

History of transient ischemic attack	116 (15.1)[d]	80 (10.9)	73 (9.6)[a]	37 (11.4)	11 (9.6)
Smoking (> 20 cigarettes/d)	87 (11.3)[a]	86 (11.7)[b]	28 (3.7)[b]	41 (12.7)[b]	18 (6.9)
Chronic obstructive pulmonary disease	74 (9.6)	61 (8.3)	62 (8.1)	20 (6.2)	6 (5.3)
Peripheral vascular disease	100 (13)[d]	57 (7.8)	50 (6.6)	3 (0.9)[d]	4 (3.5)[d]
Heart valve disease	11 (1.4)[b]	21 (2.9)[b]	130 (17)[b]	6 (1.9)[d]	6 (5.3)
Congestive heart failure	43 (5.6)	24 (3.3)[d]	72 (9.4)[b]	8 (2.5)[d]	1 (0.9)[a]
Obesity (body mass index ⩾ 30 kg/m^2)	36 (4.7)	47 (6.4)[b]	17 (2.2)[d]	13 (4)	5 (4.4)
Oral anticoagulants	18 (2.3)[a]	7 (1)[b]	63 (8.3)[b]	2 (0.6)[b]	4 (3.5)
Alcohol abuse (> 80 g/d)	26 (3.4)[a]	21 (2.9)	5 (0.7)[a]	10 (3.1)	4 (3.5)
Chronic liver disease	17 (2.2)	15 (2.1)	15 (2)	10 (3.1)	0
Previous intracerebral hemorrhage	9 (1.2)	9 (1.2)	7 (0.9)	6 (1.9)	1 (0.9)

Data expressed as frequencies and percentages in parentheses. [a]$P < 0.05$; [b]$P < 0.001$; [d]$P < 0.01$.

infarcts, and ischemic heart disease (OR = 1.33), which is an epiphenomenon of clinically significant atherosclerosis and a potential cause of recurrent cerebral ischemia.

In lacunar infarction, the vascular profile includes hypertension (OR = 2.64) and diabetes mellitus (OR = 1.55). Both hypertension and diabetes are the main risk factors, a fact that is consistent with previous histopathological studies and data reported in main clinical series of patients published in the literature[25,81-87]. Obesity is also an independent risk factor associated with lacunar infarcts. The frequency of the different risk factors is different in patients with lacunar infarcts from those in patients with lacunar syndromes not due to lacunar infarction[88,89] (Table 5).

In cardioembolic ischemic stroke, cardiac sources of embolism including atrial fibrillation (OR = 20.01), valve heart disease (OR = 5.60) and ischemic heart disease (OR = 2.09) are the most prevalent heart conditions[89,90].

Table 4 Results of multivariate analysis: cardiovascular risk factors independently associated with the different subtypes of ischemic infarction in 2704 consecutive patients with cerebral infarction collected from the "Sagrat Cor Hospital of Barcelona Stroke Registry"[7]

	Odds ratio (95%CI)
Atherothrombotic infarction	
Peripheral vascular disease	2.28 (1.68-3.08)
Hypertension	1.84 (1.53-2.2)
Diabetes mellitus	1.66 (1.36-2.03)
Previous transient ischemic attack	1.50 (1.16-1.95)
Chronic obstructive pulmonary disease	1.41 (1.04-1.93)
Previous cerebral infarction	1.40 (1.12-1.76)
Ischemic heart disease	1.33 (1.06-1.68)
Atrial fibrillation	0.36 (0.28-0.45)
Heart valve disease	0.23 (0.12-0.43)
Lacunar infarction	
Hypertension	2.64 (2.19-3.20)
Diabetes mellitus	1.55 (1.23-1.90)
Obesity ($\geqslant$ 30 kg/m^2)	1.50 (1.01-2.25)
Oral anticoagulation	0.37 (0.16-0.82)
Heart valve disease	0.22 (0.17-0.28)
Cardioembolic	
Atrial fibrillation	20.01 (15.98-25.05)
Heart valve disease	5.60 (3.60-8.71)
Ischemic heart disease	2.09 (1.57-2.78)
Dyslipidemia	0.69 (0.50-0.94)
Diabetes mellitus	0.68 (0.52-0.89)
Hypertension	0.67 (0.54-0.85)
Previous transient ischemic attack	0.66 (0.46-0.95)
Smoking (> 20 cigarettes/d)	0.54 (0.34-0.88)
Obesity ($\geqslant$ 30 kg/m^2)	0.38 (0.20-0.73)
Undetermined cause	
Hypertension	0.12 (0.09-0.17)
Peripheral vascular disease	0.13 (0.04-0.41)
Atrial fibrillation	0.15 (0.10-0.23)
Diabetes mellitus	0.21 (0.13-0.32)
Ischemic heart disease	0.24 (0.13-0.42)
Heart valve disease	0.34 (0.14-0.80)
Previous cerebral infarction	0.61 (0.40-0.93)
Unusual cause	
Atrial fibrillation	0.15 (0.07-0.32)
Diabetes mellitus	0.17 (0.07-0.38)
Ischemic heart disease	0.21 (0.08-0.58)
Hypertension	0.27 (0.18-0.42)

In patients with cerebral infarctions of undetermined cause (or essential) and in patients with infarctions of unusual cause (haematological disorders, infections, vasculitis and other entities), classical cardiovascular risk factors are less frequent[91,92].

Finally, the role of emerging and less-well documented stroke risk factors as described above is still inconclusive but further characterization in well-designed clinical studies will add knowledge to develop more tailored primary and secondary preventive strategies in stroke.

Abstract

Tick-borne encephalitis is an infection of central nervous system caused by tick-borne encephalitis virus transmitted to humans predominantly by tick bites. During the last few decades the incidence of the disease has been increasing and poses a growing health problem in almost all endemic European and Asian countries. Most cases occur during the highest period of tick activity, in Central Europe mainly from April to November. Tick-borne encephalitis is more common in adults than in children. Clinical spectrum of the disease ranges from mild meningitis to severe meningoencephalitis with or without paralysis. Rare clinical manifestations are an abortive form of the disease and a chronic progressive form. A post-encephalitic syndrome, causing long-lasting morbidity that often affects the quality of life develops in up to 50% of patients after acute tick-borne encephalitis. Clinical course and outcome vary by subtype of tick-borne encephalitis virus (the disease caused by the European subtype has milder course and better outcome than the disease caused by Siberian and Far-Easter subtypes), age of patients (increasing age is associated with less favorable outcome), and host genetic factors. Since clinical features and laboratory results of blood and cerebrospinal fluid are nonspecific, the diagnosis must be confirmed by microbiologic findings. The routine laboratory confirmation of the tick-borne encephalitis virus infection is based mainly on the detection of specific IgM and IgG antibodies in serum (and cerebrospinal fluid), usually by enzyme-linked immunosorbent assay. There is no specific antiviral treatment for tick-borne encephalitis. Vaccination can effectively prevent the disease and is indicated for persons living in or visiting tick-borne encephalitis endemic areas.

Key words: Tick-borne encephalitis; Diagnosis; Epidemiology; Clinical manifestations; Treatment; Prevention/vaccination

Core tip: Tick-borne encephalitis (TBE) is the most common tick-borne central nervous system infection in Europe and Asia. It is caused by three subtypes of TBE virus: European, Siberian and Far-Eastern. Because of relatively severe clinical course, the absence of etiologic treatment, considerable proportion of patients with incomplete recovery after acute illness, as well as due to increasing incidence it represents a growing public health problem that could be substantially reduced with vaccination.

epidemiology, clinical characteristics, and management. *World J Clin Cases* 2015; 3(5): 430-441 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i5/430.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i5.430

INTRODUCTION

Tick-borne encephalitis (TBE) is an important viral infection of the central nervous system in Europe and in several regions in Asia. It is caused by the Far-Eastern, Siberian and European subtype of tick-borne encephalitis virus (TBEV). Although the disease is preventable by vaccination, the incidence has been increasing during the last few decades and consequently represents a growing health problem in almost all endemic European and Asian countries. With the increase of tourism TBE is becoming a problem also outside endemic regions[1].

Most cases occur during the highest period of tick activity, in Central Europe mainly from April to November[2-4]. TBE caused by the European virus subtype usually presents as meningitis or meningoencephalitis and has a biphasic course in approximately two-thirds of patients. Up to 50% of patients have long-term sequelae[4]. An occasional clinical manifestation is an abortive form of the disease[5]. Treatment is based on the symptomatic measures. However, TBE can be successfully prevented by safe and highly effective vaccine[4].

ETIOLOGY

The neurotropic TBEV was first described as the cause of TBE by Zilber more than 75 years ago[6]. It is a spherical lipid-enveloped RNA virus, a member of genus Flavivirus within the Flaviviridae family. The mature virion is composed of 3 structural proteins-capsid (C), membrane (M), and envelope (E). Protein E is a major antigen which induces production of neutralizing antibodies. It can be inactivated by pasteurization[4].

The genetic analysis shows the existence of three TBEV subtypes named as European, Siberian, and Far-Eastern subtype[2]. They are genetically very closely related; variation in amino acids sequences between subtypes is 5%-6%[7]. In spite of the pronounced genetic similarity of the subtypes the illness caused by individual subtype is not completely equivalent to those due to the other subtypes.

EPIDEMIOLOGY

TBE is endemic in Europe, Siberia, far-eastern Russia, northern China and Japan. During the past few decades endemic regions have expanded, and within many endemic areas the number of reported cases increased. The increase in the reported incidence rates is thought to be a result of complex interplay of social and ecological factors as well as due to increased medical awareness and advanced diagnostics[8,9].

The European TBEV subtype is predominantly found in Europe, but has also been identified in west Urals, and in Siberia, whereas the Siberian TBEV subtype is found in Siberia, the Baltics, and northern Finland. The Far-Eastern TBE virus subtype is endemic in far-eastern Asia and Japan, and has been identified also in central and eastern Siberia[1,2,10,11].

In Europe and Asia between 10000 and 15000 TBE cases are reported annually[12]. The number is very likely underestimated because in many countries notification of the disease is not mandatory and only in a subset of the countries TBE case definition is in place. TBE is endemic in 27 European countries, and is a reportable disease in only 16 countries[1,12,13]. European countries with the highest incidence of the disease in the period 2005-2009 were Slovenia (14.1 cases per 100000 inhabitants per year), Estonia (11.1), Lithuania (10.6), and Latvia (8.8)[1]. Pronounced yearly variations of registered TBE cases occurred. According to the latest available epidemiological data for Slovenia the incidence of the disease in 2013 was 15.0 cases per 100000 inhabitants[14].

The primary reservoirs and hosts of TBEV in nature are small rodents; humans do not play any role in the maintenance of TBEV in nature and they are only accidental hosts. TBEV is transmitted to humans mainly by hard tick bites; in Europe the principal vector is *Ixodes ricinus* (*I. ricinus*), in parts of Eastern Europe, Russia and in far-east Asia the vector is *Ixodes persulcatus* (*I. persulcatus*) whereas in Japan Far-Eastern TBEV subtype has been demonstrated in *Ixodes ovatus* ticks. In endemic areas in Central Europe approximately 0.1% to 5.0% of ticks harbor the virus (depending on the time of the year and geographical location); in Siberia infection rates of up to 40% are reported for *I. persulcatus*[4,15]. In Slovenia, the prevalence of ticks infected with TBEV was found to be 0.47%; 0.54% in 2005 and 0.43% in 2006[16]. Approximately 1% of all TBEV infections in humans are probably acquired by consuming infected unpasteurized milk or milk products from infected livestock, particularly goats[2]. This means of transmission has to be considered particularly in cases of local epidemics. Outbreaks due to oral virus transmission are more common in Eastern Europe and the Baltic states than in Central Europe[17,18]. A few cases of laboratory-acquired TBEV infections have been documented in the literature[19].

TBE cases usually happen in the warm months between April and November, which is also the period of the highest tick activity[20]. In Central Europe, where the dominant tick species is *I. ricinus,* a two-peak distribution of TBE cases can be seen (first in June and July, second in September and October), whereas in the Ural region, Siberia and the Far East, where *I. persulcatus* is widespread, cases as a rule occur in May and June[21]. In all age groups men are affected more frequently than women[14,22-24]. On average, 10%-20%

of all reported cases of TBE occur in children[25]. It should be pointed out that due to its unspecific clinical presentation TBE in children is often missed and is diagnosed as aseptic meningitis of unknown etiology[26].

With increasing of tourism, TBE has become a more global problem. Therefore, it should be included in the differential diagnosis of the central nervous system infections not only for those living within an endemic region but-in case of an appropriate epidemiological history-also in patients living outside endemic areas. The risk of travel-associated TBE depends on the season of travel, degree of unprotected outdoor exposure as well as on consuming unpasteurized dairy products. TBE surveillance data available in Austria shows that an overall risk of acquiring TBE for a non-vaccinated tourist, staying in a highly endemic region for 4 wk during the TBEV transmission season, has been estimated at approximately 1 case per 10000 person-months of exposure, which is approximately equivalent to the risk of contracting typhoid fever or malaria while traveling in India[27,28].

PATHOGENESIS AND PATHOLOGY

After an infected tick bite TBEV replication occurs locally. Dendritic skin cells (Langerhans cells) are assumed to be the first cells for viral replication and to transport the virus to local lymph nodes. From this initial site the TBEV than disseminate to extraneural tissues, especially spleen, liver and bone marrow, where further multiplication maintains viremia for several days. During the viremic phase (which clinically corresponds to the initial phase of TBE) the virus probably reaches the brain[29,30]. The exact mechanism by which TBEV breach the blood-brain barrier is not known; four possible routes have been postulated: (1) peripheral nerves; (2) highly susceptible olfactory neurons; (3) transcytosis through vascular endothelial cells of brain capillaries; and (4) diffusion of the virus between capillary endothelial cells. The primary targets of TBEV infection in central nervous system are neurons[31].

According to rather limited information the neuropathological findings are nonspecific. Cerebral and spinal meninges usually show diffuse infiltration with lymphocytes and sometimes neutrophils. The most extensive meningeal inflammation is in the vicinity of the cerebellum. Pathological lesions which consist of lymphocytic perivascular infiltrations, accumulation of glial cells, nerve cells necrosis, and neuronophagia are localized in the grey matter and are most often present in the medulla oblongata, pons, cerebellum, brainstem, basal ganglia, thalamus, and spinal cord. Rarely, oligodendrocytes are infected. In the motor area of the cerebral cortex degeneration and necrosis of the pyramidal cells, lymphocytic accumulation, and glial proliferation are present[29,32].

MANIFESTATIONS OF TBEV INFECTION

The large majority of infections with TBEV are asymptomatic; published data suggest that the ratio of asymptomatic infections is between 70% and 98%[4,33]. However, the proportion of asymptomatic cases is hard to ascertain because patients with mild clinical signs and symptoms may remain undiagnosed.

The incubation period of TBE ranges from 2 to 28 d and is usually 7-14 d. After alimentary TBEV transmission the incubation period is as a rule shorter, usually 3 to 4 d[20]. Investigation of a recent small outbreak of TBE after drinking raw goat milk infected with TBEV in Slovenia revealed infection with the virus in four out of four exposed individuals. Of them, three developed symptomatic infection 2 to 3 d after the milk consumption, while the one who had been vaccinated against TBE remained healthy[18].

In about 75% of patients with TBE due to the European TBEV subtype the disease has a typical biphasic course. The majority of patients with monophasic course of the disease has central nervous system involvement (meningitis, meningoencephalitis), while a small fraction has a febrile illness with headache but no meningitis (*i.e.,* the initial phase of TBE not followed by the second, meningoencephalitic phase of the disease), named abortive form of TBE or "febrile headache"[4,5,20,34].

The initial phase correlate with viremia and usually presents with non-specific symptoms such as moderate fever, headache, body pain (myalgia and arthralgia), fatigue, general malaise, anorexia, nausea, and others[3]. This phase lasts for 2 to 7 d and is followed by amelioration or even an asymptomatic interval that usually lasts for about 1 wk (1-21 d). Than the second phase appears: in approximately 50% of adult patients it presents as meningitis, in about 40% as meningoencephalitis, and in around 10% as meningoencephalomyelitis[4,34].

Meningitis, encephalitis, myelitis

Meningitis and encephalitis are the most frequent clinical forms of TBE. Meningitis typically manifests with high fever, headache, nausea and vomiting; many patients have photophobia, and some vertigo. Meningeal signs are present in most of patients. Encephalitis can be manifested by impaired consciousness ranging from somnolence to stupor and, in rare cases, coma. Other manifestations comprise personality changes, behavioral disorders, concentration and cognitive function disturbances, tongue fasciculations and tremor of extremities; very rarely focal or generalized seizures, delirium and psychosis develop. Flaccid pareses, that are a typical characteristic of meningoencephalomyelitis, usually arise during the febrile phase of the disease, and are occasionally preceded by severe pain in the affected muscle groups. The upper extremities are more often affected than the lower extremities and the proximal segments more frequently than the distal ones. Patients with pareses of respiratory muscles rather commonly require artificial ventilatory support. Involvement of the central portions of the brainstem and medulla oblongata are associated with poor prognosis. Myelitis usually occur with encephalitis, and only very rarely as the only manifestation of TBE[4,20,35,36].

In patients with TBE the involvement of cranial nerves has been reported. Published data suggests that cranial nerve involvement is rare and mainly asymmetrical, that its occurrence varies with the severity of clinical presentation of TBE, and that in most cases it has a favorable outcome[24,37,38]. Cranial neuritis most commonly affects ocular, facial, pharyngeal and vestibular nerves[4,20]. Of 1218 adult patients with TBE, who were hospitalized at the Department of Infectious Diseases, University Medical Centre Ljubljana, Slovenia from 2003 to 2009, 11 (0.9%) developed peripheral facial palsy during the course of the disease (nine had unilateral and two had bilateral facial nerve involvement; no one had a central facial palsy) and in three of them TBE was associated with borrelia infection[39]. In regions where TBE and Lyme borreliosis are endemic, concomitant infection with TBEV and *Borrelia burgdorferi* sensu lato should be considered.

Occasionally, patients with TBE have pronounced variability in heart rate or other signs of autonomic nervous system dysfunction[40].

Abortive form of TBE

Data on this manifestation of TBE are limited. It manifests with moderate fever, headache, fatigue, and other symptoms of initial phase of the disease that are not followed by nervous system involvement. The fever typically endures for several days, and the outcome of the disease is excellent[41,42]. In Central Europe the majority of patients with the initial phase of TBE develop the second, central nervous system phase of the disease. In 2002, Lotric-Furlan *et al*[5] published a prospective clinical study on the etiology of febrile illnesses after a tick bite. Among 56 patients with confirmed TBE, only one (2%) had an isolated initial phase, whereas all the others (55, 98%) diagnosed at the time of the initial phase developed the second phase of the disease with pleocytosis.

In Russia this clinical manifestation is named "fever form," and is reported to represent up to 50% of all clinical presentations of TBE[43].

TBE with normal cerebrospinal fluid cell counts

A patient with encephalitis and serologically confirmed TBEV infection but without CSF pleocytosis has been reported[44]. In larger studies of serologically proven TBE, CSF pleocytosis was found in all patients[3,4,24,33]. This finding however, might be due to selection bias because in these studies CSF pleocytosis was one of the inclusion criteria for the diagnosis of TBE.

Chronic progressive form of TBE

There is no agreement on the existence of chronic TBE. Cases of a chronic progressive form of TBE have been identified in Siberia and the Russian Far East. This form of TBE is believed to be caused by the Siberian TBEV subtype. Both mutation in the *TBEV NS1* gene as well as an inappropriate T-cell immune response have been implicated to be associated with chronic progressive disease[3]. According to information from Western Siberia 1.7% of patients with acute TBE develop a chronic progressive form of the disease[45]. Clinical presentations include Kozshevnikov's epilepsy, lateral sclerosis, progressive neuritis, progressive muscle atrophy, and a Parkinson-like disease. Pronounced dissimilarities in the incubation period, in time to the onset of individual neurological signs/symptoms, and in the survival time after the onset of the disease have been reported[2]. Nevertheless, progressive form of TBE is most probably not present or is extremely unusual in disease caused by European TBEV subtype. In the study carried out in Lithuania, where both, European and Siberian TBEV subtypes are present, progressive course was noted in two out of 133 consecutive patients with acute TBE[24].

Post-encephalitic syndrome

TBE may cause long-lasting morbidity which often has an impact on patients' quality of life and, sometimes, necessitates an alteration of lifestyle. Many nonspecific neurological/neuropsychiatric symptoms and residual neurological dysfunctions have been reported in some prospective and several retrospective studies, but findings are hard to compare due to diverse study designs, distinct definitions, and variable follow-up times. Most studies also failed to comprise a control group; as a result findings are difficult to interpret because of unclear distinctions between post-encephalitic syndrome, other sequelae of TBE, and symptoms present in general population. Published data suggest that 40% to 50% of patients after acute TBE develop a post-encephalitic syndrome[46]. The most frequently reported symptoms have been cognitive disorders, neuropsychiatric complaints (such as apathy, irritability, memory and concentration disorders, altered sleep pattern), headache, hearing loss and/or tinnitus, disturbances of vision, balance and coordination disorders, and flaccid paresis or paralysis[24,37,38,47-49].

Lithuanian prospective clinical follow-up study showed that 46% of patients with TBE had sequelae 1 year after the onset of acute illness[24]. In a review by Haglund and Günther four retrospective and four prospective studies on the long-term morbidity from TBE were included. Up to 46% patients suffered permanent sequelae at long-term follow-up[47]. In 2009, Misić Majerus *et al*[48] published a prospective study on TBE post-encephalitic syndrome. Of 124 patients aged 16-76 years, who were followed for at least 3 years, 49 (40%) developed moderate or severe post-encephalitic syndrome lasting for up to 18 mo. Permanent sequelae were seen in 14 (11.3%) patients: spinal nerve paresis in 5, hearing impairment in 6, dysarthria in 2, and severe mental disorder in 1 patient.

CLINICAL COURSE OF ACUTE DISEASE AND LONG TERM OUTCOME

Course of acute TBE and its long-term outcome depend upon the subtype of TBEV infection. The disease caused

by the European TBEV subtype usually has a biphasic course, with a severe neurologic deficit in approximately 10% of patients, and a case-fatality rate of less than 2%[4,20]. The abortive form of TBE is rare-the initial phase most of the time move on to the second phase of the disease[5]. Long-lasting sequelae are identified in up to 50% of adult patients[46]. Infections with Far Eastern TBEV subtype often cause an illness with a gradual onset, more severe course, higher rates of severe neurologic sequelae, and a fatality rate of 20%-40%. Little information with a respect to the clinical course of the disease is available for Siberian TBEV subtype. The case-fatality rate is 2%-3% and some reports from Russia suggest an association with a chronic progressive form of TBE[2,21].

Published data suggest the relationship between age of patients and severity of TBE. The disease caused by European TBEV generally has milder course and better outcome in children than in adults. Nevertheless, TBE cases with severe clinical course, permanent sequelae and even death have been described not only in adults but also in children[23,50]. The predominant form of TBE in children and adolescents is meningitis. A summary of 8 studies on 1169 children with TBE, published from 1963 to 2005, showed that meningitis was present in 802 (69%), meningoencephalitis in 356 (30%), and meningoencephalomyelitis in 11 (1%) patients. Twenty out of 945 patients (2.1%) had long-term neurologic sequelae[25]. Limited information is available on the relationship between age and severity of TBE in adults. Mickiene *et al*[24] reported about this correlation but no precise data were given. Comparison of patients over an under 60 years revealed several differences in the course and outcome of TBE and corroborated previous postulation that TBE is a more severe disease in the elderly[22].

Some clinical studies have shown that TBE with monophasic presentation is associated with a more severe course of the acute disease[3,51-55].

The comparison of clinical course of TBE in unvaccinated and vaccinated patients did not reveal significant differences in disease severity[56].

The outcome of TBE is associated with clinical presentation. The risk of incomplete recovery is higher for patients who have more severe clinical illness during acute phase of TBE[24].

In recent years, genetic factors with potential impact on the course and outcome of TBE have been of scientific interest, resulting in several investigations. For example, the assessment of the role of chemokine receptor CCR5 indicated that *CCR5*Δ23 allele may predispose for TBE[57]. Barkash *et al*[58,59] reported on the association between *CD209* gene promoter region polymorphism and predisposition to severe forms of TBE, and on possible association between 5 OAS single nucleotide polymorphisms and the outcome of TBEV infection in a Russian population. Interesting new findings on the role of host genetic factors in TBEV infections may appear in future.

DIAGNOSIS

A case of TBE is delineated by the presence of: (1) symptoms/signs indicating meningitis or meningoencephalitis; (2) an elevated cerebrospinal fluid cell count (> 5×10^6 cells/L); and (3) microbiologic evidence of TBEV infection (the presence of specific IgM and IgG antibodies)[60].

Blood and cerebrospinal fluid analysis

In patients with TBE blood and cerebrospinal fluid findings are nonspecific. In the first (viremic) phase of TBE leukopenia and/or thrombocytopenia is established in approximately 70% of patients, rarely abnormal liver function test results are seen[61]. In the second phase of the disease mildly elevated leukocyte count may be present in peripheral blood (rarely > 15×10^9/L); erythrocyte sedimentation rate and concentration of C-reactive protein are normal in the majority of patients but may be elevated, particularly in some long-lasting severe cases. Cerebrospinal fluid examination typically reveals elevated leukocyte counts (usually lower than 500 cells/mm^3), a normal glucose concentration, and a normal to slightly elevated protein concentration. Early in the course of the disease neutrophils may predominate, while later cerebrospinal fluid profile is characterized by a predominance of lymphocytes. Elevated lymphocyte counts may last for several weeks after clinical improvement[20,62].

Microbiological investigations

At the time when neurological symptoms/signs occur TBEV has already been cleared from the blood (TBEV is present in blood in the initial but not in the meningoencephalitic phase of the disease) and is only very exceptionally present in cerebrospinal fluid. Consequently, isolation of TBEV from blood and detection of viral RNA by reverse transcriptase PCR in blood and cerebrospinal fluid of patients with TBE have a limited diagnostic yield and are as a rule not used in clinical practice[63]. Reverse transcriptase PCR assays is mainly limited to the initial phase of the disease and could be a useful method in a diagnostic procedure of febrile illness occurring after a tick bite in areas where several tick-borne diseases are present[64].

The routine laboratory confirmation of the TBEV infection is based mainly on the demonstration of specific antibodies in serum (and cerebrospinal fluid), usually by highly sensitive and specific enzyme-linked immunosorbent assay[63,65]. In the majority of patients specific serum IgM and IgG antibodies are present at the beginning of the meningoencephalitic phase of the disease; rarely only IgM antibodies to TBEV are found in the first serum sample. In such cases a second serum sample has to be tested 1-2 wk later, because the demonstration of IgM antibodies alone does not suffice for the diagnosis. TBEV IgM antibodies can be detected in the serum for several months (up to 10 mo or even longer) after acute infection, whereas TBEV

IgG antibodies persist for a whole life, and mediate an immunity that prevents symptomatic reinfection[63,66]. In cerebrospinal fluid specific IgM and IgG antibodies are detectable several days later than in serum, and in almost all cases by day 10[63,67].

However, some limitations are necessary to take into account when using and interpreting serological testing. Specific TBE IgM antibodies may be detectable for several months after acute TBEV infection (as well as in some persons after the first two doses of primary immunization) and may lead to erroneous interpretation in case of another central nervous system disease/infection within this time period[63,66]. Because of the close antigenic relationship between TBEV and other flaviviruses cross-reactive antibodies are induced by infections or vaccinations. This may pose a diagnostic challenge in people vaccinated against yellow fever or Japanese encephalitis and in travelers having acquired dengue, West Nile or other flavivirus infections[68]. Such potential problems in TBE serodiagnosis can be resolved by the quantification of IgM antibodies in a single serum sample taken at the time of hospitalization. High IgM values (> 500 Arbitrary Units) are indicative of a recent infection with TBEV. Lower IgM values, however, may require the analysis of a follow-up sample and/or a specific neutralization assay to exclude the possibilities of long persisting IgM antibodies after infection or those induced by vaccination as well as cross reactive IgM antibodies[69]. Carefulness in the interpretation of TBE serology is also needed in patients with meningoencephalitis or meningitis who had been vaccinated against TBE. In the majority of patients with vaccination breakthroughs serological response is distinct from those found in unvaccinated persons with TBE and consequently vaccination breakthrough cases may be overlooked. These cases are characterized by a delayed development of specific IgM response (during the initial week of the meningoencephalitic phase of TBE specific IgM antibodies are usually not detectable) associated with a rapid increase of specific serum IgG antibodies[70-72]. For a reliable diagnosis of TBE in persons previously vaccinated against TBE, demonstration of intrathecal production of TBEV antibodies is required[34].

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of TBE is extensive and includes a wide variety of central nervous system infections due to other infectious agents as well as noninfectious diseases.

In the initial, viremic phase of TBE, when a patient present with fever, headache, arthralgia, myalgia, and malaise the differential diagnosis may include various viral syndromes; if nausea, vomiting, diarrhea, and anorexia are present, gastroenteritis is a possible explanation. When signs and symptoms of central nervous system involvement develop, TBE needs to be differentiated from encephalitis or aseptic meningitis due to many other viruses. Differential diagnosis comprises also other tick-borne diseases such as Lyme borreliosis, babesiosis, human granulocytic anaplasmosis, tick-transmitted rickettsioses, and tularemia[20].

In many endemic regions TBEV geographically overlaps with bacterial tick-borne pathogens such as *Anaplasma phagocytophilum* and *B. burgdorferi* s.l. Both diseases caused by the two agents, human granulocytic anaplasmosis and Lyme borreliosis, are treatable with antibiotics, and caution must be taken to distinguish them from TBE[20]. Concomitant TBEV and *B. burgdorferi* s.l. infections, as well as concomitant TBEV and *A. phagocytophilum* infections have been described[60,73-76].

The initial, viremic phase of TBE and human granulocytic anaplasmosis have a similar clinical and laboratory presentation. Both diseases are characterized by fever and headache, and both are typically associated with thrombocytopenia and leukopenia; in certain patients also mild abnormalities in liver tests are present. Nevertheless, a clinical report on chills, myalgia and arthralgia, and laboratory findings of elevated concentration of C-reactive protein and lactate dehydrogenase values point to the diagnosis of human granulocytic anaplasmosis and not in favor of the initial phase of TBE[77].

TREATMENT

There is no specific antiviral treatment for TBE. Patients as a rule need hospitalization and supportive care based on the severity of signs/symptoms, and usually encompasses administration of antipyretics, analgesics, antiemetics, maintenance of water and electrolyte balance, and if necessary administration of anticonvulsive agents. In patients with neuromuscular paralysis leading to respiratory failure, intubation and ventilatory support are necessary. In a large prospective German study, 12% of patients were treated in intensive care unit and in 5% assisted ventilation was required[38]. Among Slovenian patients with TBE, hospitalized at the Department of Infectious Diseases, University Medical Centre Ljubljana, in years 2000 to 2004, 6.9% were hospitalized in intensive care unit and 22.5% of them needed mechanical ventilation[22].

Cerebral edema is a potential complication of acute viral encephalitis that aggravates the clinical picture and portends poor neurologic outcome. Patients who have significantly raised intracranial pressure are often treated with intravenous mannitol and/or steroids[78]. Mannitol produces a shift of fluid from the edematous brain back into the intravascular space and subsequently increases circulation volume and improves cerebral perfusion pressure, and lowers intracranial pressure through cerebral autoregulation. It also acts on erythrocyte membrane fluidity and through reducing blood viscosity improves blood flow and oxygen delivery. A rebound phenomenon in intracranial hypertension occurs in about 5% of patients. To avoid complications,

it is frequently recommended that mannitol no longer be administered when the serum osmolality exceeds 320 mOsm/L[78,79]. Despite a rather common clinical practice to treat patients who have significantly raised intracranial pressure with intravenous mannitol, there are no reliable (comparative) studies substantiating the usage of mannitol in patients with TBE.

It has been demonstrated that the use of dexamethasone results in a reduction of brain edema in acute viral encephalitis[80]. In the Baltics and some Eastern European countries patients with TBE are quite common given corticosteroids. The use of steroids is based on the impression that they produce a good and rapid clinical response in patients with TBE, but the validation of the impression in controlled studies has been limited. In a Lithuanian study corticosteroids were used in 81 out of the 133 patients with TBE. Among patients with mild, moderate, and severe disease, 39.7%, 70.7%, and 100% received corticosteroids, respectively. Hospitalization was significantly prolonged among these patients, compared with patients who received only symptomatic treatment. Because all patients with severe disease received corticosteroids it was hard to assess their role in the outcome of TBE[24]. In the group of Polish patients with TBE dexamethasone was used in 54.8% of patients with meningitis, in 69.6% of patients with meningoencephalitis and in 78.3% of patients with meningoencephalomyelitis. In this study the duration of hospitalization was significantly longer only in patients who received dexamethasone longer than 10 d[49]. Perhaps corticosteroid treatment is effective in certain cases, but until the results of the randomized studies are available they cannot be recommend as a standard treatment approach[24,49].

A case report on a patient with severe TBE who substantially improved after application of high dose intravenous immunoglobulins late in the disease course[81], and reports on the successful treatment of encephalitis due to other arboviruses with high doses of intravenous immunoglobulins, prompted Růžek *et al*[82] to propose the implementation of randomized controlled treatment study on the efficacy of high dose intravenous immunoglobulins in patients with severe TBE. Such a proposal should not be interpreted as an indication for treatment of TBE with immunoglobulins.

NONSPECIFIC PREVENTIVE MEASURES

Nonspecific preventive measures comprise pasteurization of milk, reduction of tick population, and personal protective procedures.

Since milk from endemic regions may contain TBEV, pasteurization, and avoiding consumption of unpasteurized milk and dairy products, prevent infection of humans[3,18].

Population of ticks can be reduced by impacts on the environment (*e.g.,* by regular cutting grass around the house, by usage of acaricides, and/or by control of deer population).

Nonspecific personal preventive measures include avoidance of ticks (which means avoidance of contact with vegetation, especially in deciduous and mixed forests with a rich understory and a layer of decaying vegetation on the ground that provides sufficient humidity for the development and survival of ticks), wearing light-colored clothing (light colors enable that ticks are better noticeable) with long sleeves and slacks stuck in socks or footwear (to diminish tick access to the skin), use of repellents, careful examination of the whole body for the presence of ticks, and removal of the attached ticks as soon as possible[83]. However, TBEV is present in salivary glands of the infected tick and may be transmitted from the saliva of an infected tick within a few minutes after attachment[3]. Although the recommended personal measures appear to be self-evident for the prevention of tick-borne diseases including TBE, the effectiveness of certain measures is limited, questionable or has not been properly assessed. Additional problem is that only a small proportion of exposed persons follow the recommended procedures in everyday life[84,85].

VACCINATION

Historically, immunoglobulins containing gamma globulin against TBEV were used as a prophylaxis against TBE within 96 h after a tick bite in the TBE endemic regions (post-exposure prophylaxis). However, due to reports indicating a more severe disease course in children who had received the immunoglobulin[86-88] and because protection was rather unreliable[88], the usage of the immunoglobulins (passive immunization) in European Union has been abandoned[89]. Nevertheless, according to recent studies in Russia, timely single administration of a specific immunoglobulin preparation in a dose of 0.05 mL/kg body weight was protective in approximately 80% of the cases[90]. Further analysis of these findings is needed.

Active immunization is the most effective way to prevent TBE[3,4]. Given that TBE is a zoonosis, that the source of infection is an infected animal, and that TBEV is transmitted by a tick bite and does not spread from human to human, vaccination enables only individual protection. Consequently, high immunization rate of a population in a given environment does not protect persons who are not vaccinated.

Recommendations for TBE vaccination

Because TBE incidence varies within and between different endemic areas recommendations for public vaccination strategies should be based on risk assessments conducted for individual region.

World Health Organization (WHO) recommends vaccination to people of all age groups, including children, in highly endemic areas (≥ 5 cases/100000 per year). In regions where the pre-vaccination incidence of TBE is low to moderate (5 year incidence < 5 cases/100000 per year) immunization should target

persons in the most vulnerable groups. The WHO also recommends TBE vaccination for people travelling from nonendemic areas to rural endemic areas up to altitudes of 1400 m[91].

Central European Vaccination Awareness Group strongly recommends the introduction of universal TBE vaccination for persons > 1 year old for all countries at very high risk of TBE infections. For countries with a very low risk of TBE, recommendations for TBE vaccination should only apply to persons travelling to endemic regions[92].

Vaccines

Two vaccines against TBE, FSME-IMMUN® and Encepur®, are registered in Europe. They contain inactivated European subtype of TBEV-FSME-IMMUN is based on strain Neudorf 1, Encepur on strain K23. Both vaccines prevent not only the disease caused by the European but also those caused by the Siberian and Far-Eastern subtype of TBEV. Procedures used in the preparation of the two vaccines are similar (viruses are grown in chick embryo fibroblast cells, are inactivated by formaldehyde and are purified), and in both vaccines the adjuvant is aluminum hydroxide[89]. Both vaccines are registered for adults and children aged 1 year and older (vaccines for children are called FSME-IMMUN 0.25 mL Junior, and Encepur Kinder, respectively).

In addition to European vaccines, two vaccines based on Far-Eastern subtype of TBEV are registered in Russia (TBE-Moscow and EnceVir); also in these vaccines viruses are grown in chick embryo cells and are inactivated with formalin. Another vaccine, which is produced and used in China, is also based on the Far-Eastern subtype of TBEV[89].

Vaccination schedule

Several vaccination schedules exist; all of them consist of primary (basic) vaccination followed by booster doses. For a complete primary (basic) vaccination three doses, usually with an interval of 1-3 and 5-12 mo between first and second, and second and third dose, respectively, is required. Immunity is maintained with booster doses: the first booster dose is administered 3 years after completion of the primary vaccination, later on one dose is needed every 5 years. Due to the deterioration of the immune response in persons aged > 60 years (FSME IMMUN) or > 50 years (Encepur) boosters are recommended at 3 years intervals in this age group[89].

Vaccination can begin at any time, but immunization with the first two doses is preferably carried out in the winter months to achieve protection before tick activity. Reports on individual cases of severe forms of TBE in subjects who had received only one dose of vaccine against TBE, had historically been an additional reason to start vaccination (receipt the first two doses) in winter. Subsequent information showed that incomplete vaccination does not pose an increased risk for severe disease as compared to unvaccinated persons of the comparable age.

When it is desired to achieve protection in a short time, "fast schedule" can be used in accordance with the manufacturers' instructions[3,4,85]. In contrast to classic approach, in "rapid vaccination" the second dose is usually administered 14 d instead of 1 to 3 mo after the first dose. Protection efficacy is comparable to that seen after classical schedule; however, scientific data on "quick schedule" is less comprehensive than for the conventional approach.

In a person who had not received the recommended doses according to the schedule but with longer intervals, vaccination does not need to be started again from the very beginning but continue with missing doses[93]. Example: if someone had received only two doses of TBE vaccine 5 years ago and afterwards forgot to get the third dose, the vaccination should proceed with the third dose of basic vaccination and then with booster doses according to schedule. Or: a person who had received complete basic vaccination but for 15 years had not obtained any booster dose, does not need to repeat basic vaccination but just get the first booster dose and then continue immunization with booster doses according to the recommended schedule. Longer intervals between doses generally do not reduce antibody concentrations after completion of TBE vaccination, but protection in the period before the delayed dose is less reliable[93].

Persons who had acquired TBE are esteemed to be protected against the disease and do not need vaccination.

Mode of application, dosages

TBE vaccine is administered intramuscularly into the deltoid muscle; in young children it can be given in the anterolateral thigh. The vaccine may be administered simultaneously with other vaccines (live or inactivated) but not on the same place[89].

Doses depend upon the age of the recipient; the age limits for vaccines available in Europe slightly differ. In subjects younger than 16 years, the dose of the FSME-IMMUN vaccine is 0.25 mL, while for persons who have 16 years or are older 0.5 mL is recommended; in subjects younger than 12 years, the dose of the Encepur vaccine is 0.25 mL, while in older the dosage is 0.5 mL.

Efficacy and safety

Both European vaccines are safe and effective; particularly voluminous data exist for FSME-IMMUN vaccine of which more than 100 million doses were used.

Fourteen days after the second dose of basic vaccination protective antibodies develop in about 85% of the subjects, while after three doses more than 98% of persons with normal immunity are protected[89].

In Austria, where the vast majority of the population is vaccinated, the incidence of TBE declined dramatically. The estimated protection after vaccination (field

effectiveness) is more than 98% for persons vaccinated according to the recommended program and more than 90% for those who received basic vaccination, but were later not vaccinated according to the planned schedule[94].

Side effects are mild and relatively rare. They are more frequent after the first dose of vaccine than with later doses. Most commonly local pain and tenderness on pressure at the injection site take place; redness and swelling occur less often. Short-term fever after vaccination is rare in adults but relatively common in young children. Neurological complications are very rare[89].

Storage

The vaccine must be stored in a refrigerator at a temperature between 2 ℃ and 8 ℃. Storage at higher temperatures and freezing are not suitable[89].

Limitations and contraindications

Vaccination is not carried out in subjects with acute febrile illness.

Vaccination is contraindicated in the case of: (1) A severe allergic reaction after previous dose of TBE vaccine; (2) Information on severe allergic reactions to vaccine components (in addition to the active ingredients, TBE vaccine also contains remnants of formaldehyde, neomycin, gentamicin and protamine sulfate); and (3) Anaphylactic hypersensitivity to eggs (TBE viruses are grown in chick embryo fibroblast cells).

Controlled clinical trials to assess the safety of TBE vaccine during pregnancy are not available; thus, pregnant women are vaccinated only after a careful individual assessment of the potential risks and benefits. There is also no sufficient data on the safety of vaccination during lactation. It is not known whether the vaccine components are excreted in human milk or not, however, mother's antibodies produced after vaccination against TBE are probably present in the milk and consequently breast-feeding baby may come in contact with them. Given that TBE vaccines are based on inactivated virus, the damage of fetus or breast-feeding child is highly unlikely.

Although there is no evidence that vaccination may trigger autoimmunity or worsen the course of autoimmune diseases, caution is needed in subjects with an autoimmune disease since information to ensure the safety of vaccination in this group of patients is limited[89].

The manufacturer of the vaccine and some recommendations suggest that in immunocompromised persons the efficacy of vaccination is verified by serological testing approximately four weeks after the second dose, and that-in case of an inadequate antibody response-the second dose is repeated and followed by the third dose in accordance with the normal vaccination schedule. According to some suggestions similar approach may apply also to all subsequent doses. Although the approach appears logical, there is no convincing clinical data to substantiate its use. As a rule the effectiveness of protection after vaccination against TBE is not verified by the detection of antibodies against TBEV in serum.

CONCLUSION

TBE is an important tick-borne central nervous system infection in Europe and Asia. Due to relatively severe clinical course combined with the absence of etiologic treatment, considerable proportion of patients with incomplete recovery after acute illness and increasing incidence, it represents a growing (public) health problem that could be substantially reduced with vaccination.

Abstract

This article reviews the imaging anatomy of temporomandibular joint (TMJ), describes the technique of multi-detector computed tomography (MDCT) of the TMJ, and describes in detail various osseous pathologic afflictions affecting the joint. Traumatic injuries affecting the mandibular condyle are most common, followed by joint ankylosis as a sequel to arthritis. The congenital anomalies are less frequent, hemifacial microsomia being the most commonly encountered anomaly involving the TMJ. Neoplastic afflictions of TMJ are distinctly uncommon, osteochondroma being one of the most common lesions. MDCT enables comprehensive evaluation of osseous afflictions of TMJ, and is a valuable tool for surgical planning. Sagittal, coronal and 3D reformatted images well depict osseous TMJ lesions, and their relationship to adjacent structures.

Key words: Temporomandibular joint; Temporomandibular joint trauma; Congenital anomalies of temporomandibular joint; Temporomandibular joint arthritis; Multi-detector computed tomography

Core tip: This pictorial review describes the common as well as uncommon bony afflictions of the temporomandibular joint (TMJ) with classical images. Bony afflictions of the TMJ constitute a significant bulk of lesions around this joint. However, very little literature is available on imaging evaluation of non-articular disc, osseous disorders. Computed tomography (CT) is the workhorse for evaluation of osseous lesions around the joint and this article focuses on the CT evaluation of these lesions, and also on optimal imaging strategy, which is essential for surgical planning.

INTRODUCTION

Temporomandibular joint (TMJ) is a complex joint essential for the uniquely human -function of speech[1], and the functions of mastication and swallowing. A number of congenital, traumatic, inflammatory, and rarely neoplastic disorders can affect the TMJ causing symptoms like pain, trismus, malocclusion and facial asymmetry. It is crucial to distinguish between different TMJ disorders as the etiology of the disorder determines the clinical course, management and prognosis.

It has been difficult to evaluate the TMJ on conventional radiographs because of overlap by bones of skull base and face. With the advent of multidetector row computed tomography (CT) technology, it has become possible to acquire thin slices, do multiplanar reformatted reconstructions, and hence image the joint in exquisite detail.

ANATOMY

The TMJ is composed of osseous and soft tissue components[2,3]. The osseous component is formed by the temporal bone superiorly that forms the glenoid fossa and the articular tubercle, and by the mandibular condyle inferiorly. The joint capsule and the articular disc are the soft tissue components of the joint. The articular disc has a thin central part and thick anterior and posterior bands[3,4].

MULTI-DETECTOR CT TECHNIQUE

The patient lies supine on the CT table and is instructed not to move or swallow during the scanning process. The scan should start at the level of inferior orbital margin and end at the level of tip of the chin. The scan area must include the external auditory canals. Slice thickness and slice interval for acquisition should be 0.5-1 mm. Sagittal images are reconstructed from the raw data perpendicular to the plane of mandibular condyles as seen on axial plane, and coronal images are reconstructed parallel to the condyles as seen on axial plane (Figure 1), with a slice thickness and inter-slice gap of 2-3 mm[5].

TEMPOROMANDIBULAR DISORDERS

The term "Temporomandibular disorders" encompasses a variety of lesions which involve the TMJ, muscles of mastication, and the adjacent musculoskeletal structures of the head and neck[6]. Most patients with Temporomandibular disorders are children and young adults (less than 20 years of age in our experience). The articular disc, the masticatory muscles and other soft tissues around the TMJ are best evaluated by MRI, and are beyond the scope of discussion of the present article. The other groups of disorders affect the glenoid fossa and the mandibular condyle and include a spectrum of congenital, traumatic, inflammatory and neoplastic diseases, and these are discussed in detail here.

Congenital and developmental disorders

Embryology: The TMJ develops between 7 and 11 wk of gestation. The mandibular condyle and the squamous temporal bone are formed by intramembranous ossification and the articular disc is formed by condensation of mesenchyme in the region of TMJ[7]. Hypoplastic mandibles are seen in Turner syndrome, hemifacial atrophy, and Silver Russell syndrome (a syndrome of intrauterine and post natal growth retardation, facial dysmorphism and clinodactyly) and whereas hyperplastic mandibles are seen in Marfaan's syndrome and Proteus syndrome (a syndrome characterized by highly variable, asymmetric overgrowth of tissues that may include macrodactyly, vertebral anomalies, connective tissue nevi and vascular malformations).

Hemifacial Microsomia (Goldenhaar syndrome-Oculo-Auriculo-Vertebral syndrome): Hemifacial microsomia is a developmental anomaly that affects 1 in every 5600 live births[8]. It is the second most common developmental anomaly of the face and cranium after cleft lip and cleft palate[8]. It arises due to aberrant development of the first branchial membrane and the first and second branchial arches. Abnormal development of the mandible, nose, ear, lip and soft palate are the hallmarks of this condition (Figure 2); associated anomalies include upper limb defects, tetralogy of Fallot, CNS malformations, renal agenesis or malposition, and speech and hearing disorders[8,9]. Asymmetric development of the mandible is the sine qua non for the diagnosis of hemifacial microsomia Association with chromosomal anomalies as deletions of 5p, 6q, duplications of 22q, and trisomies 7, 9, 18, 22, and maternal use of drugs as thalidomide and retinoic acid have been described[8,9].

An accurate pre-operative assessment of the mandible is mandatory for good surgical outcomes and multi-detector computed tomography (MDCT) plays a valuable role here by depicting the anatomy of the mandible and the glenoid fossa in exquisite detail. The OMENS classification system (Orbital asymmetry, mandibular hypoplasia, ear deformity, nerve involvement, soft tissue abnormality)[10,11] is used to describe the mandible in patients with hemifacial microsomia-the degree of dysmorphism increases from grade 1 to grade 5. Grade 1 is a normally shaped but small mandible; Grade 2 is a small mandible with abnormal shape, with Grade 2A assigned to a condyle in normal position and Grade 2B assigned to an infero-medially and anteriorly displaced condyle; Grade 3 is complete aplasia of the ramus and condyle, glenoid fossa and TMJ.

Non syndromic congenital mandibular hypoplasia: Mandibular hypoplasia is a common craniofacial

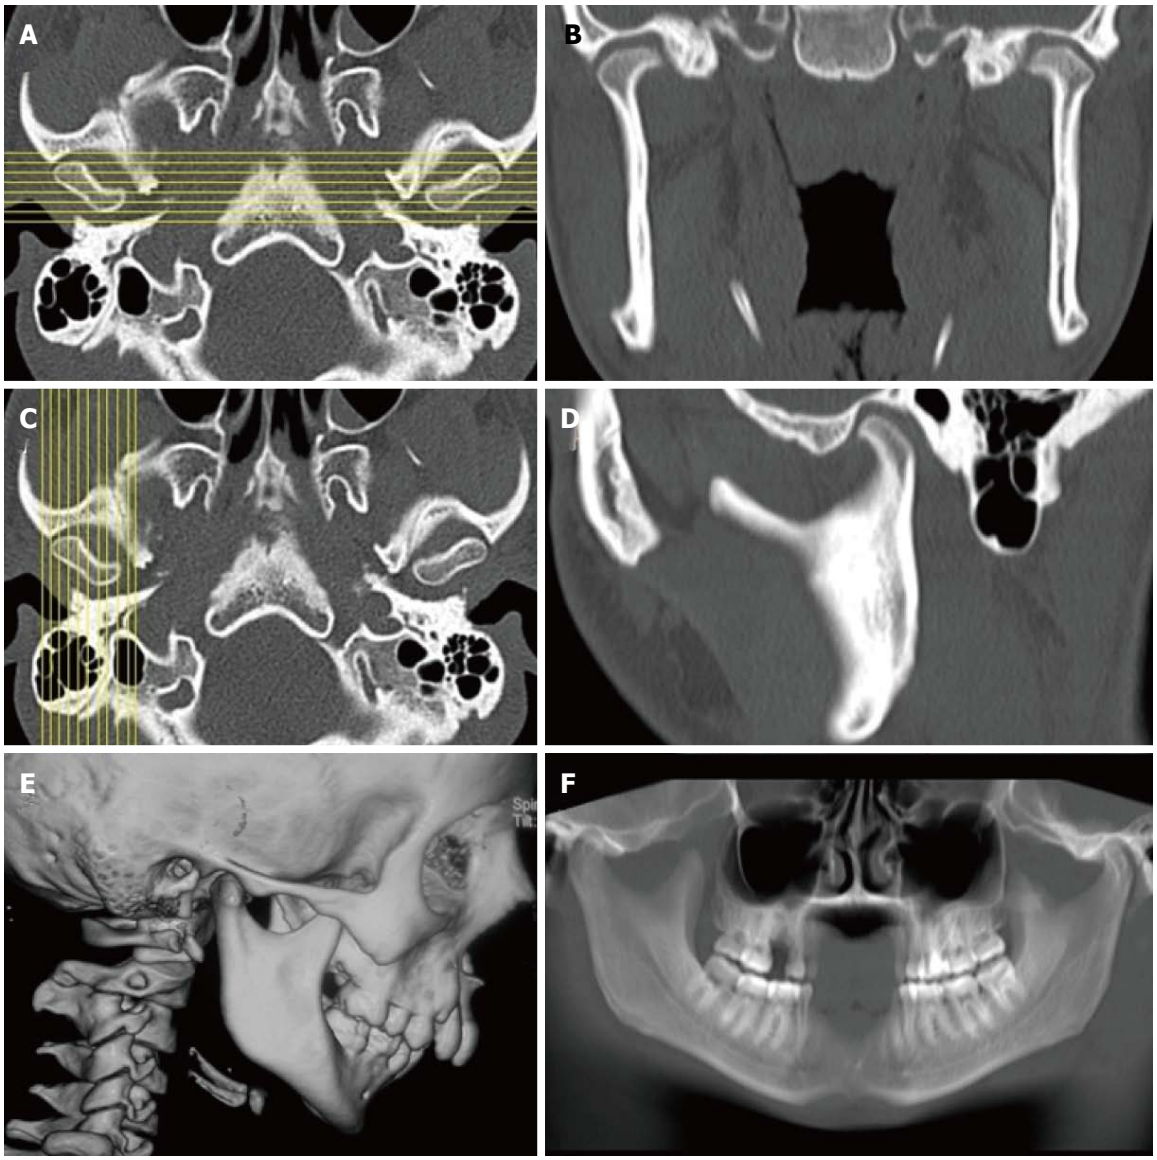

Figure 1 Technique of reconstruction. A, B: Sagittal images are reconstructed perpendicular to the plane of the glenoid fossa; C, D: Coronal images are reconstructed perpendicular to the plane of sagittal images; E, F: The joint anatomy is well depicted in 3D reformatted and reconstructed panoramic image.

Figure 2 Goldenhaar Syndrome in a young boy. Shaded surface display (A) image shows micrognathia, downward slanting left palpebral fissure and hypoplastic left pinna. 3D reformatted images show the normal right hemimandible (B) and hypoplastic body and ramus of left hemimandible with underdeveloped mandibular condyle and glenoid fossa (C).

anomaly and can be congenital, developmental, or acquired in origin, and may be unilateral or bilateral (Figure 3). Acquired causes of hypoplasia include oncologic defects, radiation damage, trauma, and hemifacial atrophy. Treatment consists of initial surgical moving of mandibular components into predetermined

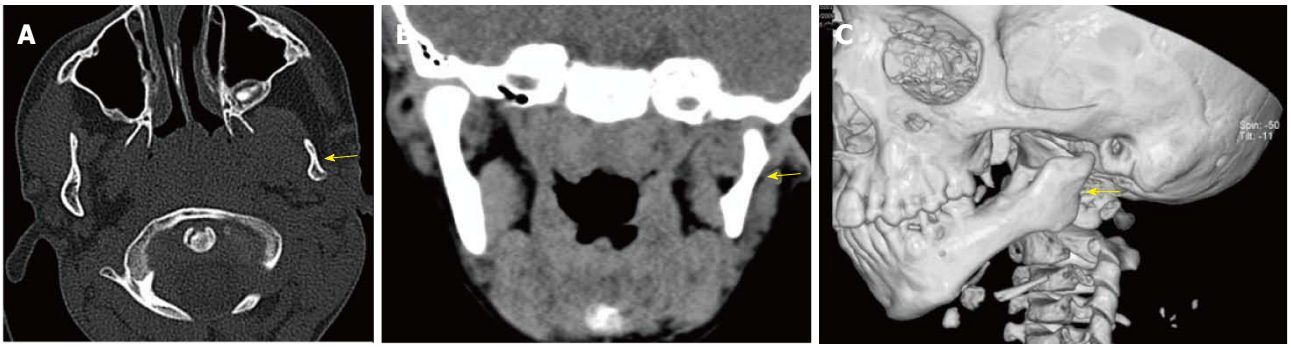

Figure 3 Mandibular hypoplasia in a 7-year-old boy. Axial (A), coronal (B) and 3D reformatted (C) images show show small left hemi-mandible with hypoplastic mandibular condyle and glenoid fossa (arrows).

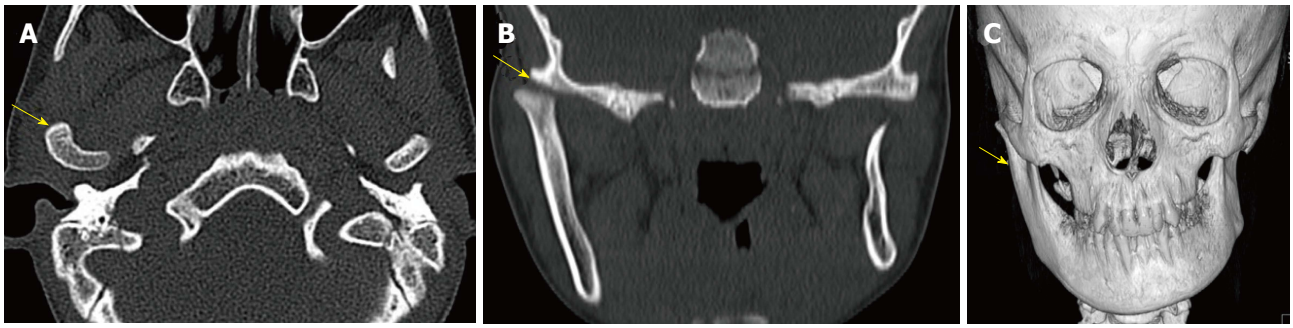

Figure 4 Condylar hyperplasia. Axial (A), coronal (B) and 3D reformatted images (C) show enlarged left mandibular ramus and condyle (arrows).

optimum followed by orthodontic treatment to correct dental malocclusion. MDCT provides the road map for surgical planning.

Condylar hyperplasia: Condylar hyperplasia is a disorder of uncertain etiology seen in patients between the ages of 11 and 30 years[12]. The mandibular condyle continues to grow relentlessly even though the normal growth period has ended (Figure 4). The condition can be treated by condylectomy during the period of active growth; and surgical mandibular repositioning for persisting symptoms after growth has stopped. MDCT defines the size of the condyle, and its relationship to adjacent structures.

Osteochondroma may cause similar symptoms and signs as condylar hyperplasia and must be distinguished. Osteochondromas are seen as localized to a part of the condyle on CT, whereas diffuse enlargement of the condyle is seen in condylar hyperplasia.

Trauma

MDCT with axial and coronal reformatted images is the modality of choice for evaluation of acute trauma to TMJ[3,13]. The temporomandibular joints, the mandible, the maxilla, and the paranasal sinuses can be evaluated in a single scan. The Strasbourg Osteosynthesis Research Group classification defines 3 main types of condylar fractures: diacapitular fracture through the condylar head (DF), fracture of the neck of the condyle, and fracture of the base of the condyle (CBF)[14]. Fractures of the condylar head are further classified as-extracapsular or intracapsular; undisplaced or displaced (Figure 5). On imaging, the radiologist should describe the type of fracture, relationship of the fractured fragment to the mandible as well as glenoid fossa, angulation, presence of vertical compression, and damage to the soft tissues, *i.e.*, the articular disc and the joint capsule.

Condylar fractures lead to anterior and medial displacement of the condylar process due to unbalanced action of the lateral pterygoid muscle which inserts into the condylar process, articular disc and capsule of TM joint. On clinical examination, the mandible is seen deviated towards the side of fracture with anterior open bite and malocclusion. If a condylar fracture is diagnosed, one must carefully look for associated fractures of skull base that can lead to CSF otorrhea and complications as meningitis.

Most of the fractures of condylar head are managed by closed reduction. The indications for open reduction are: displacement of the condyle into the external auditory canal or middle cranial fossa, lateral displacement of the condyle, inability to occlude, open wound with gross contamination or foreign body within the joint[14,15].

Arthritides

The most common arthritides affecting the TMJ are degenerative and traumatic arthritis; rheumatoid, metabolic, infectious arthritis, and spondyloarthropathies

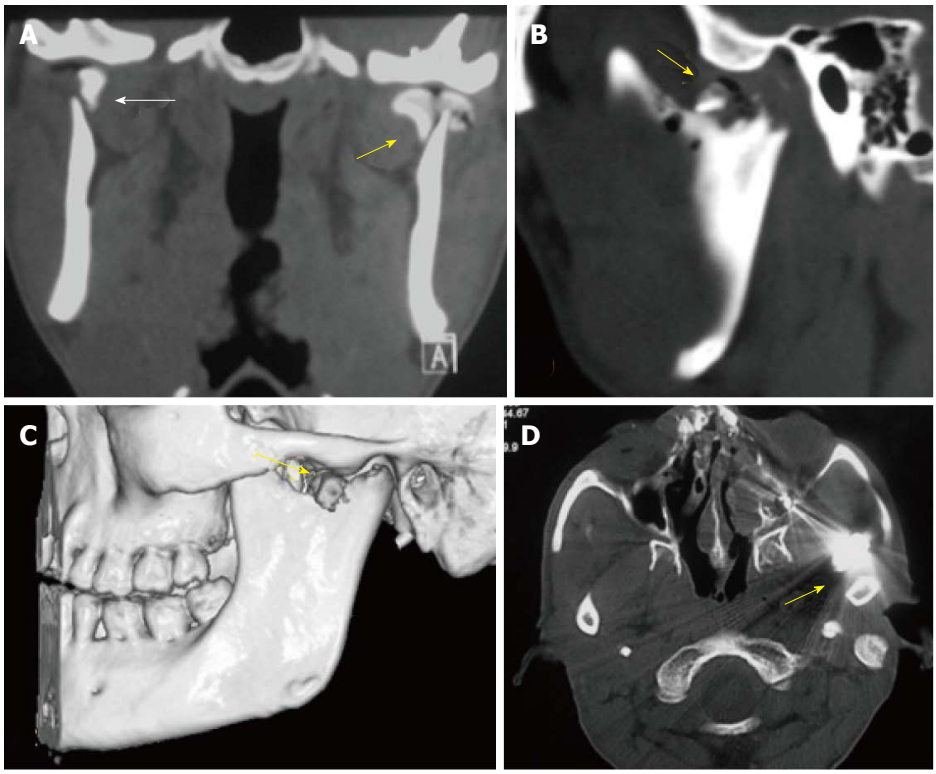

Figure 5 Condylar fractures in different patients. Coronal (A), sagittal (B) and 3D (C) reconstructed CT images depict bilateral displaced, extracapsular (right- bold arrow), and intracapsular (left- arrow) condylar head fractures with involvement of the articular surface on the left side. The intra-articular air on the left side indicates an open wound (arrow). Open joint wound with a foreign body (bullet in another patient- D) or gross contamination are indications for open surgery.

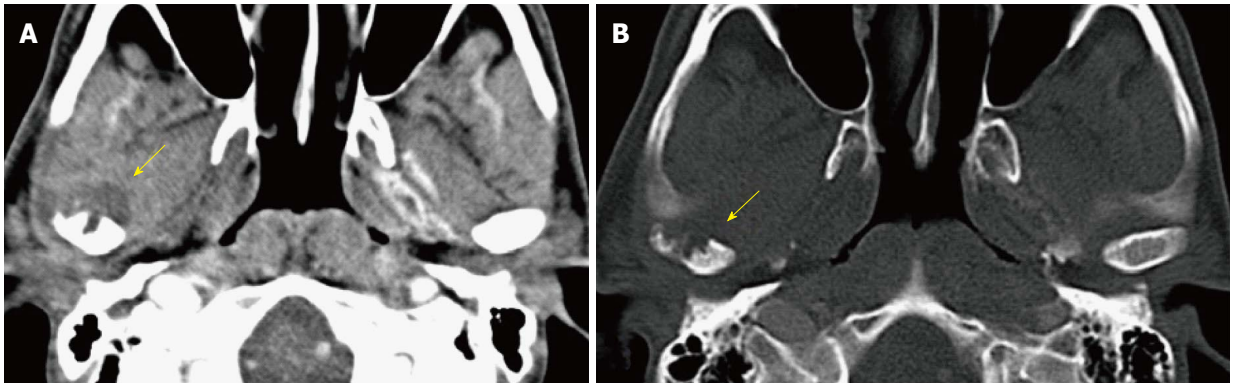

Figure 6 Pyogenic arthritis in a 33-year-old woman with fever and pain around right ear. A: Soft tissue edema with loss of fat planes (arrow) around right temporomandibular joint is seen in axial computed tomography (CT) image (A); B: Bony erosions in the condyle are well seen in axial CT image in bone window setting (arrow).

are less seen frequently[3,16,17]. Degenerative arthritis is secondary to internal derangement of the joint due to articular disc abnormalities. Arthritis after trauma is seen in untreated, ignored fractures of the condyle and these frequently progress to ankylosis.

Infective arthritis is seen secondary to other infections of the head and neck (Figure 6). Patients present with an acutely painful and swollen joint with malaise, and CT reveals erosions of the articular surface of condyle and/or glenoid fossa, and inflammatory changes in surrounding muscles. Rarely, a sequestrum may form within the joint (Figure 7). If untreated, it may progress to fibrous or bony ankylosis.

Rheumatoid involvement of the TMJ is characterized by synovial proliferation and secondary erosive changes of the bone, with destruction of the condyle and articular eminence[17]. Eventually, bony ankylosis ensues with destruction of the intervening soft-tissue structures.

TMJ ankylosis

The term "ankylosis" is defined as joint fixation or fusion leading to chronic, painless restriction of joint movements. It may also cause facial asymmetry and deviation. Trauma and infection are the most common causes of TMJ ankylosis[18]. The initial traumatic insult may not be apparent and intra-articular hematoma leads to scarring and excessive bone formation, eventually causing fusion of the joint. TM joint infection is mostly due to contiguous spread from otitis media and mastoiditis, hematogenous spread is less common. Other rare causes include inflammatory arthritis (juvenile rheumatoid arthritis[19], psoriatic arthritis[20], ankylosing spondylitis[21]), or iatrogenic after surgery.

TMJ ankylosis can be classified into two categories:

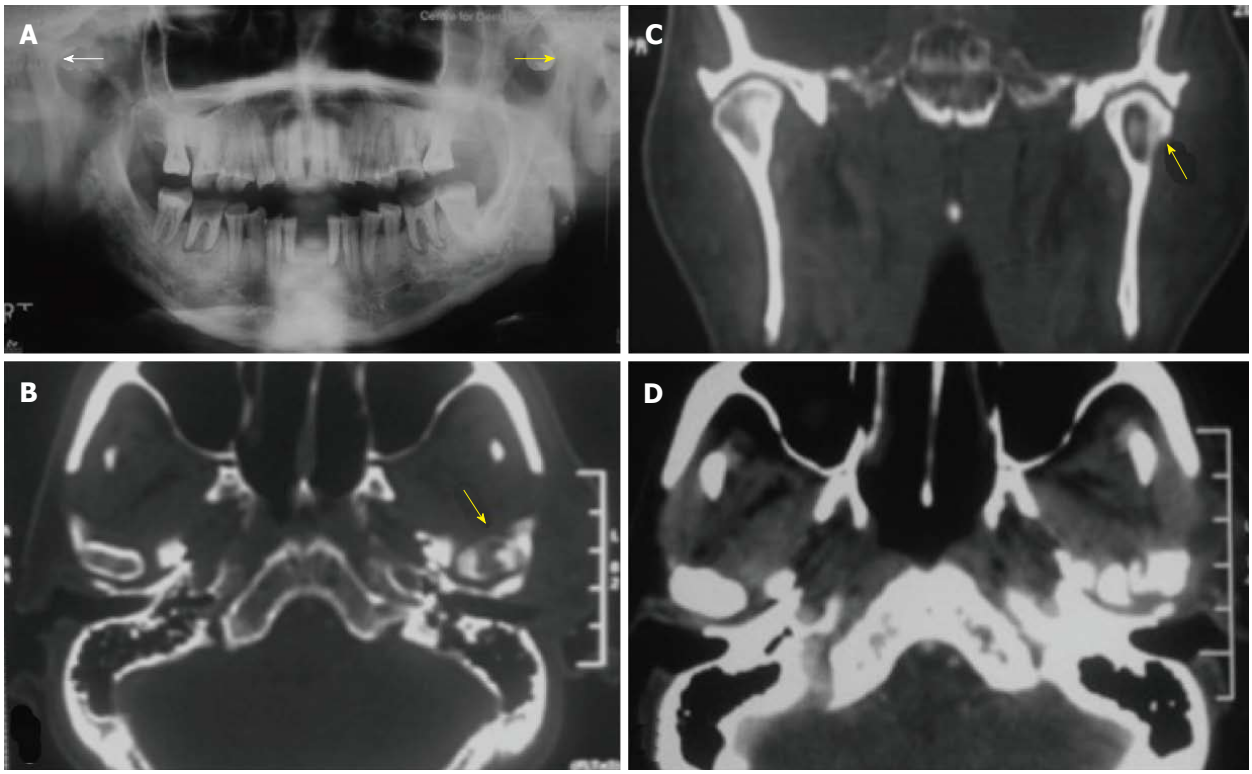

Figure 7 Chronic osteomyelitis of temporomandibular joint in a 55-year-old patient. Sclerosis of left mandibular condyle is seen in panorex radiograph (A); a bony sequestrum is seen within the left mandibular condyle in axial (B) and coronal (C) reformatted computed tomography (CT) images; axial CT section in soft tissue window (D) shows inflammatory changes in tissues around the temporomandibular joint.

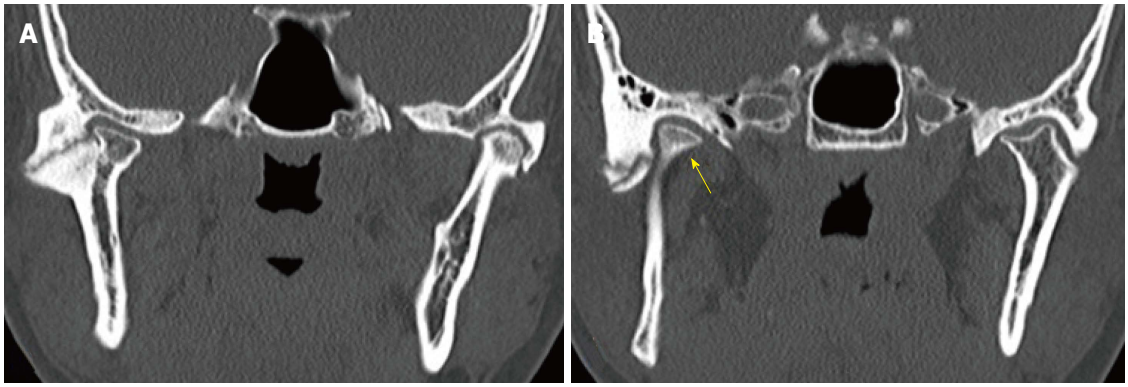

Figure 8 Post traumatic ankylosis in a 28-year-old male patient. Coronal reformatted multi-detector computed tomography images demonstrate ankylosis and pseudo-joint formation in both temporomandibular joints (A); mandibular condyle is displaced anteriorly and medially (B). The referring clinician needs to know the relationship of the condylar mass to adjacent skull base structures.

type Ⅰ, medially angulated condyle with deformed articular fossa and a mild-to-moderate amount of new bone formation; and type Ⅱ, no recognizable condyle or fossa but instead a large mass of new bone[22]. Type I is etiology-specific and seen after antecedent trauma. TMJ ankylosis is surgically treated by excision of the ankylosis, with or without autogenic, allogeneic or alloplastic graft replacement. MDCT provides a detailed three-dimensional image of the condylar mass and its relationship to adjacent structures of the skull base, which is essential for surgical planning (Figure 8).

Tumors and tumor like conditions

Neoplastic lesions rarely involve the TMJ. Osteochondroma, osteoma, eosinophilic granuloma, chondrosarcoma and bone cysts have been described in the literature[3,23]. Synovial chondromatosis, pigmented villonodular synovitis (PVNS), pseudogout, fibrous dysplasia, hyperparathyroidism and giant cell reparative granuloma are some tumor like conditions which may involve the TMJ[23]. Contiguous tumors of external ear and parotid, and metastases from carcinoma breast, kidney, lung, colon and rectum and lymphoma may also

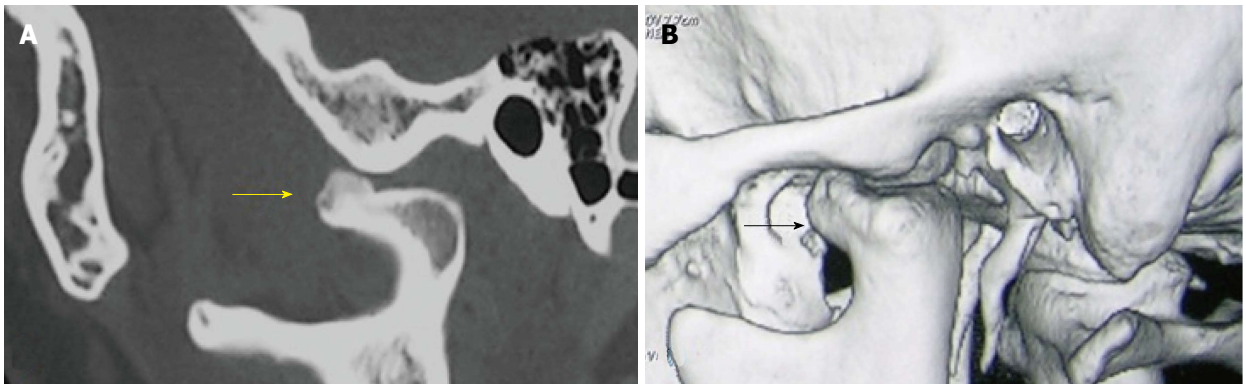

Figure 9 Osteochondroma in a 32-year-old man presenting with trismus. Sagittal (A) and 3D reconstructed (B) images demonstrate a bony outgrowth arising from the mandibular condyle (arrow), just beneath the articular eminence.

Figure 10 Jacob's disease in a 17-year-old boy presenting with restricted mouth opening. Axial (A), sagittal (B) reformatted computed tomography images depict "pseudo-joint formation" between enlarged coronoid process of mandible and zygomatic arch (arrows).

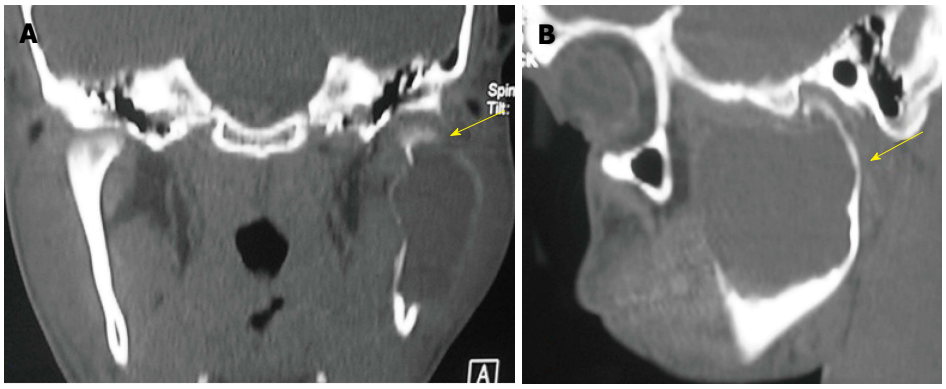

Figure 11 Aneurysmal bone cyst of the mandible in a 17-year-old boy present with left cheek swelling since one year. Coronal (A) and sagittal (B) reformatted computed tomography images depict a large, expansile, lytic lesion involving left mandibular condyle and ramus.

involve TMJ[3].

Of the above tumors, osteochondroma of the mandible deserves a special mention (Figure 9). It is an indolent tumor that is seen at the condyle or the coronoid process tip. It may become large enough to present as a facial mass or it may cause trismus. An MRI should be performed if there is a rapid change in the size of mass or pain develops in a previously asymptomatic mass. A cartilaginous cap that exceeds 2 cm in thickness on MRI is suspicious for a malignant transformation to chondrosarcoma, although such a transformation is quite rare.

Jacob's disease (first described by Jacob in 1899), is a rare entity in which a pseudo-joint develops between a sessile coronoid process osteochondroma or a hyperplastic coronoid process, and the zygomatic process of maxilla causing severe restriction of jaw movement[24]. The length of the coronoid processes can be accurately measured on MDCT and changes in the zygomatic arch are also well depicted (Figure 10).

Aneurysmal bone cyst of the TMJ is another uncommon, tumor-like non-neoplastic affliction of the Temporomandibular joint (Figure 11). It usually affects children and young adults less than 20 years of age.

The patients present with slowly increasing swelling in the cheek and preauricular region. The lesion may be unilocular or multilocular on imaging and has a non-specific imaging appearance. It is characterized by presence of well defined blood spaces lined by endothelium on histology. MDCT evaluates the lesion and defines its extent of (involvement of condyle, mandibular ramus, temporal bone, presence of breach of cortex) and is necessary for deciding surgical management (curettage *vs* block resection).

CONCLUSION

Trauma, internal derangement with possible sequelae (osteoarthritis), and inflammation are the most common of pathologic conditions involving the TMJ. MDCT enables comprehensive evaluation of osseous afflictions of TM joint, and is a valuable tool for surgical planning.

Abstract

AIM: To structure the rate of intraoperative complications that requires an intraoperative or perioperative resolution.

METHODS: We perform a literature review of Medline database. The research was focused on intraoperative laparoscopic procedures inside the field of urological oncology. General rate of perioperative complications in laparoscopic urologic surgery is described to be around 12.4%. Most of the manuscripts published do not make differences between pure intraoperative, intraoperative with postoperative consequences and postoperative complications.

RESULTS: We expose a narrative statement of complications, possible solutions and possible preventions for most frequent retroperitoneal and pelvic laparoscopic surgery. We expose the results with the following order: retroperitoneal laparoscopic surgery (radical nephrectomy, partial nephrectomy, nephroureterectomy and adrenalectomy) and pelvic laparoscopic surgery (radical prostatectomy and radical cystectomy).

CONCLUSION: Intraoperative complications vary from different series. More scheduled reports should be done in order to better understand the real rates of complications.

Key words: Intraoperative complications; Laparoscopy; Surgical complication; Urology; Cancer

Core tip: We decided to perform this literature review to light and to arrange the intraoperative rates of laparoscopic urological cancer complications, which are such as messy in the different manuscripts published. This idea leaves from an urological team which performs more than 150 laparoscopic procedures per year since 2005.

INTRODUCTION

The consequences of errors during laparoscopic surgery are unpredictable and can vary from no adverse effects to fatal events. An adverse event is the result of the combination of an active failure and a penetration of all the defences and safeguards which ought to be in place to prevent it, in these terms, safe surgery is dependent on systems designed to prevent all errors. Most of the intraoperative complications are consequence of consecutive and cumulative errors without individual consequence but globally result into a complication. Surgeon, team, technique, technology/device and organization errors are different kind of mistakes that can finally explain an intraoperative complication[1].

Some risk factors have demonstrated statistical significance to develop a surgical complication related to laparoscopic surgery for urological cancer: type of procedure (*i.e.,* partial nephrectomy, radical cystectomy or radical prostatectomy), abnormal renal function and more than 4 h of surgery. Other conditions as body mass index, ASA score, previous abdominal surgery or surgeon experience have not demonstrated significant association. However there is a trend to decrease of complications when surgical experience increases[2].

General rate of perioperative complications in laparoscopic urologic surgery is 12.4%. The rate of complication of Laparoscopic Radical Nephrectomy is 14%, Laparoscopic Partial Nephrectomy is 23%, Laparoscopic Nephroureterectomy is 22.1%, Laparoscopic adrenalectomy 10%, Radical Prostatectomy 6.7% and Radical cystectomy 33.3%-48.3%. General Intraoperative complications were rated in 4.7%. Nevertheless, most of the manuscripts published do not make differences between pure intraoperative, intraoperative with postoperative consequences and postoperative[2,3].

We pretend to review the rate of intraoperative complications that requires an intraoperative or perioperative resolution. In some cases we describe the possible resolution and the possible prevention.

MATERIALS AND METHODS

A literature review of Medline database was completed. There were no limits of date. English published papers were reviewed, for non-English papers only the abstract were visualized. A combination of the following key words was used: laparoscopy, intraoperative complications, pathologic processes, radical nephrectomy, partial nephrectomy, nephroureterectomy, adrenalectomy, radical prostatectomy and radical cystectomy. From the diverse literature manuscripts and abstracts searched, the authors selected 40 manuscripts to review. The research was focused on intraoperatory laparoscopic procedures inside the field of urological oncology. Laparoscopic complications for other non-oncological conditions were excluded (pyeloplasty, simple nephrectomy, living donor nephrectomy, adenomectomy or bladder augmentation), likewise postoperative complications were also excluded. Only pure laparoscopic procedures were included; removing hand assisted, ablative or single port approaches. Most of the manuscripts were high volume retrospective monoinstitution series, there are some review articles, a few meta-analysis of retrospective data and single cases of extremely rare conditions.

RESULTS

We expose the results with the following order: retroperitoneal laparoscopic surgery (radical nephrectomy, partial nephrectomy, nephroureterectomy and adrenalectomy) and pelvic laparoscopic surgery (radical prostatectomy and radical cystectomy).

Retroperitoneal laparoscopic surgery

Radical nephrectomy: The general rate of intraoperatory complications during a laparoscopic radical nephrectomy varies from 1.7% to 16%. The conversion to open surgery due to notorious bleeding or technical difficulty is 2.5%. The intraoperatory complications can be systematized as follows.

The rate of complications linked with trocar placement varies from 0.09% to 0.27%. There are no normalized devices to perform the pneumoperitoneum and most of the surgeons use the Veress needle, the optical port and the Hasson port, with a rate of injuries of 0.18%, 0.27% and 0.09% respectively[4].

The injuries reported are bowel, solid organs, vessels from the abdominal wall and diaphragm. Intraoperatory laparoscopic repair by suturing and hemostatic agents (fibrin glue, bio glue, bio patches) are used in many cases[5].

The Mayo Clinic series described two complications related to specimen handling and retrieval. One specimen was fractured by the Endo-Catch bag when the kidney was not completely entrapped prior to closure. The other specimen was a partial nephrectomy in which part of the tumor was fragmented during dissection. In this fragmented specimen fractures were seen within the tumor but the whole mass was still completely removed and surgical margin status was negative[6].

It is the most frequent intraoperative complication with a rate of 2.37%[3]. Most described lesions are small and large bowel injuries during the aperture of the Toldt line (0.8%) and duodenum during the right hilium dissection, these lesions should be repaired immediately when noticed and in most cases intracorporeal knots are adequate, minor thermal injuries may be managed with observation. Resection and anastomosis or ileostomy/colostomy is in some cases necessary. Prevention of these lesions could be maintaining the electric devices with 1-2 cm far from the bowel during the aperture of the field, followed by

blunt dissection as aspiration devices when the proper plane line is opened. There are also described indirect lesions of the bowel by local ischemia due to accidental enclosure of mesenteric artery; it required end to end vascular anastomosis and bowel resection. It is also reported partial ischemic lesions of splenic flexure of large bowel managed conservatively[6,7].

Laparoscopic operations involving the left kidney and adrenal gland may be complicated by pancreatic injury owing to the proximity of the pancreatic tail to the surgical field[8]. Pancreatic injury is described in 0.69% left laparoscopic urology procedures and 2.1% during left radical nephrectomy. No cases of injury of the right side of pancreas have been described for urological procedures. In most cases the injury was not noticed during the intervention and the solution was conservative with nasogastric tube, parenteral nutrition and somatostatin, according with the general surgeon experience, most of the pancreatic fistulas closes within 2 wk[9]. If detected intraoperatory, endovascular stapler can be used or over sewn, also tissue glue can be used as adjunctive agent[8]. Possible prevention methods are a complete mobilization of spleen, transecting the splenophrenic attachments and allowing the pancreas and spleen to move together; just like being attentive when the features significantly distort the normal anatomy.

The injury of the spleen is reported in 1.4% of left radical nephrectomies. In most cases can be managed conservatively with electric devices and haemostatic agents but if the lesion is large might requires open conversion. The prevention could be a gentle traction to avoid tearing[6].

Liver injury and gallbladder injury are described in 1.1% and 1.4% respectively. There are no reports found about the mechanism of injury (except of the optic port placement[7]), management and prevention[3].

Chylous ascites is a rare complication caused by unrecognized interruption of the cisterna chyli or other major retroperitoneal lymphatic channels and establishment of a lymphoperitoneal fistula. It is described in surgery for renal cancer as the third cause[10]. The overall incidence of chylous ascites was 5.1% (32 of 622 cases), including 4 severe refractory cases (0.6%). The incidence was higher in those who underwent lymphadenectomy (13.9% with lymphadenectomy and 4.0% without lymphadenectomy). Only 1 patient underwent explorative laparotomy due to persistent severe chylous ascites despite 8-wk conservative management. Most cases were successfully managed conservatively by total parenteral nutrition and a low fat diet. To prevent this complication the authors suggested meticulous clipping of all perihilar and retroperitoneal fibrous fatty tissue during major vessel dissection, especially for left nephrectomy or extensive lymphadenectomy[11].

There are three mechanical devices to control the renal hilium: vascular staples, metallic clips and polymer clips. It is described the estimated total device-related complications in 1.1% for staples, 2.0% for metallic clips and 0.2% for polymer clips.

Food and Drug Administration report of 2172 cases does not conclude that one device is safer than another. Analysing the intraoperative complications over the total complications there are 352 failures noted: staples (63%-223 total complications: 1% death, 22% severe bleeding, conversion to open surgery 35%), metallic clips (33%-111 total complications: 1% death, 2% severe bleeding, conversion to open surgery 7%) and polymer clips (5%-18 total complications: 17% death, 22% severe bleeding, conversion to open surgery 44%)[12].

The leading causes of failure reported in stapling devices were staple line malformation (47%) and locking up (29%). In titanium clips, jamming/feeding difficulties (27%) and trouble closing or "scissoring" clips (26%) were the most common. In locking clips, dislodgement (44%) was most frequently reported.

The presence of accessory polar arteries not identified during the hilium dissection is a common cause of bleeding. Grasping the stump and positioning a clip are described as an intracorporeal solution[5].

Sometimes calcified and atherosclerotic arteries are the cause of absence of closure or arterial rupture. Preoperative TC examination is mandatory and these conditions must be taken into account because intraoperative resolution is difficult to perform[7].

Defining intraoperative haemorrhage as bleeding which requires intraoperative blood transfusion or open conversion, it was described as 2.2%-2.8% in the biggest series[2] and it is the second most frequent intraoperative complication for radical nephrectomy. Separately, venous bleeding is 1.8% and arterial bleeding is 1%. It is one of the most described causes of open conversion. Increasing pneumoperitoneum pressure and using Haemostatic agents (bio glue, fibrin glue, fibrin patches) could be used as first option; intracorporeal knotting solution requires high volume of cases and huge experience. No air emboli were noted in the literature review[13].

The pleural injury is described in 0.4%-0.6% of upper abdominal laparoscopy. Eleven cases were noticed during radical nephrectomy (9 radical and 2 cytoreductive). When noticed, the surgeon can directly watch the defect or can indirectly watch the diaphragm billowing, which is named floppy diaphragm. Sometimes the damage of pleura is unnoticed anyway and sometimes is intentional because of tumoral infiltration. The rupture can be treated intracorporeally with running suture, with a technique defined by Cleveland Clinic[14]. There is also the possibility of conservative management with torax tube and postoperative surveillance. When the rupture is unnoticed the management should be conservative with thorax tube, this condition used to be done when organs as spleen or liver are covering the defect[14,15].

Partial nephrectomy: Most of the considerations for radical nephrectomy could be added to partial

nephrectomy in terms of adjacent organs and diaphragm for upper pole masses, instead, the control of the hilum and the parenchymal bleeding have distinctive features for this kind of technique. The rate of intraoperatory complications is 5.5% and the rate of open conversion is 2%-6%[16].

There are many devices designed to control de ischaemia of the kidney (laparoscopic bulldog, Satinsky clamp and the Rumel tourniquet), including the possibility of no hilar control for small exophytic masses not exceeding the diameter of 2 cm[17]. Injury of the renal vessel may compromise the entire procedure as well as the long term results.

Severe intraoperatory bleeding is described to be 3.5%-3.8% in different laparoscopic series[18,19].

In order to prevent urine leakage and vascular fistula/pseudoaneurim, two layers of suture should be performed. First line approximation of the interstitial tissue with running suture with two absorbable clips at the beginning and the end of the suture to earn ischaemia time. Parenchyma repair is performed with a second running suture, secured with Hem-o-locks with the same plan as first described. To ensure from slipping first hem-o-lock is enforced with by a knot and two clips are sited at the end of the suture. It is also described the use of haired sutures for this procedure[16]. Replacing the knotting by Hem-o-lock sutures let speeding up the procedure. Haemostatic agents as fibrin glue, bio glue or patches can add haemostasis and minimize the bleeding.

Radical nephroureterectomy: Most of the considerations for radical nephrectomy could be added to nephroureterectomy with the special complications of nerve injury and vascular injury during the dissection of the distal ureter. There are 3 techniques described (open, endoscopic, pure laparoscopic) for the management of distal ureter and each one have got their one special intraoperative complications. The rate of intraoperatory complications is 5.4% and the rate of open conversion is 2.3%[20,21].

The complications and their prevention should be similar to radical nephrectomy, instead it is described a rate of neural injury of 0.8%, during the middle and distal ureter dissection. Also a perforation of diverticulum at sigmoid sigma was specifically reported[7].

Adrenalectomy: The average of complication during laparoscopic adrenalectomy in high volume laparoscopic series is 3.2%, varying between 2.1% and 7.8% in different laparoscopic series. The open conversion rate varies between 0.3%-9.6%, and most frequently explained by technique problems than bleeding[22-24].

For this procedure are described diaphragmatic lesions in 1.16%. The Cleveland series described 1 non intentional diaphragmatic lesion and 4 intentional lesions during a transthoracic adrenal approach. Laparoscopic repair was attempted and a goretex patch placement was performed for transthoracic adrenalectomy. A special laparoscopic technique is described for this issue[14].

It is the most common intraoperative complication described (1.3%-1.74%). The vessels involved by order are adrenal vein, cava vein and renal vein. In most cases is the cause of open conversion, when possible intracorporeal laparoscopic suturing is attempted[22].

It is the second intraoperative complication 0.04%-6.3%. The authors of the series consulted noticed 4 spleen injuries (controlled with hemostatic agents and two of them required open conversion), 2 hepatic injuries (controlled with hemostatic agents), 1 intestinal injury and 1 pancreatic laceration. Nevertheless, pancreatic injury has been described in 8.6% during left adrenalectomy[8].

Laparoscopic pelvic surgery

Laparoscopic radical prostatectomy (LRP) is probably considered the most complex technique of minimally invasive urologic surgery. Paradoxically intraoperative complications in these procedures are rare, regardless of the technique used, either transperitoneal, extra-peritoneal robot-assisted or single port. Laparoscopic radical cystectomy (LRC) is a more recent technique, with smaller series, and perhaps thereby, relatively contemporary publications report higher rates of complications. Published data are very incomplete, as most of the published series refer only to postoperative complications, without naming those occurring during surgery and resolved without further impact that increased surgical time.

Conversion to open surgery: Conversion from laparoscopic to open surgery should be considered a complication in itself, although it has many causes. The rate of conversion to open surgery for LRP is estimated at 0.2%-1%, with no demonstrated differences between classical laparoscopy and robot-assisted laparoscopy[25]. This meta-analysis shows data published since 1990, and probably in contemporary series the percentage is even lower, among other factors, because the lack of experience in open surgery in younger surgeons. In the first communications on the LRC conversion rates reached 10%[26], while contemporary series show conversion rates of 0%[27]. It is necessary to note that although the more recent series include learning curves have the advantage of the technique is mature, and surgeons already experienced in PRL.

Intestinal injuries: Bowel injuries during pelvic laparoscopy should be divided in intestinal rectal injuries and intestinal non rectal injuries. Non rectal intestinal lesions are rare in the RLP, from 0.02% to 0.14%[25]. In the series of LRC no bowel injuries are reported. It seems unlikely that no intestinal injury happen during cystectomy, so there is probably not a correct record of complications[26,27]. Overall intestinal lesions occur after the creation of pneumoperitoneum with a

Veress needle, in the blind placement of the first port, and can be largely avoided by creating the access by minilaparotomy. They can also occur in the blind part of the field, tearing with the clamps of the assistant. In these two first cases may be missed during surgery, causing significant postoperative morbidity. Less common are those caused by release of adhesions, which also tend to be diagnosed and easily treated with a suture without further consequences.

Rectal lesions occur during dissection of the backplane, usually in the most distal part of the lateral pedicles and the prostatic apex. It is the most frequent intraoperative complication of LRP and occurs in 1.1% of cases, but shows an important heterogeneity among published series, from 0.2% to 8%. This heterogeneity may be explained by the inclusion in publications of learning curves at the beginning of the art.

The series of robotic surgery show significantly lower rates of between 0.2% and 0.4%. These differences should be taken with caution, because in general the series of LRP are mature series, by surgeons with much previous experience, subsequent in time and with a very high number of cases per surgeon[28]. For anatomical reasons in LRC rectal injuries occur almost exclusively in male patients, and the authors have not found reports of rectal injury in women.

Rectal injuries reported in LRC are isolated. Older series report rates of up to 20%, but with very few cases, while contemporary series report a rate of about 0%-1%[27-30]. The data from this series, however, are probably incomplete, since only recorded injuries causing clinical complications postoperatively. Risk factors for rectal injury are: history of radiation therapy, hormone therapy, infection, previous prostate or rectal surgery and advanced tumor stage, all of them controversial. The surgeon's experience is inversely related to the risk of rectal injury, but this risk never disappears[31]. Most rectal lesions are diagnosed by direct vision, in which case it must be repaired immediately. There is consensus that the closure must be performed in two planes with absorbable suture and checked for leaks by blowing air through a rectal probe. For rectal injury during LRC, peritoneal flap placement on the rectal lesion is simple and generally must be performed, but is mandatory in cases where an orthotopic bladder is made. In the LRP interposing a flap of tissue between the bladder and rectal levels or performing a colostomy is not essential in primary watertight closures, although it seems advisable in patients with lesions larger than 2 cm or history of radiotherapy[32]. Injuries not diagnosed during surgery may present as early postoperative abdominal septic conditions, but more often they are diagnosed several days or even weeks after surgery by pneumaturia, fecaluria and urinary tract infections. An important gesture to avoid postoperative morbidity in rectal lesions is anal dilation. The rectum is a high-pressure reservoir. Anal dilatation decreases this pressure for at least the first few days, the critical period of healing[26]. Although its efficacy is not fully tested in the literature, many authors advise, and is a simple and quick gesture. Another controversial item is the utility of the previous bowel preparation, exclusively mechanical, or associating antibiotics. Although its value does not clearly shown, most authors still use[32].

For the treatment of rectal injury during prostatectomy the protocol described by Blumberg offers a simple and practical algorithm[33].

Ureteral injuries: The anatomical relations of the ureter make it susceptible to be injured during prostatectomy or cystectomy. Its frequency is very low in LRP series published between 3% and 0.04%, which is supported by population studies[34] without showing differences between the results of LRP and robot-assisted LRP. There is a clear inverse relationship with the number of cases performed by the surgeon, but often occur after overcoming the learning curve. The most common site of injury is the juxtavesical ureter; which is injured during the section of the posterior bladder neck or during dissection of the seminal vesicles[35]. If they are diagnosed during surgery, most cases require ureteral reimplantation or end to end anastomosis, which only determines an increased surgical time. The problem is that the majority of ureteral injuries go unnoticed, leading to increased postoperative morbidity, increased hospitalization time and often the need for further reoperation. As risk factors for ureteral injury during prostatectomy have been reported: history of infections, transurethral resection of the prostate, the presence of prostatic middle lobe and large prostate sizes. For more proximal lesions described risk factors include abdominal surgery, radiotherapy and extended pelvic lymphadenectomy[36]. Intraoperative ureteral injuries are not described in the literature as a complication of LRC, probably because the surgical technique can be adapted to the length of ureter feasible.

Neurological injuries: Obturator nerve injuries occur in 2% of patients underwent LRP with significant variability among published series, from 0% to 4%. In robotic frequency series appears to be less, 0.4%, but this difference does not seem significant[25].

In the series of cystectomy no injuries obturator nerves are described[37]. The injury usually occurs during the performance of pelvic lymphadenectomy, and heterogeneity of the published data is probably due to variability in the indications and extent of lymphadenectomy. If the section is made with a cold cut with not much tissue destruction can be attempted immediately by epineural nerve repair points[38]. If a thermal injury occurs is probably necessary to discard the injured nerve ends, which prevents direct anastomosis without tension. In that case have been described good results by immediate repair with interposition of a segment of sural nerve[39]. In the event that goes unnoticed is easily diagnosed in the early postoperative by the functional impairment resulting

denervation of the adductor. Treatment is then based on the rehabilitation and physiotherapy, with varying results but almost never complete.

Vascular injuries: Vascular lesions in radical prostatectomy described in the literature are rare, 0.1%-0.7% for laparoscopic surgery, and the series of robot-assisted LRP are even more rare, the 0.03%-1%[25]. In cystectomy communications vascular injuries are also punctual, but in most of the series do not appear as a complication. Among the published data, it is noteworthy Castillo's series, with a percentage of 11% intraoperative vascular lesions, including iliac venous injury, iliac artery injury and one epigastric artery injury. Despite the high number of vascular lesions does not describe other intraoperative complications[40]. Generally the vascular injuries occur in the external iliac vein while performing lymphadenectomy. Unlike what happens in retroperitoneal surgery in most cases it is possible to repair by laparoscopic suturing, mainly without further consequences[26,40]. The keys for the control of a venous injury are: bleeding control with pressure, raising the pressure of CO_2, obtains a good control dissection and proximal and distal to the lesion ends and finally a careful suturing.

DISCUSSION

Most of the papers reviewed described retrospective personal or institutional series. In general, there is no clear separation between intra and postoperative complications, making difficult to centre in some aspects as technique errors in order to avoid them in the future. In this terms, it should be necessary to assess the surgical complications in normalized forms as Clavien for postoperative and Satava for intraoperative. The results on retroperitoneal laparoscopy are based on huge series with many years of experience with the exception of adrenalectomy which is both performed by general surgeons and urologists. In laparoscopic pelvic surgery, the results on prostatectomy are deep and the rate of intraoperative complications is lacking. The laparoscopic cystectomy is a less studied technique with current result still heterogeneous. In spite of the high index of perioperative complications, the rate of intraoperative complication is also lacking.

COMMENTS

Background

The authors decided to perform this literature review to light and to arrange the intraoperative rates of laparoscopic urological cancer complications, which are such as messy in the different manuscripts published. In general, laparoscopic complications are described as postoperative but it is infrequent to find manuscripts regarding specifically intraoperative complications and their possible prevention or solution. The authors think it is important the existence of a document to sum up this issue, mainly for urologist used to perform this kind of procedures by this approach. This idea leaves from an urological team which performs more than 150 laparoscopic procedures per year since 2005.

Research frontiers

Nowadays laparoscopy is one of the most frequent approach for the treatment of urological oncology field. It should be necessary the development of a systematic review to statistically report the complications of the most frequent procedures. It also should be necessary the cooperation between high volume institution to light the annual incidence and prevalence of the intra and postoperative complications, clearly separated in order to futures reviews.

Innovations and breakthroughs

A narrative review of the intraoperative complications for the most frequent urological cancer procedures. From people point of view, there is no other similar manuscript summarizing intraoperative laparoscopic complications in English medical literature.

Applications

To compare the local rate of complications with the general rate reviewed and to inform to young urologist that start in laparoscopy the possible problems that they can find.

Terminology

Laparoscopy: is an operation performed in the abdomen or pelvis through small incisions (usually 0.5-1.5 cm) with the aid of a camera. It can either be used to inspect and diagnose a condition or to perform surgery.

Peer-review

The manuscript is interesting and the authors have performed a good study.

Abstract

Colorectal lipomas are the second most common benign tumors of the colon. These masses are typically incidental findings with over 94% being asymptomatic. Symptoms-classically abdominal pain, bleeding per rectum and alterations in bowel habits-may arise when lipomas become larger than 2 cm in size. Colonic lipomas are most often noted incidentally by colonoscopy. They may also be identified by abdominal imaging such as computed tomography or magnetic resonance imaging. We report a case of a sixty-one years old male who presented to our emergency room with a 6.7 cm × 6.3 cm soft tissue mucosal mass protruding transanally. The patient was stable with a benign abdominal examination. The mass was initially thought to be a rectal prolapse; however, a limited digital rectal exam was able to identify this as distinct from the anal canal. Since the mass was irreducible, it was elected to be resected under anesthesia. At surgery, manipulation of the mass identified that the lesion was pedunculated with a long and thickened stalk. A laparoscopic linear cutting stapler was used to resect the mass at its stalk. Pathology showed a polypoid submucosal lipoma of the colon with overlying ulceration and necrosis. We report this case to highlight this rare but possible presentation of colonic lipomas; an incarcerated, trans-anal mass with features suggesting rectal prolapse. Trans-anal resection is simple and effective treatment.

Key words: Colorectal lipoma; Rectal prolapse; Trans-anal resection

Core tip: Colorectal lipomas are typically asymptomatic. They are incidentally found on colonoscopy or radiologic imaging. This report portrays a rare presentation of colonic lipomas as an incarcerated prolapsed mass through the anus, and highlights trans-anal resection as a simple, safe and effective treatment. Thus, it describes an uncommon pathology with a unique presentation that sets a diagnostic and therapeutic challenge.

INTRODUCTION

Lipomas of the gastrointestinal (GI) tract were first described by Bauer in 1757[1]. Although they are rare findings, cases of these benign tumors have been reported throughout the world for many years. Colonic lipomas originate from the connective tissue of the intestinal walls and are most commonly submucosal[2]. Chronic irritation or inflammation as well as the excessive accumulation of adipose tissue secondary to the underdevelopment of arterial, venous and lymphatic circulation, are a few of the speculated factors associated with the formation of these tumors[3]. Lipomas occur with greater frequency within the ascending colon, but can be present in any part of the GI tract from the hypopharynx to the rectum[4]. Generally, colonic lipomas are solitary, well-delineated and sessile masses[5]. They predominately affect females and those within the 6th-7th decade of life[3,6-8]. Although malignancy is rare in these masses, complications including, hemorrhage, infarction, obstruction, and intussusception can occur[2,5,8]. Thus, symptomatic lesions are routinely removed through surgical interventions such as endoscopic excision, segmental resection or hemi-colectomy in an open or laparoscopic fashion[9,10]. Unfortunately, at present there are no clinical trials which validate the most appropriate methods by which colonic lipomas should be diagnosed and treated. Much of patient management is thus dependent on case reports discussed within literature. This paper presents a unique report of a sixty-one years old man with a prolapsed ano-rectal mass that was identified as a submucosal lipoma of the rectum after trans-anal surgical excision. By analyzing this case, we will attempt to review the common practices used in managing patients with colonic lipomas.

CASE REPORT

A sixty-one years old male patient with a diagnosis of schizophrenia and chronic constipation presented to the emergency room with a prolapsed ano-rectal mass. The patient noticed the propulsion of the mass while defecating four hours prior to his presentation to our hospital. Associated anal pain and minimal bright red blood per rectum were reported; however, all remaining review of systems was negative. The patient had no previous history of gastrointestinal symptoms or pathologies-denies change of bowel habits and any history of hemorrhoids or prolapse. He had never undergone a colonoscopy. On physical examination, the firm, well circumscribed, tender, hyperemic mass

Figure 1 Protruding mass from anal canal in the emergency room (left lateral decubitus position).

was noted to be 6.7 cm × 6.3 cm in size (Figure 1). There appeared to be a layer of superficial necrotic tissue. It did not appear to be originating from the anus or hemorrhoidal tissue as a limited digital rectal exam was able to identify this as distinct from the anal canal. It was irreducible despite attempts by emergency room and surgical staff (manipulation, squeezing and pushing). Abdominal exam was unremarkable and no systemic signs of infection were noted. Preoperative laboratory studies including hematology, chemistry and coagulation profiles were all within normal ranges. The differential diagnosis included other types of prolapsed neoplastic lesions or an atypical presentation of either thrombosed internal hemorrhoids *vs* rectal procidentia.

The patient was admitted to the colorectal surgical service. Given the patient's pain and discomfort and given that the mass was irreducible, the patient was taken to the operation room for exam under anesthesia with planned resection. After sedation, the patient was placed in a high lithotomy position. Digital rectal examination and further manipulation of the mass identified that the lesion was pedunculated with a long (mucosal origin could not be identified) and thickened stalk (2 cm in diameter). As the mass was retracted externally, the stalk could be visualized and was transected by a 60 mm laparoscopic linear cutting stapler (Figure 2). The mass was completely removed and the specimen was sent to pathology. Afterwards, examination of the anus and the distal rectum was performed with an anal retractor. The staple line was not visualized and there existed no active hemorrhage. The bowel was not adequately prepped for endoscopic evaluation so we planned on postoperative colonoscopy after complete bowel preparation.

Post-operatively the patient was stable and denied any pain. He tolerated food, passed gas and also had a bowel movement. The patient was discharged home on post-operative day one with instructions to follow up with a colonoscopy in 2 wk.

Pathology report determined the mass to be a 6.7 cm × 6.3 cm × 4.8 cm polypoid submucosal lipoma of the colon with overlying ulceration and necrosis (Figure

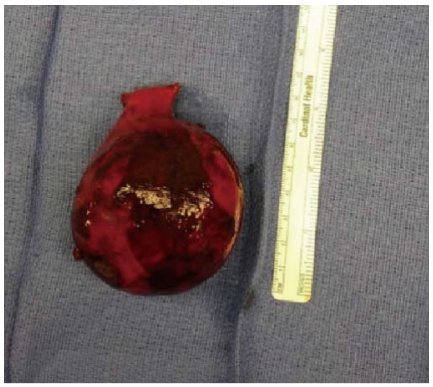

Figure 2 Gross view of the resected specimen.

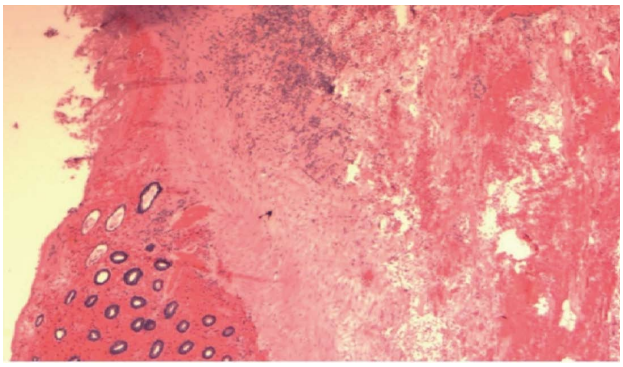

Figure 3 Histopathology (HE, 2 ×) showed colonic lipoma; the colonic mucosa (left side) has atrophy and ischemic necrosis with hemorrhage.

3). No malignancy was identified.

DISCUSSION

Lipomas are the second most common benign tumor of the colon after adenomatous polyps[3,5,9] with an incidence of only 0.035%-4.4%[6,9]. Colonic lipomas most commonly occur between the ages of 50-65[3,6-8] and as Jiang *et al*[6] noted can have up to a 66.7% female predominance. They are most commonly located within the ascending colon (61%)[3,6,7] followed by descending colon (20.1%), transverse colon (15.4%), and least commonly the rectum (3.4%)[3,6,11,12].

Three types of colonic lipomas exist: submucosal, which account for 90% of all intestinal lipomas[2], subserosal and mixed[3]. Grossly, these masses can present as rounded, sessile or pedunculated lesions with smooth mucosal surfaces and a yellow color[3-8]. Histologically, a fibrous capsule is found surrounding the adipose tissue giving the masses a lobulated appearance[3,6]. Ulceration, granulation and fat necrosis has also been noted in the overlying mucosa of many of colonic lipomas[6,8], as identified within the lipoma found in this case report. Over 94% of colonic lipomas are asymptomatic[2,8,13] with many incidentally found during colonoscopic screening, surgery or autopsy[6,9]. Colonic lipomas are more prone to be symptomatic when they are greater than 2 cm in size[4-6,14]. More specifically, 75 percent of patients with "Giant Lipomas"-larger than 4 cm are symptomatic[15]. Symptomatic patients may have abdominal pain (42.4%), bleeding per rectum (54.5%) and alterations in bowel habits (24.2%)[6,7]. Other reported conditions may include constipation, hemorrhage, intussusception, obstruction[2,4,5,8] or anemia[2,4,16,17]. Spontaneous expulsion of these lipomas in the stool has been rarely reported[1,4,9,13,18,19] but is attributed to self-amputation of the lipoma at its stalk[9,20]. Self-amputation typically occurs in giant and pedunclated lipomas and can be caused by intussusception, procedures such as endoscopy or by other idiopathic processes[13,18,19,21].

The rare presentation of colonic lipomas makes the diagnosis a difficult task. They are often misdiagnosed as a rectal prolapse or as a colonic malignancy[3]. One initial radiographic test for colonic lipomas is a barium enema which identifies a well-defined, smooth and radiolucent mass causing an intraluminal filling defect which elongates during peristalsis (the "squeeze sign")[4,5,7,14]. Unfortunately, although barium enema is sensitive for lipomas, it is not specific to these masses and may mistake them for other endoluminal neoplastic masses[6]. Endoscopic ultrasonography is another commonly used test displaying lipomas as hyperechoic colonic lesions. It is helpful in identifying the involvement of the muscularis propria and serosa[3,5,7,9]. Information regarding the depth of the lesion in the wall of the colon is particularly important in deciding whether the lesion is capable of being safely excised endoscopically.

Three classic signs for colonic lipomas have been described during colonoscopy: the "tent sign" (lifting the overlying mucosa of the lipoma with forceps to create a tent-like shape), the "cushion sign", (forceps causing indentation of the lipoma which is resolved with their removal) and finally the "naked fat sign" (extrusion of adipose tissue from the lipoma during biopsy)[3,6,14]. However, Andrei *et al*[3] noted that although colonoscopies are successful in identifying typical lipomas, they are less sensitive for lipomas with atypical qualities such as overlying ulceration or necrosis as seen in the lipoma described in this report. In addition, colonoscopic biopsies often fail to obtain adequate samples of lesions as normal mucosa or even ulcerated and necrotic tissues can cover the adipose tissue necessary for diagnostic testing[6,14]. In situations where obtaining histologic determination of the mass is relevant, needle biopsy under endoscopic ultrasound guidance provides a safe option. The literature indicates that the study of choice for colonic lipomas is computed tomography (CT) scan[3,5,14]. This test visualizes well-defined, ovoid and homogenous intramural lesions with a fat density between -40 and -120 UH[3-5,8]. CT is specifically useful when lipomas are large (> 2 cm)[6,7] and in lipomas with associated complications such as necrosis, infarction or intussusception[2,5,8,22]. Nonetheless, the diagnostic value of CT scan is limited

by the size and partial volume of the lesion. Smaller lesions are more likely to be missed by CT while, increases in partial volume, due to the added volume of fecal matter and soft tissue make some masses appear larger than normal on CT imaging[3,14].

The treatment of colonic lipomas involves observation for asymptomatic cases and surgical intervention for lipomas with symptoms or associated complications[23]. Depending on the lipoma size, location and the presence or absence of complications, surgeons decide on endoscopic *vs* surgical intervention[8]. Endoscopic excision with snare electrocautery is the treatment of choice for lipomas smaller than 2 cm in size[5,6,9,14,23,24]. Higher risk of perforation has been reported with the endoscopic excision of lipomas larger than 2cm in size[6,9]. Newer instrumentation and techniques developed for endoscopic submucosal resection of adenomatous lesions make endoscopic resection more feasible for larger lesions. Segmental colectomy with lipectomy is the gold standard for uncomplicated lipomas larger than 2 cm[3,25]. More radical approaches to resection-hemicolectomy-is usually reserved for lipomas with wide implantable bases, deeper lesions such as those that originate in the subserosal layer, and those with excessive bleeding or associated intussusception[9]. Finally, laparoscopic removal of lipomas is also an available option for treatment[10] and is a superior tool in cases when endoscopic removal is unsafe, ineffective, or cannot obtain negative margins[26]. These surgeries have been found to cause less post-operative pain and quicker recoveries when compared to open colectomies[9,10,13,26-28]. However, Boler *et al*[26] do acknowledge that laparoscopic resection is limited by the inability to definitively locate certain lipomas. Yet, preoperative colonoscopic injection of a colonic mural marking agent such as india ink or intraoperative colonoscopy can aid in the localization of the lipoma. Overall, surgical intervention is the most effective treatment for colonic lipomas and there have been no reported recurrences in the current literature[9].

In our case, the colonic lipoma was protruding through the anus and was still attached by a viable stalk. To minimize patient morbidity and expedite therapeutic resolution of his symptoms, we resected this incarcerated tumor by a transanal approach. As of the time of creation of this manuscript, the patient has declined colonoscopic evaluation.

Colorectal lipomas most commonly present as asymptomatic, incidental findings on colonoscopy and are treated by either local endoscopic or surgical resection. Our patient demonstrates that they can also present acutely as an incarcerated, trans-anal mass with features suggesting rectal prolapse. We present this case to highlight this possible presentation. Trans-anal resection is simple and effective treatment.

COMMENTS

Case characteristics

A 61-year-old male patient presented to the emergency room with a prolapsed ano-rectal mass.

Clinical diagnosis

A firm, well circumscribed, tender, hyperemic ano-rectal mass was noted to be 6.7 cm x 6.3 cm in size.

Differential diagnosis

Prolapsed neoplastic lesion, thrombosed internal hemorrhoid, rectal procidentia.

Laboratory diagnosis

Hematology (CBC), Chemistry (BMP) and Coagulation profile (PT INR. PTT) were all within normal range.

Pathological diagnosis

Pathology report determined the mass to be a 6.7 cm x 6.3 cm x 4.8 cm polypoid submucosal lipoma of the colon with overlying ulceration and necrosis.

Treatment

The prolapsed ano-rectal mass was resected trans-anally by the use of laparoscopic linear cutting stapler.

Related reports

Very few cases of colorectal lipomas were reported with a similar presentation (prolapsed ano-rectal mass) and management (ano-rectal excision).

Term explanation

Lipoma is a benign tumor of the adipose tissue. Rectal procidentia is another term for rectal prolapsed.

Experiences and lessons

The authors report this case to highlight this rare but possible presentation of colonic lipomas; an incarcerated, trans-anal mass with features suggesting rectal prolapse. Trans-anal resection is simple and effective treatment.

Peer-review

The manuscript is well written and the result of the management is acceptable.

Abstract

The current case report is related to a male patient with diabetes, obesity [body mass index (BMI) 33], hypertension and recurrence of anemia associated to melena and deep asthenia. M.P., a 60-year-old obese individual, was referred to our department by the primary care unit (PCU) of our hospital for severe anemia (Hemoglobin 6.5 g/dL) associated to episodes of melena and abdominal pain. In the past 5 mo the patient referred to the local hospital 3 times for episodes of melena (hemoglobin levels showed anemia 9.8 g/dL) but the main gastroenterological exams were completely negative (colonoscopy and gastroscopy). The PCU of our Hospital, after stabilization of the main parameters and blood transfusion for the low levels of hemoglobin, referred the patient to gastroenterologists: the patient was subjected to both colonoscopy and gastroscopy that were negative. Due to the condition of acute severe hemorrhage the patient, during the first 3 h from the access to the PCU, was subjected to arteriography that did not reveal any hemorrhagic foci or vascular alterations. The video capsule for the study of the small bowel showed the presence of blood beginning from the third portion of duodenum but deep gastroscopy did not reveal it. The patient was then subjected to double balloon endoscopy that revealed a severe diverticulosis of the small bowel with blood from the diverticula. The entero-tomografia computerizzata confirmed the diagnosis and revealed an extension of the diverticula for almost the entire small bowel (no diverticula in the colon). The patient was subjected to wide spectrum antibiotic therapy with resolution of the symptoms and stabilization of hemoglobin levels. The surgeon suggests no indication to surgery for the wide area involved from the disease and potential high risk of complication due to the high BMI. At home, the patient started a monthly therapy with rifaximin and probiotics associated to mesalazine. At present, after 12 mo from the last episode of hemorrhage, the patient is in good clinical condition, reduced his body weight of about 7 kg and the hemoglobin levels appear in slow progressive increase (last measurement 13.2 g/dL).

Key words: Small bowel; Diverticulitis; Abdominal pain; Anemia; Intestinal bleeding

Core tip: The current case report adds an additional tool for the treatment of small bowel diverticula. Although the best recognized treatment is represented by surgical approach, the current case demonstrates the possibility of effective treatment by pharmacological approach. The pharmacological approach allows to treat patient with high surgical risk and all patient with contraindication to surgery; moreover the small bowel preservation avoid all the symptoms and signs of malabsorbtion, inevitably occurring after surgery.

Small bowel diverticulitis with severe anemia and abdominal pain. *World J Clin Cases* 2015; 3(5): 462-465 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i5/462.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i5.462

INTRODUCTION

Small bowel diverticulosis is an uncommon pathology and may exist in two different forms: congenital or acquired. The congenital form is represented exclusively by Meckel's diverticulum, which is a true diverticulum located on the antimesenteric border of the small bowel, to a variable distance from ileo-cecal valve between 40 to 80 cm[1]. Conversely, the acquired forms of the small bowel diverticula are also named false diverticula: they are lesions consisting of mucosa, submucosa, and serosa without a tunica muscularis[2].

Multiple diverticulosis of the jejunum represents an uncommon pathology of the small bowel that is often asymptomatic. An incidence of about 0.5%-2.3% found in small bowel contrast studies and of 0.3%-4.5% found in autopsies have been reported in the literature[3,4].

In a few percentage of case this condition may lead to several and unspecific symptoms such as malabsorption, anemia, chronic abdominal pain and discomfort. Major complications may be characterized by diverticulitis, hemorrhage, obstruction and perforation, which are described in very selected number of cases[5-7].

The management of symptomatic jejunal diverticulosis is a challenge for clinicians. We herein report a case of a 60-year-old man presented at the primary care unit (PCU) of our hospital for acute abdominal pain associated to vomiting and deep asthenia in a patient with diabetes, obesity [body mass index (BMI) 33], hypertension.

CASE REPORT

M.P., a 60-year-old obese individual, was referred to our department by the PCU of our hospital for severe anemia (Hemoglobin 6.5 g/dL) associated to episodes of melena and abdominal pain.

In the past 5 mo the patient referred to the local hospital 3 times in 5 mo for melena associated to deep asthenia and one episode of lipotimia (hemoglobin levels showed anemia with values respectively of 9.5, 9.1 and 9.8 g/dL); in the described episodes, both colonoscopy and gastroscopy were negative for the identification of blood sources.

At the present, M.P. occurred to the PCU of our hospital for the forth episode of abundant melena associated to abdominal pain and low-pressure levels (100/50 mmHg).

The main laboratories examinations showed a 6.5 g/dL of hemoglobin levels associated to low levels of iron, with no additional alterations.

The patient was transfused with red packed blood cells and the clinical conditions were stabilized. The patient was referred to the gastroenterologist when the main parameters were: cardiac frequency 90, Saturation 97%, PA 110/70 mmHg.

Both Gastroscopy and colonoscopy were completely negative for the presence of lesion potentially involved in bleeding.

During the first 4 h from the access to the PCU, taking into consideration the gastroscopy and colonoscopy previously executed in other hospital, the patient was subjected to arteriography that did not reveal any alteration or potential sources of bleeding.

After adequate preparation, the patient repeated the colonoscopy that showed regular mucosa and no alteration able to justify massive bleeding. The patient performed video-capsule endoscopy examination that revealed the presence of mucosal areas with blood, extended from the upper part of the jejunum for several centimeters, with no other specifications.

In order to better investigate the small bowel, the patient was subjected to double balloon examination that revealed the presence, just down to the Treitz ligament, of a pattern with numerous and giant diverticula of jejunum.

The entero-tomografia computerizzata (TC) and small bowel contrast study (Figure 1) subsequently confirmed the jejunal diverticula, located in the in the right and upper part of the abdomen, apparently related to most of the jejunum; the same diverticula were particularly tick with edema of the mucosal layer, as typical sign of inflammation.

We first referred the case to the surgical department of our Hospital for evaluation: but no criteria for emergency procedures were present, since no active bleeding was occurring at that time; on the other hand, the high number of comorbidities strongly contraindicated any potential surgical procedure.

Due to this analysis and the hemodynamic condition of stability, we decided to start treatment with rifaximine (1200 mg/die), probiotics and mesalazine (1600 mg/die); with the objective to use at home a monthly-based therapy characterized by 1 wk of rifaximine and probiotics and 2 wk of mesalazine.

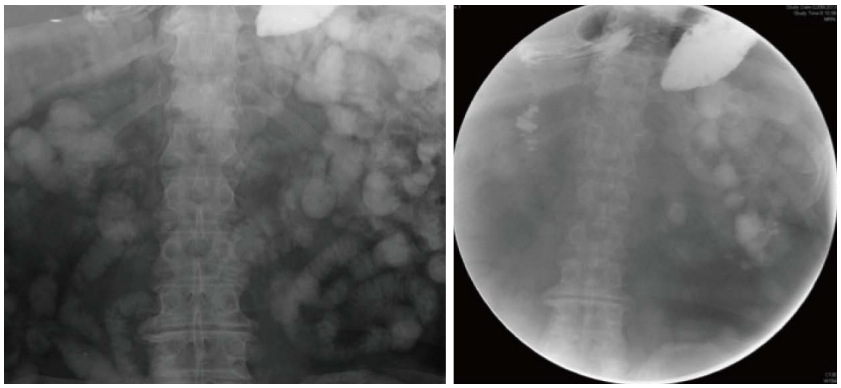

Figure 1 Small bowel contrast study: Imaging of diverticula of the jejunal diverticula, located in the right and upper part of the abdomen.

No additional episodes of bleeding occurred, with a progressive increase of hemoglobin; the patient was discharged after 12 d with no major complications.

At the present, after 12 mo of follow-up, no additional episodes of bleeding occurred, the level of hemoglobin reached 13.2 g/dL and no episodes of abdominal pain were referred. The patient continues treatment with rifaximine, probiotics and mesalazine on a monthly base.

DISCUSSION

Jejunal diverticulosis was described for the first time by Somerlingin 1794 and by Sir Astley Cooper in 1807. These false diverticula are commonly located on the mesenteric border of the jejunum[8]. The main feature that jejuna diverticula shares with colonic diverticula is that mucosal herniation occur through gaps in the muscle layers[9].

Regarding the portion of the bowel interested by the pathology: Jejunal diverticula may be the only site in the gastrointestinal tract or being associated to colonic diverticula (35%), duodenal diverticula (26%) and esophageal diverticula (2%)[7,8]. Small bowel diverticula are more frequent in male and its prevalence increases in elderly[10].

The low prevalence and the poor symptoms described in the clinical practice may lead to misdiagnosis, or relatively delayed-diagnosis[11].

In the specific clinical case reported in this manuscript, the patient was deeply studied and carefully evaluated with second level examinations only at the forth access to the PCU and only in the condition of severe anemia (hemoglobin 6.5 g/dL) and probably active bleeding. Furthermore, the condition of bleeding necessarily bring the attention to the endoscopic evaluation of the intestinal tract, such as gastroscopy and colonoscopy, that may delayed the time of diagnosis without solving the main problem.

In the specific case the TC imaging analysis was performed only in a condition of hemodynamic stabilization of the patient and overall secondarily to the double-balloon endoscopic examination. The evidence-based flow chart presumably leads to a different approach in the general management of the pathology: in hemodynamically stable patient, endoscopic techniques (gastroscopy or colonoscopy) may be used. Secondarily, small bowel contrast studies and computed tomography scans are able to visualize such regions and thus establish the diagnosis[12]. In our case we preferred to directly perform the double balloon instead of waiting for the radiologic imaging techniques.

As reported in literature, hemorrhage from jejunal diverticula generally presents as lower gastrointestinal bleeding that may be acute or chronic with iron deficiency anemia noted[13].

Although the treatment of choice in bleeding is represented by surgical resection of the source of bleeding with primary anastomoses, the case report described had several contraindication for surgical approach: first, the history of cardiopathy and the low rate of pulmonary reservoir; second, the obesity that greatly limits the feasibility of the technical procedure; third, the lack of a specifically localized source of bleeding, that do not allow to perform a selective resection of the bowel, but may lead to the resection of a too large portion of the bowel[14].

Due to the high number of contraindications to the surgical approach, we decided proposing the patient for pharmacologic treatment.

The drugs used mainly consist in the same protocol existing for the colonic diverticula, characterized by rifaximine, probiotics, and mesalazine cyclically, on a monthly-based therapy.

To date, no exhaustive data are provided in literature on the efficacy of the current used pharmacological therapy and no study of comparison between potential pharmacological therapy and surgical treatment are otherwise described[15]. Furthermore, it is important to take into consideration the high surgical risk due to several comorbidities occurring in this specific patient. Surgeon of our department presented to the patient the potential effect of the surgical therapy and the possibility to obtain a complete resolution of the pathology informing the patient on the main risks of the procedure. In the specific case, the patient refused to perform additional examinations and expressed the clear choice of non-surgical treatment.

Both rifaximine and mesalazine represent an

off-label therapy in the specific case of small bowel diverticula and no study, as far as we know, are present in literature discussing this issue[16].

In conclusion, in the general management of small bowel diverticula, acutely showing complication such as hemorrhages, the treatment of choice should be considered the surgical procedure with the resection of the tract of intestine affected by the bleeding[17]. However, it is important to take into consideration two major points occurring in this patient: active bleeding with anemia without the possibility to specifically localize the source of bleeding; second, the presence of major contraindications to surgery[18].

The current case report describe a single patient that referred to the hospital with a severe anemia in the course of acute intestinal bleeding from small bowel diverticula, with no indications to surgery. In the specific case report, the patient referred to the PCU 4 times in the time lap of 8 mo. At the current state, the last acute episode of bleeding was observed 12 mo ago, the hemoglobin levels are progressively increasing (last value was 13.2 g/dL) only with oral administration of iron.

Thus, in the flow chart of therapeutic opportunities for patients with small bowel diverticula, even with previous complication of bleeding, pharmacological therapy option should be considered, especially in the presence of major contraindications for surgical procedures.

COMMENTS

Case characteristics

Patient develops sever anemia and abdominal pain.

Clinical diagnosis

Double-balloon endoscopy revealed the presence of small bowel diverticula.

Differential diagnosis

Signs and symptoms may suggest all the different conditions of upper gastrointestinal (GI) bleeding.

Laboratory diagnosis

Low hemoglobin levels represent the main sign.

Imaging diagnosis

Double balloon endoscopy and radiographic GI imaging revealed the presence of diverticula.

Pathological diagnosis

Melena and anemia represent the main features of the clinical case.

Treatment

Mesalazine and wide spectrum antibiotics.

Related reports

The majority of case report of complicated small bowel diverticula suggests the resolution of the pathological condition by surgical approach.

Experiences and lessons

The pharmacological treatment in complicated small bowel diverticula should be considered as a treatment option in addition to surgical approach, particularly in those patients that present absolute contraindication or high risk to surgery.

Peer-review

It is comprehensive and elaborating.

Abstract

Trichobezoars (hair ball) are usually located in the stomach, but may extend through the pylorus into the duodenum and small bowel (Rapunzel syndrome). Rapunzel syndrome remains uncommon; with fewer than 40 cases reported. To the best of our knowledge, this case may be the first well-documented case with a length of 75 cm. They are almost always associated with trichotillomania and trichophagia or other psychiatric disorders. In the literature several treatment options are proposed, including removal by conventional laparotomy, laparoscopy and endoscopy. Herein, we are reporting an interesting case of an 18-year mentally retarded girl with history of trichotillomania and trichophagia who presented to our emergency department with a history of central abdominal pain associated with vomiting and constipation for five days. An examination showed a trichobezoar requiring emergent surgical intervention, and indicating the need for psychiatric treatment. The trichobezoar was treated successfully by laparoscopy.

Key words: Giant Trichobezoar; Therapy Endoscopy; Trichotillomania; Rapunzel syndrome; Laparoscopy

Core tip: Laparoscopic management is ideal for trichobezoar due to an improved cosmetic appearance, fewer postoperative complications, and reduced hospital stay. It has a better outcome with many benefits over laparotomy and is slowly becoming the treatment of choice. After trichobezoar removal, prognosis is good if psychiatric therapy to control habitual trichophagia is successful.

INTRODUCTION

A trichobezoar is an unusual condition hair bundles in stomach and small intestine, leading to intestinal obstruction usually affecting younger females[1,2].

It is mainly associated with a psychiatric disorder, trichotillomania having tendency of pulling hairs and significant hair loss. The large number of patients with this disorder are having problem of depression, anxiety and poor self-image[3]. The feel pleasant while pulling the hairs. The prevalence of the condition is 0.06% to 4%[4]. Due to smoothness, the ingested hairs resist digestion as well as peristalsis and get accumulated in the gastric mucosal folds. Eating of hairs for a long period leads to trichobezoar. Its main location is in stomach. However, in some cases, there is extension in to small intestine and exceptionally in to large intestine, then the condition is labeled as Rapunzel syndrome. Rapunzel syndrome was first discovered by Vaughan *et al*[5] in 1968. Fragmentation and dislodgement lead to obstruction[6-8]. As they are clinically asymptomatic, many times there is delay in diagnosing the condition. Due to availability of newer techniques of removal, *i.e.,* Laparoscopy and endoscopy, routinely laprotomy is not preferred[7-9]. Herein, we are reporting a similar interesting case of trichobezoar, removed on laproscopy.

CASE REPORT

A mentally retarded an adolescent girl (18 years age) came to Jatal Hospital and Research Centre with history of trichotillomania and trichophagia. She was eating her own hairs since last 10 years. She was presented with central colicky abdominal pain along with episodes of vomiting for 7 d. she was clinically conscious, with signs and symptoms of mild dehydration, anemic and had no signs of jaundice. The systemic parameters are normal.

Patient's upper gastrointestinal diagnostic endoscopy was performed and showed heavy large trichobezoar (hairball) in the stomach (Figure 1). Computed tomography (CT) scan was not done, in view of poor economical status of the patient and also as it was not indicated. Accordingly, patient was planned for emergency laparoscopic management.

A 10 mm umbilical port (telescopic port) was used having 30° telescope. Two 5 mm ports, one at right hypochondriac region and the other at midaxillary line was used. The one used at mid-axillary line was an operating port of 10 mm. Fourth port, *i.e.*, a 5 mm port at epigastric region to retract the left lobe of liver was used (Figure 2).Laparoscopic gastrostomy was performed with the help of harmonic scalpel. There was a giant trichobezoar extending from stomach through pylorus upto the jejunum (Rapunzel Syndrome). Successful complete removal of trichobezoar was done laparoscopically. The length of the trichobezoar was 75 cm. (Figure 3). On follow up patient is doing well since one month and she is under treatment of psychiatrist.

DISCUSSION

Continued hair ingestion in the patients of trichophagia forms a tight, growing hair balls leading to obstruction in the intestine. After accumulation the hair traps the viscous materials, *i.e.,* mucin, blood that forms tight and compact growing hairballs, not easy to remove[10]. In addition, the gastric churning helps to trap new hair into already formed hairballs. Mucus gives the hairball a shiny surface. Due to denaturation of proteins in the acidic environment of stomach; the color of the ball remains black. The foul smelling breath that results from fermentation of fats[11]. Many times, the patient remains asymptomatic for many years, until the point of obstruction[11]. Subsequent gastrointestinal blood loss leads to anemia.

Depending on the composition they are classified as: Trichobezoars. Phytobezoars, Medication bezoars and Lactobezoars. Phytobezoars are more common that composed of indigestible fruits, vegetable fibers, skin, or seeds[12]. Phytobezoars are mainly associated with a history of previous gastric surgery, conditions of reduced gastric acidity, delayed motility or poor gastric mixing. Medication bezoars composed of undigested tablets or semiliquid drugs. Lactobezoars are predominantly seen in lowbirth- weight or premature babies fed with a highly concentrated milk formula during the first weeks of life[12].

Rapunzel syndrome is defined as a bezoar extending down in to small intestine and exceptionally in to large intestine leading to obstruction[11]. Rapunzel syndrome is very unusual with less than 40 cases documented[11]. It is a reflection of psychiatric illness and no associated with gastrointestinal motility and first discovered by Vaughan *et al*[5].

Various modalities are used for diagnosis of this rare condition. A contrast upper gastrointestinal series often diagnostic of trichobezoars. They are also easily diagnosed on abdominal ultrasonography and or computed tomography scan[12,13]. However, upper GI endoscopy is an effective diagnostic tool to confirm the presence of a trichobezoar. Endoscopy also helps the clinician to differentiate between a trichobezoar and another foreign body[14].

Several treatment modalities are available for the treatment of trichobezoar, *i.e.,* open surgery, Laparoscopic or endoscopic removal by mechanical fragmentation or using chemicals[11]. The main drawback of above methods is they are not useful in large trichobezoars[14].

Previously open surgery and or laprotomy was a treatment of choice[14]. However, they have post-operative complications, *i.e.,* perforation, infection of wound, pneumonia etc[14]. Other surgical complications are upper digestive tract bleeding, anemia, bowel intussusception and rarely death.

With the availability of newer less invasive modes, laparoscopic removal is preferred but it seems to be difficult. The advantages are less hospital stay, cosmetically accepted and minimal complications[14]. However, there are chances of spillage of hairs into the peritoneal cavity and requires more time[10,14].

To conclude psychiatric treatment and follow up

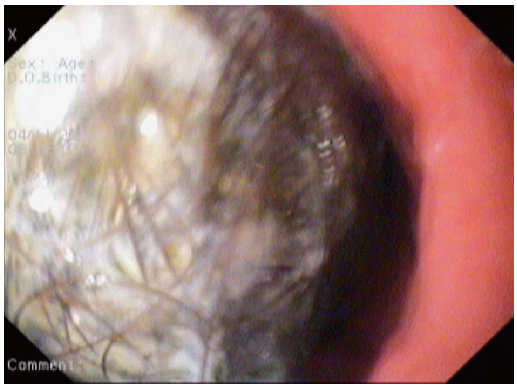

Figure 1 Upper gastrointestinal endoscopy shows a large hairball.

Figure 2 Showing laparoscopic ports.

is very important in the treatment and prevention of recurrence of Rapunzel syndrome. The long term prognosis is excellent[11].

COMMENTS

Case characteristics

Complained of central colicky abdominal pain with episodes of vomiting and constipation.

Clinical diagnosis

Trichobezoars.

Imaging diagnosis

Computed tomography scan was not performed due to the poor economical status of the patient and also as it was not indicated.

Pathological diagnosis

Trichobezoars.

Treatment

Laparoscopic removal followed by psychiatric therapy is ideal and is successful to control habitual trichophagia in this case.

Peer-review

The authors have performed a good study, the manuscript is interesting.

Figure 3 Large trichobezoar measuring 75 cm in length.

Abstract

Congenital pulmonary airway malformation (CPAM), previously known as congenital cystic adenomatoid malformation is a congenital disorder of the lung similar to bronchopulmonary sequestration. In CPAM, usually an entire lobe of lung is replaced by a non-working cystic piece of abnormal lung tissue. This abnormal tissue will never function as normal lung tissue. The underlying cause for CPAM is not known. It occurs in approximately 1 in every 30000 pregnancies. The association between CPAM and malignancy has been well documented. There is a small risk (0.7%) of *malignant transformation* within the cyst. So early diagnosis and surgical resection is important to prevent the grave complications. Herein, we are reporting two interesting cases of CPAM and one belonged to Type Ⅱ and other belonged to Type Ⅲ of Stocker's classification.

Key words: Congenital pulmonary airway malformation-Type Ⅱ; Congenital pulmonary airway malformation-Type Ⅲ; Surgical resection

Core tip: Congenital pulmonary airway malformation (CPAM) is a rare disease with various clinical presentations and having the risk of future malignant transformation. Early pulmonary resection for asymptomatic CPAM is required and recommended to make a definitive diagnosis and determine the prognosis of the disease.

Bolde S, Pudale S, Pandit G, Ruikar K, Ingle SB. Congenital pulmonary airway malformation: A report of two cases. *World J Clin Cases* 2015; 3(5): 470-473 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i5/470.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i5.470

INTRODUCTION

Congenital pulmonary airway malformation (CPAM) is rare condition with a reported incidence of 1:25000 to 1:35000. About 15%-50% of cases of congenital cystic lung disease are reported to be CPAM[1-3].

This condition was first discovered by Stoerk[1]

in 1897. The abnormality is mainly attributed to a maturation defect. It is classified into 5 major types based on clinical and pathological features. It is important to make early pathological diagnosis by surgical excision in congenital cystic lung diseases to determine the prognosis. Most CPAM lesions are manageable with the proper assessment, diagnosis and surgical interventions[4].

CASE REPORT

Case 1

A male baby was born to primigravida mother with a history of 8 mo amenorrhoea. The mother's prenatal parameters are within normal limits. The baby was having high grade fever and respiratory symptoms. High resolution computed tomography of thorax revealed approximately 4 cm × 3.7 cm × 4.8 cm sized round to oval lesion involving right lower lobe. It showed multiple tiny communicating cystic areas in the central portion and solid peripheral portion. Patchy consolidation was noted surrounding this lesion. Possibilities of CPAM (Type Ⅱ) or pulmonary blastoma were suggested.

Clinical diagnosis of low birth weight with early onset sepsis and CPAM Type Ⅲ was kept. Lobectomy was planned and performed. The resected specimen of right lower lobe of lung was sent for histopathological evaluation.

Right lower lung lobectomy specimen was solid, firm in consistency measuring 6 cm × 5 cm × 3 cm in size. The cut surface showed solid gray white area with slit like opening and few small cysts measuring smaller than 0.3 cm in diameter. Foci of large areas of haemorrhages were also noted (Figure 1).

Microscopy revealed small cystic and predominantly solid areas. Cystic areas showed bronchiole like structures lined by simple cuboidal epithelium which are surrounded by alveolar spaces (Consistent with immature lungs). Some alveoli and cystic spaces filled with acute inflammatory exudates with microabscess formation. Intraalveolar haemorrhages were also noted (Figure 2).

Finally, the case was diagnosed as CPAM [congenital cystic adenomatoid malformation (CCAM)] Type Ⅲ with acute pneumonia and focal intraalveolar hemorrhages.The patient is doing well on follow up till date since 4 mo.

Case 2

A 31 years old female $G_3P_2L_2$ with history of nine months of amenorrhoea came to the outpatient department with USG abdomen and pelvis report suggestive of CCAM with Polyhydramnios, displacing the heart towards left. Labour was induced. After birth baby did not cry, for which resuscitation was done but in vain, the baby was cyanosed. Clinically it was diagnosed as; female child with Very Low Birth Weight with CPAM. Baby was shifted to NICU (Neonatal intensive care unit). Baby was initially responding but after few hours, succumbed to death and autopsy was performed.

Autopsy findings revealed Heart and Lung together weighing 40 grams. Left lung measured 5 cm × 2 cm × 1 cm. It was firm in consistency. Right lung measured 7 cm × 3 cm × 3 cm. Pleural surface of right lung and cut surface showed tiny cysts ranging in size from 0.5-2 cm in diameter involving the entire parenchyma of right lung. No other anomalies were noted.

Microscopically sections studied from right middle and lower lobe showed multiple, cystically dilated abnormal bronchiole like structures lined by cuboidal to columnar epithelium resting on thin fibromuscular wall. Sections from left lung and right upper lobe show evidence of hyaline membrane disease characterised by alveoli and airways lined by eosinophilic membrane.

On autopsy findings, the case was finally diagnosed as CPAM Type Ⅱ (Figure 3).

DISCUSSION

CPAM is an unusual condition characterised by immature, malformed lung tissue with cystic appearance. CPAM is seen mainly in newborns, still born infants and is an unusual condition in children beyond infancy. It is a hamartomatous lesion that is usually symptomatic in first few days of life. The patients with CPAM can present as neonates with severe, progressive respiratory distress due to cyst expansions. Hydrops may be present[3].

Exact etiology of CPAM is not known, it is to be considered as hamartomatous malformation and abnormal proliferation of the pulmonary tissue at different sites.

It has been proposed that designation of this lesion "CCAM" be changed to "CPAM" to reflect the fact that the lesions described as cystic are present in only 3 of the 5 types and "Adenomatoid" only in one type (Type Ⅲ). CPAM more accurately encompasses all five types of this classification[1].

CPAM Type 0-Acinar dysplasia/agenesis is rare malformation largely incompatible with life. Lungs are small, firm with diffusely granular surface. Microscopically, it shows bronchus like structures with muscle, glands and numerous cartilage plates and loose, vascular mesenchymal tissue[1].

CPAM Type Ⅰ-It accounts for nearly 65% of cases. It is operable with good prognosis. Grossly, lesion is predominantly cystic type (measuring 3-10 cm in diameter) surrounded by smaller cysts. Microscopically, the large, thin walled cysts are lined by ciliated pseudostratified columnar epithelium with some mucin producing cells. The wall composed of fibromuscular and elastic tissue and occasional cartilage plate[1].

CPAM Type Ⅱ-it accounts for 10%-15% of cases and mainly seen in first year of life. It has poor prognosis

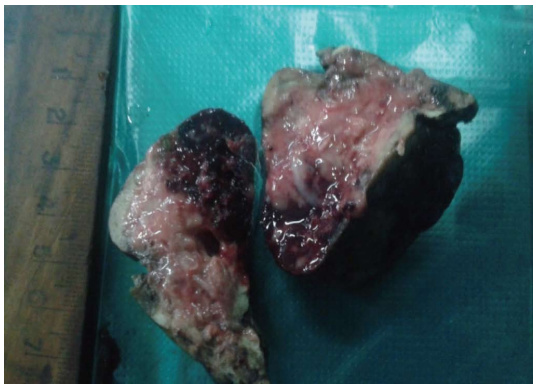

Figure 1 Congenital pulmonary airway malformation Type III-Cut section of lung showing solid areas with few slit like spaces with focal areas of haemorrhages.

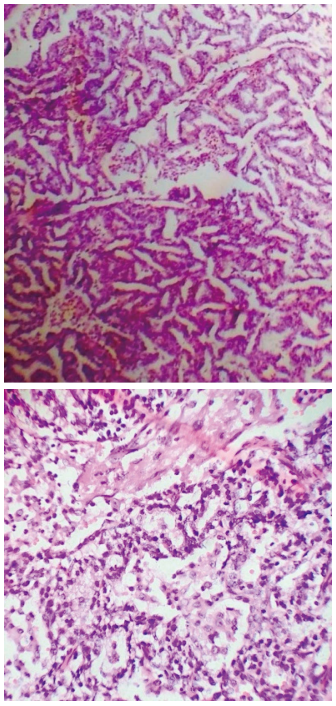

Figure 2 Photomicrograph showing congenital pulmonary airway malformation Type III with pneumonia. Neutrophilic infiltrate in alveoli and cystic spaces. (HE × high power).

because it is frequently associated with other congenital anomalies. Grossly lesion is composed of medium sized cysts measuring 0.5 to 2.0 cm in diameter that are evenly distributed and blend with the adjacent normal parenchyma. Our second case belonged to this type of CPAM. Cysts were arranged in back to back fashion and bronchiole like structures and lined by cuboidal to columnar epithelium with thin underlying fibromuscular layer. Mucous cells and cartilage plates were absent. CPAM Type 2 has been noted in nearly 50% cases of extralobar sequestration[1].

CPAM Type Ⅲ- Chin and Tang (1949) have described this lesion. It is infrequent and accounts only about 5% of cases. It is small cystic or solid type, exclusively seen

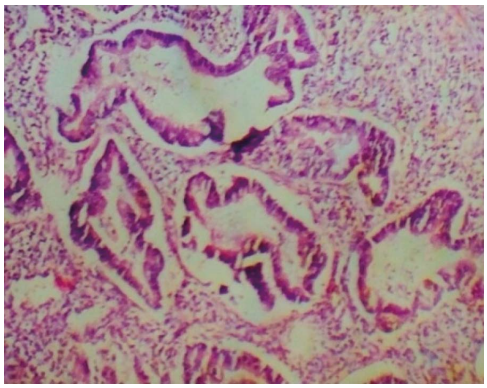

Figure 3 Photomicrograph showing congenital pulmonary airway malformation Type II-Bronchiole like structures are lined by cuboidal to columnar epithelium with back-to-back arrangement (HE × high power).

in first few days to months of life with characteristic male preponderance. It is commonly associated with maternal polyhydramnios, foetal anasarca. So it has high mortality rate. Increased Alfa-fetoprotein level can be noted in second trimester. Grossly cysts are small measuring less than 0.2 cm in diameter, affecting large bulky mass involving an entire lobe or even an entire lung. Microscopically the lesion resembles an immature lung devoid of bronchi. It consists of irregular, stellate shaped bronchiole like structures lined by cuboidal epithelial cells, surrounded by alveolar ductules and saccules that are lined by cuboidal epithelium giving the adenomatoid appearance that is why originally named as CCAM. Mucous cells, cartilage, rhabdomyomatous cells are not seen[1,4].

CPAM Type Ⅳ-It is hamartomatous malformation of the distal acinus and accounts for 10%-15% of cases with an age range of newborn to 4 years. This lesion involves a single lobe. Grossly large, thin walled cysts are lined by flattened epithelium-alveolar lining cells with underlying loose, fibrovascular mesenchymal tissue[1].

Clinical examination and chest X-ray invariably identify CPAM. On antenatal ultrasonograpy CPAM lesions can be identified in a population of infants who are asymptomatic at birth[5,6]. Most of these CPAM (10%-15%) are associated with other congenital anomalies, *e.g.*, CPAM Type Ⅱ is associated with bilateral renal agenesis, extralobar pulmonary sequestration, cardiovascular malformation, *etc*.

The lack of bronchial cartilage distinguishes CPAM from bronchogenic cyst and the distinctive rows of mucous cells from simple foregut cyst[2].

Congenital lobar emphysema can be distinguished from CPAM by the presence of bronchovascular markings extending to the periphery of the involved lobe and by atelectasis of adjacent tissue[7].The distinction from a sequestration of the intralobar variety may be difficult but a systemic blood supply would favour sequestration[8].

The association between CPAM and malignancy has

been well documented. Malformation and proliferation cause hamartomas over the tracheobronchial tree. Type Ⅰ CPAM may involve malignant transformation of mucinous bronchioloalveolar carcinoma[9-11]. Type Ⅱ CPAM may involve malignant transformation-Rhabdomyosarcoma. Type Ⅲ CPAM requires examination of the entire lesion to exclude pulmonary blastoma by confirming whether or not sarcomatous differentiation is present in the solid parts[8,12,13].

Surgical resection in asymptomatic infants is more beneficial with fewer complications compared with intervention following development of symptoms. It is the gold standard for management of CPAM for both pathological diagnosis and treatment[6].

COMMENTS

Case characteristics

Case 1: The baby was having high grade fever and respiratory symptoms; Case 2: It was female child with very low birth weight (LBW) with Congenital pulmonary airway malformation (CPAM).

Clinical diagnosis

Case 1: Clinical diagnosis of LBW with early onset sepsis and CPAM Type Ⅲ was kept; Case 2: Clinically it was diagnosed as; female child with very LBW with CPAM.

Differential diagnosis

Case 1: Pulmonary blastoma; Case 2: Diagnosed on autopsy.

Imaging diagnosis

Case 1: On CT diagnosis of pulmonary blastoma or CPAM were suggested; Case 2: Diagnosed on autopsy.

Pathological diagnosis

Case 1: Finally, the case was diagnosed as CPAM (congenital cystic adenomatoid malformation) Type Ⅲ with acute pneumonia; Case 2: On autopsy findings, the case was finally diagnosed as CPAM Type Ⅱ.

Treatment

Case 1: Lobectomy was planned and performed; Case 2: Died immediately.

Experiences and lessons

Early pulmonary resection for asymptomatic CPAM is required and recommended to make a definitive diagnosis and determine the prognosis of the disease.

Peer-review

This is an interesting case report.

Abstract

Pheochromocytoma and ganglioneuroma form rare composite tumours of the adrenal medulla comprising less than 3% of all sympathoadrenal tumours. We present a case of intraoperatively detected adrenal medullary tumour of composite pheochromocytoma and ganglioneuroma diagnosed on histopathology, in a normotensive patient. A 50-year-old male with a past history of chronic obstructive pulmonary disease presented with abdominal pain and significant weight loss since one month. Ultrasound and contrast-enhanced computed tomography abdomen revealed a large lobulated lesion in the distal body and tail of pancreas suggestive of solid and papillary neoplasm of body and tail of pancreas. Intra-operatively, a 15 cm × 10 cm solid lesion with cystic areas was seen arising from the left lower pole of the adrenal gland pushing the pancreas which appeared unremarkable. In our case, exploratory laparotomy with tumour excision was done. Extensive sectioning and microscopic examination of this adrenal tumour confirmed a diagnosis of composite Pheochromocytoma with Ganglioneuroma on histopathology. Immunophenotyping with S-100 further supported the diagnosis. The goal of this report is to increase the awareness of this rare disease and to further identify its variable presentation.

Key words: Ganglioneuroma; Pheochromocytoma; Adrenal

Core tip: Adrenal composite pheochromocytomas may present in various ways without hypertension and conclusive symptoms. We present a case of intraoperatively detected adrenal medullary tumour of composite pheochromocytoma and ganglioneuroneuroma diagnosed on histopathology, in a normotensive patient. The goal of this report is to increase the awareness of this rare disease and

to further identify its variable presentation.

Composite pheochromocytoma masquerading as solid-pseudopapillary neoplasm of pancreas. *World J Clin Cases* 2015; 3(5): 474-478 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i5/474.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i5.474

INTRODUCTION

Composite tumours of the adrenal medulla combining features of pheochromocytoma and ganglioneuroma are extremely rare. These tumours typically combine features of pheochromocytoma or paraganglioma with those of ganglioneuroma, ganglioneuroblastoma, neuroblastoma, peripheral nerve sheath tumour or neuroendocrine carcinoma. Most cases of composite pheochromocytomas are functional, with symptoms related to increased levels of catecholamines or corticotrophin-releasing hormone or their metabolites. Associated symptoms usually include headache, palpitation, excessive perspiration and hypertension in majority of the cases. We report a case of composite pheochromocytoma with ganglioneuroma in a normotensive patient who presented with an abdominal lump, diagnosed on histopathology clinically masquerading as solid-pseudopapillary neoplasm in tail of pancreas.

CASE REPORT

A 50-year-old male, known case of chronic obstructive pulmonary disease (COPD) for 12 years, presented with lump in abdomen associated with pain since one month. He also had history of significant weight loss. There was no associated history of hypertension or diabetes mellitus. On chest examination he had decreased breath sounds in left basal region and expiratory wheeze was noted. Per abdomen examination revealed an ill defined, non-tender mass in the left hypochondrium extending to the left lumbar region. Ultrasound done showed a solid cystic mass which appeared to arise from pancreas. Contrast enhanced computed tomography (CT) scan confirmed a lobulated mass lesion measuring 10.8 cm × 8.1 cm × 9.1 cm arising from body and tail of the pancreas suggestive of a solid-pseudopapillary neoplasm of the pancreas (Figure 1A). At endoscopic ultrasound the mass appeared to originate from body of pancreas with displacement of the splenic vessels (Figure 1B).

Pre-operatively, as per the advice of the chest physician, the patient was stabilised with antibiotics and bronchodilators and further taken up for surgery under moderate risk. Intra-operatively, a highly vascular solid lesion with cystic areas pushing the pancreas, splenic artery and splenic vein upwards probably arising from the retroperitoneum was noticed. Since the patient had fluctuation in blood pressure on handling the tumour, a pheochromocytoma was suspected. Patient was stabilized with nitroglycerine and adrenal infusion and the surgery was completed. Right kidney and adrenal were unremarkable. Post-operatively the patient was extubated on day 2. On Post-operative day 3 (POD-3), the patient started developing breathlessness. He was re-intubated on POD-4 as his blood gas levels deteriorated. Arterial blood gas analysis showed features of type I respiratory failure. The patient died on POD-6.

The surgical specimens were formalin fixed and paraffin embedded. The sections were stained with routine hematoxylin and eosin stain. Immunohistochemical staining was performed by the streptavidin-biotin-peroxidase method and diaminobenzidine as chromogen. The antibodies used included S-100, Synaptophysin, Vimentin, Chromogranin and neurofilament protein. Appropriate positive and negative controls were performed.

Grossly, the left adrenal tumour was well-encapsulated and lobulated measuring 13.5 cm × 10 cm × 6 cm, and weighing 310 g. Cut-surface of the tumour showed multiloculated cystic areas along with a few solid and hemorrhagic areas. Histopathological examination showed a well-encapsulated composite tumour comprising of pheochromocytoma with ganglioneuroma (Figure 2A). The pheochromocytoma component (accounting for 10% of the mass) comprised of polygonal intermediate cells with amphophilic cytoplasm arranged in well-defined nests separated by delicate fibrovascular stroma (Zellballen pattern). These tumour cells had moderate to abundant granular eosinophilic to amphophilic cytoplasm, round to oval nuclei and single prominent nucleoli. The ganglioneuromatous component predominated (accounting for 80%-90% of the mass), and showed sheets of mature ganglion cells surrounded by fascicles of Schwann-like cells (Figure 2B). Areas of haemorrhage and necrosis were noted within the tumour. Normal compressed adrenal was found at periphery.

Immunohistochemically, the pheochromocytoma component was strongly positive for synaptophysin (Figure 2C). However, the gangliocytes were strongly positive for neurofilament protein and vimentin (Figure 2D and E). The sustentacular cells of the pheochromocytoma component and the schwannian cells of the ganglioneuroma component showed characteristic staining of S-100 (Figure 2F). MIB-1 index was noted to be less than 1%.

DISCUSSION

Composite tumours of the adrenal medulla are rare accounting for less than 3% of sympathoadrenal tumours, and typically comprise of a pheochromocytoma component along with a non-pheochromocytoma component which can include ganglioneuroma, ganglioneuroblastoma, neurofibromatosis-1 and rarely schwannoma. Less than 50 cases have been reported

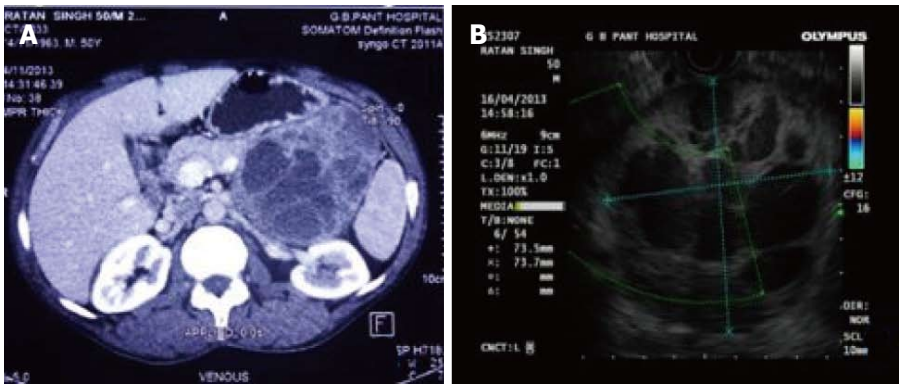

Figure 1 Contrast enhanced computed tomography and endoscopic ultrasound for pancreas. A: Contrast enhanced computed tomography shows 10.8 cm × 8.1 cm × 9.1 cm solid cystic mass arising from body and tail of the pancreas; B: Endoscopic ultrasound showing a well-encapsulated heteroechoic mass inseparable from tail of pancreas.

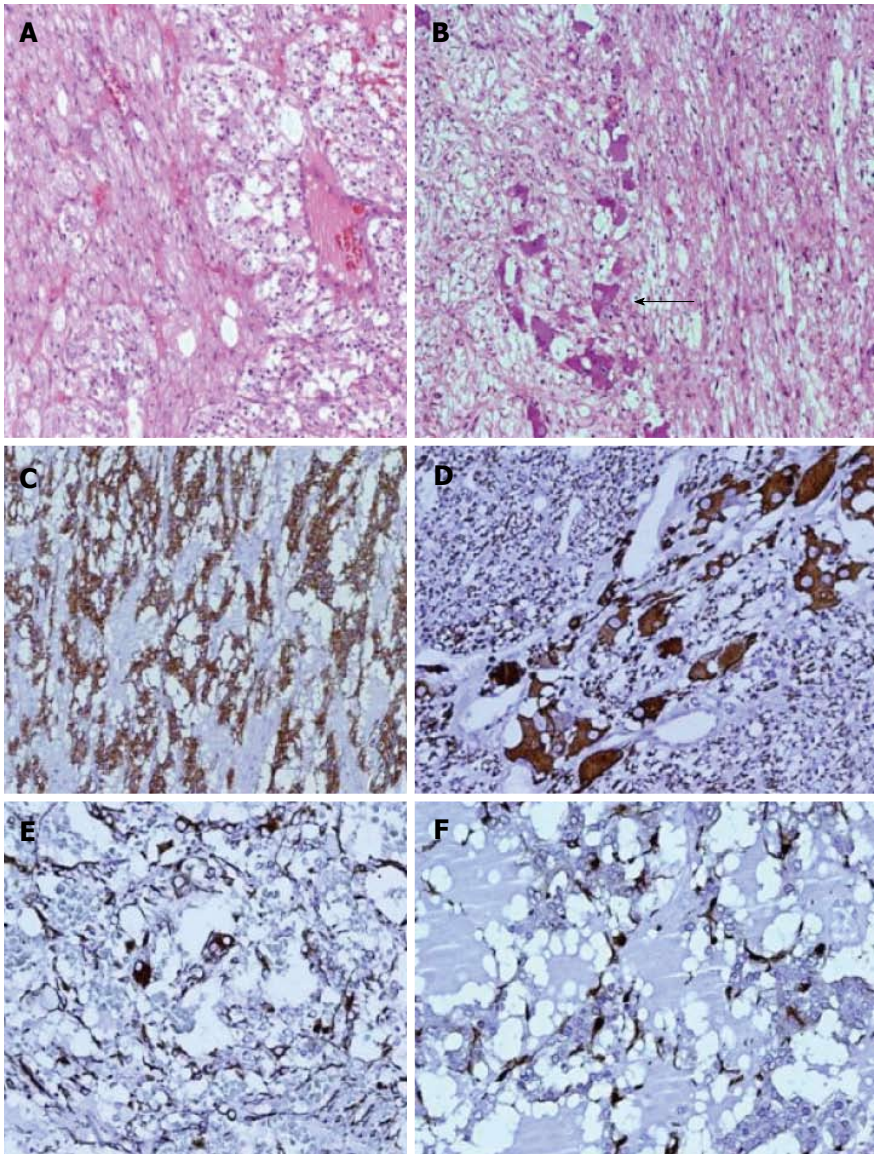

Figure 2 HE stain. A: Scattered ganglion cells with plump cytoplasm surrounded by intersecting bundles of Schwann cells (HE stain × 200); B: Two distinct components of the tumour–pheochromocytoma comprising of atypical polygonal chromaffin cells and ganglioneuroma component (arrow) with sheets of mature ganglion cells surrounded by fascicles of schwann cells (HE stain × 200); C: The chromaffin cells were strongly positive for synaptophysin (× 100); D: The ganglion cells were strongly positive for neurofilament protein (× 100); E: The gangliocytes were strongly positive for vimentin (× 200); F: The sustentacular cells of the pheochromocytoma component showed characteristic staining of S-100 (× 200).

in medical literature. Pheochromocytoma represents a tumour that originates from the adrenal medullary chromaffin cells, while ganglioneuroma is known to originate from autonomic ganglion cells or its precursors. However, both the chromaffin and the ganglion cells arise from a common embryonic progenitor which is the neural crest.

Clinical features

The age range for composite pheochromocytomas is 14-74 years (median 50 years). Patients with composite tumours tend to be older than pure pheochromocytomas. Mostly, 90% of these tumours are localized in the adrenal gland and the remainder in the urinary bladder, organ of Zuckerkandl, or elsewhere

in the retroperitoneum. Shawa *et al*[1] described 9 patients with composite pheochromocytomas and concluded that composite pheochromocytomas; and pheochromocytomas alone are indistinguishable clinically, biochemically and on imaging. Clinically pheochromocytoma can be suspected with its classical symptoms of headache, sweating and palpitations with paroxysmal or sustained hypertension. Kragel *et al*[2] found hypertension in 4 of 13 patients with composite pheochromocytomas. In a review of composite pheochromocytomas by Khan *et al*[3], 76.3% were functional. As 3/4th of these patients have symptoms of pheochromocytoma, preoperative biopsy is not advisable. Tischler *et al*[4] also has similar conclusions stating that the clinical presentation is usually as those of pure pheochromocytomas and so are the profiles of catecholamines and their metabolites. Neural components may cause a watery diarrhea-hypokalemia-achlorhydria syndrome due to increased production of vasoactive intestinal polypeptide. However, in our case, a normotensive male patient presented with an abdominal lump with no symptoms referable to pheochromocytoma.

In some patients the absence of endocrine abnormalities and symptoms of pheochromocytoma cannot be explained. One of the reasons for this is the autoregulation of the pheochromocytoma cells by the ganglion cells in the ganglioneuroma component which was first described by Aiba *et al*[5].

Imaging

Various imaging modalities can be used to differentiate the pancreatic tumours from adrenal masses and help the clinician to make a precise diagnosis and customize treatment accordingly. Abdominal ultrasound carries a diagnostic sensitivity of 87%-90% and 96% for detecting pancreatic and adrenal tumours respectively[6]. The above results differ slightly with those of other imaging modalities like contrast-enhanced CT, having a sensitivity of 89% and 92% respectively. A fine-needle aspiration biopsy guided by endoscopic ultrasound may provide tissue diagnosis in patients who are not surgical candidates, with a sensitivity of 92% and a specificity of 100%[7]. Shawa *et al*[1] in his series of 9 patients described the CT scan features of pheochromocytoma-ganglioneuroma composite tumour (PC-GN). These tumours have 43.5 Hounsfield units (HU) and there was significant enhancement on postcontrast venous-phase imaging. On delayed-phase complete wash out was seen but around 1/3rd of patients showed no washout. Five tumors (83%) were heterogeneous and four tumors (67%) had cystic components. The composite pheochromocytomas cannot be distinguished from pure pheochromocytomas based on CT scan and have similar morphology and pre and post contrast density values[1].

Pathology

Most case reports that describe composite pheochromocytomas have made diagnosis based on post operative histopathological examination and immunohistochemistry. Thus precise preoperative diagnosis is not possible in composite pheochromocytomas. Immunohistochemically, useful battery of markers include chromogranin A, synaptophysin and catecholamine biosynthetic enzymes tyrosine hydroxylase (TH) and phenylethanolamine N-methyltransferase (PNMT). In addition staining for S-100 protein, will identify Schwann cells and sustentacular cells. Neurofilament protein will identify axon like processes.

Prognosis and management of composite tumours

In the study by Shawa *et al*[1], the PC-GN composite tumor in one of the patients did not show any growth over 6 years. In addition 6 of their patients had no PC-GN recurrence during a median follow-up of 29 mo according to findings on serial abdominal imaging and/or levels of fractionated plasma-free metanephrine. According to the literature, one in eight patients with PC-GN developed recurrent disease with distant metastasis during a median follow- up of 15 mo[3,8]. Two other reported cases of PC-GN had distant metastasis at the time of diagnosis[1,4]. Including the series by Shawa *et al*[1] the rate of malignancy in PC-GN composites is almost 8%, compared with 13% to 25% in PC[9,10]. Thus, the presence of a GN composite in PC tumors does not seem necessarily to imply a worse prognosis. Malignancy in pheochromocytomas cannot be confidently predicted on the basis of clinical, biochemical, radiological or histopathological features. The only criterion that may help is the presence of distant metastasis. However, malignant tumours generally have an extraadrenal location, greater tumour weight (> 80 g), larger size (> 5 cm), exhibit high mitotic activity along with vascular/capsular invasion[4]. In our case, the tumour was largely benign as there were no histopathological features suggestive of malignancy, and MIB-1 index was < 1%. The only described treatment is surgical excision and no adjuvant chemotherapy or radiotherapy has been advised[11].

Association with genetic disorders

Of the 45 reported cases in the literature, 8 (18%) cases were associated with genetic disorders (6 cases of NF1, 1 case of MEN2A, and 1 case of Von Hipple-Lindau). Kimura *et al*[12] explained the association between NF1 and PC-GN composites by noting that neurofibromin insufficiency may induce abnormal proliferation of Schwann cells and produce neurotrophins that cause pronounced proliferation of the PC and ganglionic cells through autocrine and paracrine loops. This process eventually results in the formation of composite PC-GNs.

COMMENTS

Case characteristics

Non hypertensive/non-diabetic 50-year-old man had abdominal pain × 1 mo with anorexia and weight loss. He had an ill defined lump in left hypochondrium

and lumbar region.

Clinical diagnosis

Body tail pancreatic mass.

Differential diagnosis

Retroperitoneal tumour, renal cell carcinoma.

Laboratory diagnosis

Laboratory tests were inconclusive.

Imaging diagnosis

On ultrasound complex cystic pancreatic body tail mass. Computed tomography scan suggest Solidpseudopappilary mass body tail pancreas supported by endoscopic ultrasound findings.

Pathological diagnosis

Composite pheochromocytoma.

Treatment

He underwent surgical excision of the tumour with intra-operative haemodynamic stabilization with adrenaline and GTN.

Related reports

Composite pheochromocytomas with ganglioneuromas are rare tumours and less than 50 cases have been reported with 3/4th of the cases having symptoms of pheochromocytoma unlike this case who had only pain abdomen as his main complaint

Term explanation

PC-GN: Pheochromocytoma-ganglioneuroma.

Experiences and lessons

Composite tumours are rare in occurrence. Although they present with clinical features similar to pheochrocytoma in ¾ cases but asymptomatic tumours can mimic solid pseudopapillary tumours or other retroperitoneal tumours depending upon their location. Imaging characteristics are similar to pheochrocytoma but can have an overlap with solid pseudopapillary tumour. Treatment is surgical excision and they carry a good prognosis.

Peer-review

The case report is interesting and well written.

Abstract

Crohn's disease (CD) is a chronic idiopathic inflammatory disease of gastrointestinal tract characterized by segmental and transmural involvement of gastrointestinal tract. Ileocolonic and colonic/anorectal is a most common and account for 40% of cases and involvement of small intestine is about 30%. Isolated involvement of stomach is an extremely unusual presentation of the disease accounting for less than 0.07% of all gastrointestinal CD. To date there are only a few documented case reports of adults with isolated gastric CD and no reports in the pediatric population. The diagnosis is difficult to establish in such cases with atypical presentation. In the absence of any other source of disease and in the presence of nonspecific upper gastrointestinal endoscopy and histological findings, serological testing can play a vital role in the diagnosis of atypical CD. Recent studies have suggested that perinuclear anti-neutrophil cytoplasmic antibody and anti-Saccharomycescervisia antibody may be used as additional diagnostic tools. The effectiveness of infliximab in isolated gastric CD is limited to only a few case reports of adult patients and the long-term outcome is unknown.

Key words: Gastrointestinal tract; Crohn's disease; Isolated gastric involvement; Perinuclear anti-neutrophil cytoplasmic antibody; Anti-Saccharomycescervisia antibody

Core tip: The stomach is rarely the sole or predominant site of Crohn's disease (CD) accounting for less than 0.07% of all gastrointestinal CD. Serological testing and meticulous histopathological examination by excluding other causes of granulomatous gastritis can play a vital role to arrive at the correct diagnosis.

Ingle SB, Adgaonkar BD, Jamadar NP, Siddiqui S, Hinge CR. Crohn's disease with gastroduodenal involvement: Diagnostic approach. *World J Clin Cases* 2015; 3(6): 479-483 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/479.

htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.479

INTRODUCTION

Crohn's disease (CD) can affect any region from mouth to the anus. Isolated Gastroduodenal involvement is an extremely unusual event. The CD is diagnosed usually on the basis of clinical, laboratory, upper gastrointestinal (GI) scopy and histopathology. The anti-Saccharomycescervisia antibody (ASCA) is relatively good specific marker with minimal sensitivity. However, it is difficult to diagnose it in patients with isolated involvement of stomach and duodenum. In such circumstances other granulomatous conditions must be excluded with careful evaluation of the patient to hit the accurate pathological cause[1,2].

The famous criteria to diagnose this rare condition are: (1) evidence of noncaseating granulomas on histopathology; and (2) confirmation of changes of Crohn's disease on endoscopy or radiography[3-10].

EPIDEMIOLOGY

Incidence

It occurs in 0.5% to 4% patients of CD[3-6]. Isolated stomach and duodenum involvement accounts for less than 0.07% of all cases of CD[1].

Pattern of involvement

Most patients show involvement of terminal ileum and distal segment of large intestine[4,5,7]. Contiguous involvement of stomach and duodenal involvement is most common (60%)[6,10-12].

PATHOPHYSIOLOGY

For pathogenesis of isolated gastric CD multiple hypothesis were postulated: (1) the hygiene hypothesis relatively less trained and weak immunological system leading to ineffective immune response to newer antigens; (2) the environmental factors *i.e.*, geography, smoking, drugs, diet are also main contributing factors[13,14]; (3) immune mechanism - It is being postulated that the immune reactivity in this disease is due to "loss of immune tolerance" to self antigens of intestinal flora, resulting into an inappropriate granulomatous immune response of Chron's disease[15,16]; and (4) role of chemical mediators - interferon-γ, interleukin (IL)-12, IL-18 and increased expression of T-bet[17-19]. T-cells are not undergoing apoptosis[20-25].

CLINICAL PRESENTATIONS

Age

The disease mainly seen in the age group 30-40 years[6].

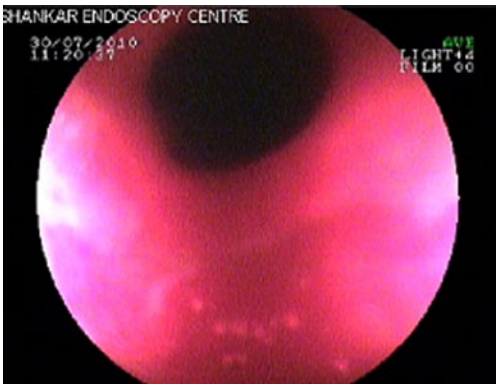

Figure 1 Endoscopic findings include patchy erythematic, gastric outlet narrowing.

Sex predilection

Male to female ratio is 1.2:1[6,12].

Symptoms and signs

Majority of the patients are usually symptomless[9]. Most of the patients are presenting with pain in epigastric region, relieved by antacids and food intake[4,9,11]. In cases with stricture formation persistent pain, nausea and vomiting are common[4]. Many times,it may simulates acid peptic disease clinically[4]. Acute blood loss may rarely occur[4,9,11,26,27].

Uncommon presentations

Uncommon presentations of CD may manifest as a single symptom or sign, such as impairment of linear growth, delayed puberty, perianal disease, mouth ulcers, clubbing, chronic iron deficiency anemia or extra-intestinal manifestations preceding the gastrointestinal symptoms, mainly arthritis or arthralgia and rarely osteoporosis[2]. In such cases, the diagnosis is challenging and can remain elusive for some time.

DIAGNOSTIC EVALUATION

Radiological signs

Aphthous ulcer is the early feature on radiography[28]. The characteristic features are presence of nodularity in the mucosa giving classic appearance of "cobblestone"[4]. Radiography examination using double-contrast medium is useful in cases with stenoses or strictures which are mainly seen in advanced disease[6,12,27,29,30]. A barium enema should be done in suspected cases of gastro colic fistula[4].

Endoscopy

Endoscopy with biopsy is an effective diagnostic modality[6,9,27,30]. Endoscopic findings include patchy erythema, gastric outlet narrowing (Figure 1) mucosa is friable, thickening of mucosa and ulcerations linear as well as aphthous[4,7,9,12]. The ulcers of CD are typically linear or serpiginous in contrast to the peptic

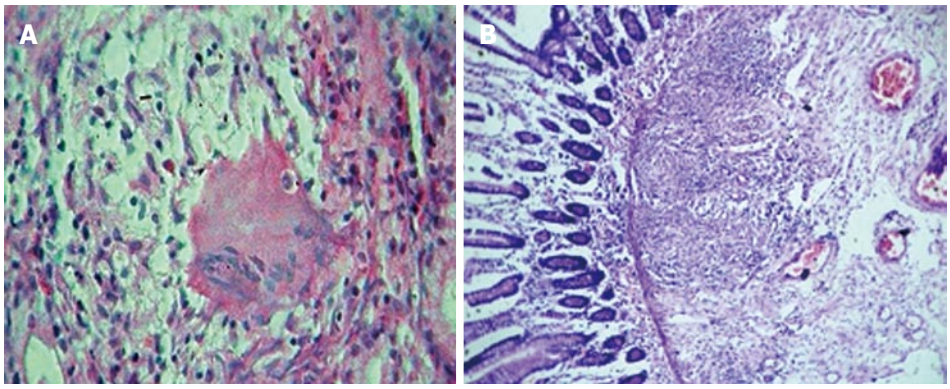

Figure 2 Biopsy showing non-caseating granulomas and oedema in the submucosa (HE × 10). A: Non-caseating granulomas; B: Oedema alongwith granulation tissue.

ulcers[27]. In cases with diffuse stomach involvement a linitis plastica appearance,is seen[31,32]. Sophisticated endoscopic features such as, bamboo-joint-like appearance and notched sign can be seen[33].

Biopsy findings

The biopsy findings are often nonspecific. Exclusion of other causes of granulomatous lesions is important. Granulomas without caseation are noted in 5% to 83% of cases (Figure 2)[9,12]. The differential diagnosis of granulomatous gastritis are *H. pylori* infection, gastric sarcoidosis, tuberculosis, syphilis, *etc*[7,9,32]. So presence of granuloma is not a definitive criterion to arrive at the diagnosis. *H. pylori* negative chronic gastritis is common feature.

Additional histological features are mucosal edema, crypt abscesses, lymphoid aggregates and fibrosis[32-34].

Serological markers

Currently, it has been stated that perinuclear anti-neutrophil cytoplasmic antibody (pANCA) and ASCA can be used as supportive diagnostic tools. Indeed, ASCA is detected in 55%-60% of children and adults with CD and only 5%-10% of controls with other gastrointestinal disorders. This finding pANCA highlights the relatively good specificity but poor sensitivity of ASCA as a marker for CD. pANCA on the other hand is more specific to ulcerative colitis.

Genetic studies

In addition, some *NOD2/ CARD15* gene polymorphisms were found to be associated with CD with gastroduodenal involvement. It is possible that these genes might also help to support the diagnosis in the atypical presentation of CD in the future[2].

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes corrosive gastritis due to ingestion of lye, gastric scirrhous carcinoma, Ménétrier's disease. Pseudolymphoma, amyloidosis can also mimic CD[29]. Although Ménétrier's disease can involve the entire stomach and produce ulcérations, it does not cause transmural disease[29]. Malignant and infiltrative processes are to be ruled out by the histological findings.

TREATMENT

Medical treatment

Proton pump inhibitors in combination with steroids are the first line of treatment in active CD. Some of the studies proved steroid-induced remission in active disease[10,11,35-39]. But, 6-Mercaptopurine and azathioprine are proved to be helpful to maintain steroid induced remission.

Balloon dialation

Strictures are treated successfully with balloon dilation[4,5,40-43].

Surgical intervention

Some of the patients requires surgical intervention, where patients are not responding to medical treatment[44]. Other situations are massive and persistent upper gastrointestinal hemorrhage, gastric outlet obstruction, and fistula or abscess formation[4,5,7,10,12,45]. The important indication is duodenal obstruction[6]. The surgical modalities of treatment include bypass surgery with gastrojejunostomy[6,7,9]. Gastrojejunostomy with highly selective vagotomy is an ideal line of management[44]. Delayed gastric emptying is a postoperative complication seen in 24% of cases, but this may be seen in stricturoplasty also[6,46,47]. Additional post operative complications are anastomotic leak, enterocutaneous fistula, intraabdominal abscess, and stomal ulceration[48].

CONCLUSION

To conclude, CD with isolated gastric involvement is an extremely unusual event in clinical practice. Endoscopic biopsy along with battery of laboratory tests is an effective tool to hit the correct diagnosis by exclusion of

various causes of granulomatous gastritis. This prevents untoward mortality and/morbidity related to disease and treatment.

Abstract

Glucocorticoids remain the cornerstone of medical therapy in giant cell arteritis (GCA) and should be started immediately to prevent severe consequences of the disease, such as blindness. However, glucocorticoid therapy leads to significant toxicity in over 80% of the patients. Various steroid-sparing agents have been tried, but robust scientific evidence of their efficacy and safety is still lacking. Tocilizumab, a monoclonal IL-6 receptor blocker, has shown promising results in a number of case series and is now being tested in a multi-centre randomized controlled trial. Other targeted treatments, such as the use of abatacept, are also now under investigation in GCA. The need for surgical treatment is rare and should ideally be performed in a quiescent phase of the disease. Not all patients follow the same course, but there are no valid biomarkers to assess therapy response. Monitoring of disease progress still relies on assessing clinical features and measuring inflammatory markers (C-reactive protein and erythrocyte sedimentation rate). Imaging techniques (*e.g.*, ultrasound) are clearly important screening tools for aortic aneurysms and assessing patients with large-vessel involvement, but may also have an important role as biomarkers of disease activity over time or in response to therapy. Although GCA is the most common form of primary vasculitis, the optimal strategies for treatment and monitoring remain uncertain.

Key words: Giant cell arteritis; Therapy; Disease management; Glucocorticoids; Immunosuppressive agents

Core tip: Giant cell arteritis (GCA) is the most common form of primary systemic vasculitis. Treatment with high doses of glucocorticoids should be initiated as early as possible to prevent ischaemic manifestations, such as blindness (occurring in up to 20%). However, glucocorticoid therapy leads to significant toxicity in over 80% of the patients. Various steroid-sparing agents have been tried, but robust scientific evidence of their efficacy and safety is still lacking. Not all patients follow the same course, but there are no valid biomarkers

to assess therapy response. The authors review the optimal strategies for treatment and monitoring of patients with GCA.

INTRODUCTION

Giant cell arteritis (GCA), also called temporal arteritis, is the most common form of primary systemic vasculitis, with an overall incidence of 15-25 per 100000 per year[1]. It affects large and medium-sized blood vessels with a predisposition for the cranial branches derived from the carotid artery; in approximately 50% of cases, the aorta and its major branches may also be involved[2,3]. It typically affects individuals aged above 50 years and is two to four times more common in women than men[4,5]. Polymyalgia rheumatica (PMR) can be present in up to 50% of the cases, beginning before, simultaneously or after the clinical manifestations of GCA, suggesting they are different spectrums of the same disease process[6].

Due to the intense myointimal proliferation and vessel occlusion, which in up to 20% of the cases may lead to blindness (usually permanent), GCA is considered a medical emergency[7,8]. Treatment with high doses of glucocorticoids should be initiated as early as possible to rapidly control inflammatory symptoms and prevent ischaemic manifestations, such as jaw claudication, visual loss and stroke. However, the burden of high-dose glucocorticoids is considerable, especially in the elderly, with over 80% of the patients experiencing significant treatment related side-effects[9]. Proven *et al*[10] have reported a high number of major adverse advents related to long-term glucocorticoid use in GCA: posterior subcapsular cataract (41%), bone fractures (38%), infections (31%), hypertension (22%), diabetes mellitus (9%) and gastrointestinal bleeding (4%).

Moreover, the optimal duration and doses of glucocorticoid treatment varies from patient to patient, as well as the need to add other immunosuppressant agents to control disease activity and reduce glucocorticoid toxicity.

The key issues in managing GCA after its diagnosis are prompt institution of correct therapy; recognition and amelioration of the adverse events related to immunosuppressant medications; and rapid identification of disease activity and flares.

Our purpose is to review the current therapeutic options, guidelines and clinical trials in GCA, as well as to discuss follow-up strategies and potential biomarkers for this condition (Figure 1).

MEDICAL TREATMENT

In GCA medical treatment is required for induction and maintenance of remission.

Induction

Glucocorticoids: Glucocorticoids remain the cornerstone of treatment in GCA since their discovery in the 1950s[11]. They should be prescribed immediately after the diagnosis of GCA is suspected, and in most cases are able to provide complete symptomatic relief within 24-48 h[12].

Despite their importance, there are no clinical trials comparing different glucocorticoid dosing regimens. Most clinicians will base their practice on personal experience and on the European League Against Rheumatism (EULAR) and British Society for Rheumatology (BSR) guidelines[9,13]. These guidelines were based on an extensive literature review of the available evidence, including published data from randomised controlled trials, and full consensus by expert opinion.

The EULAR guidelines recommend 1 mo of high-dose glucocorticoid therapy (prednisolone 1 mg/kg per day, maximum 60 mg/d) for induction of remission and pulsed intravenous methylprednisolone for patients with early onset of visual symptoms (dose not specified). The BSR guidelines advise prednisolone 40 to 60 mg (at least 0.75 mg/kg) daily until the resolution of symptoms and laboratory abnormalities for patients with uncomplicated GCA (without visual loss or jaw claudication); 500 mg to 1 g of intravenous methylprednisolone per day for 3 d for patients with visual loss or a history of amaurosis fugax; and at least 60 mg prednisolone daily for patients with established visual loss. Daily dosing is more effective than alternate day dosing, but single or divided daily doses have shown comparable results[14].

Induction treatment with high-dose pulsed intravenous (IV) methylprednisolone (15 mg/kg for 3 consecutive days followed by oral prednisone dose of 40 mg/d) has been suggested for all patients with GCA to allow faster tapering and a lower cumulative steroid dose in a double-blind, placebo-controlled, randomized trial involving 27 patients[15]. Although a greater number of patients were able to reduce their oral prednisolone to 5 mg/d by week 36 with this regimen, the small sample size was not sufficient to draw conclusions regarding the differences in steroid-related adverse events; therefore, these results should not be generalized. Larger studies are needed to address this issue[16].

The most frequent type of eye involvement in GCA is anterior ischemic optic neuropathy[17], but other visual manifestations can also occur (Table 1). A degree of controversy exists regarding induction treatment by either high-dose pulsed IV methylprednisolone or oral prednisolone in GCA patients with visual symptoms. There are patients who despite being given high doses of IV methylprednisolone still develop visual loss. This might be explained by the latent period of up to 5 d

Table 1 Eye manifestations in giant cell arteritis

Anterior ischemic optic neuropathy
Posterior ischemic optic neuropathy
Arterial occlusion (central retinal artery, branch retinal artery or cilioretinal vessels)
Amaurosis fugax
"Cotton-wool spots" (microinfarcts of the retinal nerve fiber layer)
Diplopia (involvement of muscles, cranial nerves, or brainstem)
Ocular ischaemic syndrome (hypotension, ischaemic iritis)

Adapted from Ness *et al*[17].

between starting treatment and controlling the arteritic process in the wall of the posterior ciliary arteries; as well as by the decreased perfusion pressure in the vascular bed of the optic nerve head that makes it very prone to ischaemia due to any minor fall of the systemic blood pressure[18]. Another proposed explanation is that glucocorticoids may have a pro-coagulant effect by enhancing platelet activation[19], but this needs further confirmation. Although conflicting data exist[18,20-22], most clinicians, especially ophthalmologists, will prescribe IV steroids when presented with a patient with GCA with acute visual impairment.

Other immunosuppressive therapy: The key to successful induction therapy is to initiate glucocorticoids as quickly as possible, given their rapid onset of action. Other immunosuppressive treatments prescribed at presentation of the disease have been tried, particularly with the aim of allowing a faster withdrawal of steroids or help controlling severe manifestations of the disease; however, results have been conflicting and generally disappointing[23-25].

Nevertheless, when a patient has an unacceptable high-risk of glucocorticoid-related side effects, such as concomitant severe osteoporosis and poorly controlled high blood pressure or diabetes mellitus, it might be feasible to add another immunosuppressive (*e.g.*, methotrexate[26]) at the onset of the disease to allow a safer and faster tapering of glucocorticoids.

Maintenance

Glucocorticoids: Glucocorticoid reduction should be considered only in the absence of clinical symptoms, signs and laboratory abnormalities suggestive of active disease. The tapering regimen is variable; it is highly dependent on the clinician's personal experience, disease severity and response to treatment, use of concomitant immunosuppressive agents, the patient's compliance and the occurrence of steroid related toxicity. Nevertheless, the BSR[13] has proposed a standard tapering scheme after 1 mo of treatment: reducing by 10 mg of prednisolone every 2 wk to 20 mg, then another 2.5 mg every 2-4 wk to 10 mg, followed by a decrease of 1 mg every 1-2 mo.

During steroid tapering, flares occur in up to 50% of patients, requiring escalation of glucocorticoids and a more prolonged treatment course. An increase of 5-10 mg/d of prednisolone is usually sufficient to treat a common relapse; however, in the presence of ocular or neurological symptoms an increase to the original induction dose (0.75-1 mg/kg per day) should be considered.

There are no reliable predictors to determine treatment duration. Hernández-Rodríguez *et al*[27] have suggested that the intensity of the systemic inflammatory response at baseline may influence the number of disease relapses and time needed to safely withdrawal steroids. Different studies have shown different treatment durations[28-30], but typically 2 to 3 years are necessary for the patients to be weaned off glucocorticoids without any clinical features of active disease. In some cases, particularly when the disease is recurrent or there is secondary adrenal insufficiency, the treatment duration may exceed 5 years[31,9].

Other immunosuppressive therapy: The search for an effective disease-modifying agent for the treatment of GCA has proven elusive. Few clinical trials have been performed; the number of patients enrolled is limited and the duration of follow up is often short. A number of drugs have been studied, with disappointing results to date.

However, given the significant burden of morbidity associated with long term glucocorticoid treatment, current BSR guidelines for the management of GCA recommend consideration of the early introduction of methotrexate or alternative immunosuppressant therapy following a relapse[13] and EULAR guidelines for the management of large vessel vasculitis recommend that an immunosuppressant agent should be considered for use in large vessel vasculitis as adjunctive therapy[9].

Of the limited available evidence, methotrexate may be of benefit in the management of GCA. Three prospective randomised double blind placebo controlled trials have addressed this issue. In 2001, Spiera *et al*[23] randomised 21 patients with newly diagnosed GCA to high dose corticosteroids plus methotrexate (up to 20 mg once weekly) or placebo. At study completion there were no differences between the methotrexate and placebo groups with regard to cumulative steroid dose, relapse or adverse events[24]. In a similar study, in the same year, Jover *et al*[26] randomised 42 patients to high dose corticosteroid and methotrexate (10 mg per week) or placebo. Significant differences were reported in terms of reduction in relapse (one relapse $P = 0.02$, multiple relapses $P = 0.004$) and lower mean cumulative steroid dose ($P = 0.0009$) for the methotrexate treated group. Adverse events were similar in the two groups. In 2002, Hoffman *et al*[32] randomised 98 patients with newly diagnosed GCA to glucocorticoids plus either methotrexate (up to a maximum of 15 mg once weekly) or placebo. No differences were observed in cumulative steroid exposure or in the number of adverse events between the methotrexate and placebo treated groups. One patient in the methotrexate treated group relapsed *vs*

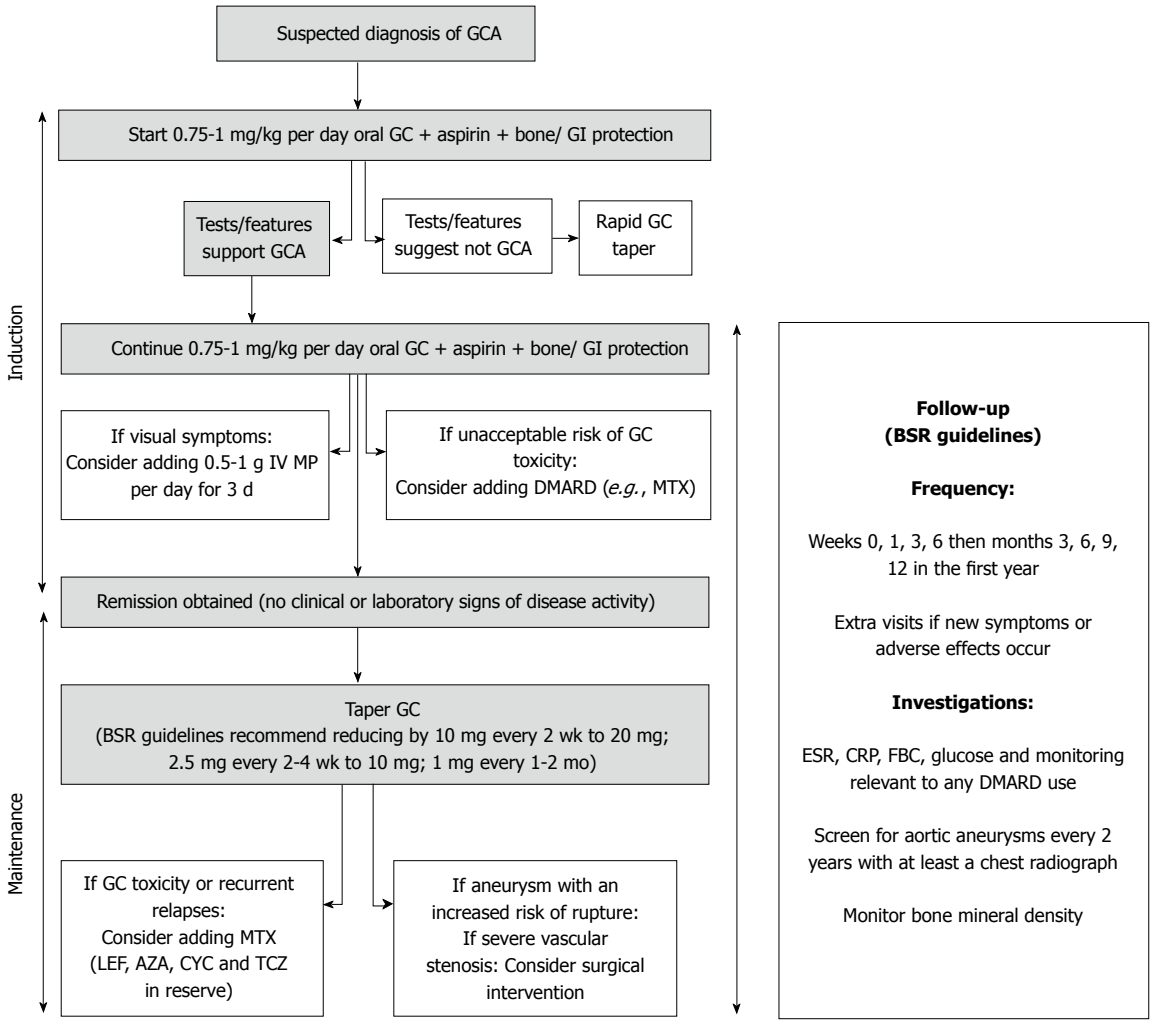

Figure 1 Current schema for giant cell arteritis treatment. AZA: Azathioprine; BSR: The British Society for Rheumatology; CRP: C-reactive protein; CYC: Cyclophosphamide; DMARDs: Disease-modifying antirheumatic drugs; ESR: Erythrocyte sedimentation rate; FBC: Full blood count; GC: Glucocorticoids; GI: Gastrointestinal; GCA: Giant cell arteritis; IV: Intravenous; LEF: Leflunomide; MP: Methylprednisolone; MTX: Methotrexate; TCZ: Tocilizumab.

five patients in the placebo group. A subsequent meta-analysis of individual patient data from these three trials demonstrated a modest reduction in relapse and glucocorticoid exposure in the methotrexate treated groups. However, adverse events remained similar between the groups[33].

Azathioprine is often considered as a potential steroid- sparing agent in GCA. Evidence supporting its use is limited. Only one double blind randomised placebo controlled trial was performed, which included 31 patients with GCA or PMR, or both (not differentiated) randomly assigned in a double blind fashion to either a standard glucocorticoid treatment schedule plus placebo or standard treatment plus azathioprine (150 mg once daily). At week 52 the treatment arm had a statistically significant reduction in steroid requirements ($P < 0.05$). However, the maintenance steroid dose was low in both arms at week 52, and the differences observed (1.9 ± 0.84 mg *vs* 4.2 ± 0.58 mg) while statistically significant are in practical terms of limited clinical significance[34].

Two small cases series have suggested that leflunomide has a steroid sparing effect in patients with PMR and GCA[35,36]. Adizie *et al*[36] demonstrated the efficacy of leflunomide in patients with difficult to treat disease. However, these results require replication in prospective randomised placebo controlled trials.

A number of retrospective studies have looked at cyclophosphamide use in patients with GCA, particularly in those who were steroid resistant, dependent or toxic and who had failed either methotrexate or azathioprine. Overall a significant sustained response was demonstrated (in up to 80%), with lowering of steroid doses. However, substantial treatment related adverse events observed limits it routine use[37-40].

Neither hydroxychloroquine nor cyclosporine have demonstrated any benefit in clinical trials in the management of GCA[41-43].

TNF-α is upregulated in GCA with elevated serum levels in active disease and increased expression of TNF-α in the temporal artery wall of patients with GCA[44]. However TNF-α inhibition in GCA has proven disappointing. Three randomised double blind placebo controlled trials of TNF-α inhibitors (infliximab, adalimumab and etanercept) have failed to show promise

in the treatment of patients with GCA. Neither the infliximab nor the adalimumab studies met their primary endpoints and the infliximab trial was stopped prematurely following the interim analysis[25,45]. Nevertheless, patients on etanercept did have a statistically significant lower cumulative steroid dose after 1 year; however, given that only 17 patients in total were enrolled in this study, firm conclusions cannot be made[46].

More recently, treatment with tocilizumab, a monoclonal IL-6 receptor blocker, has shown potential in a number of case studies and case series in the treatment of patients with PMR and GCA in terms of improvement of clinical symptoms and reduction in the acute phase response[47-50]. GiACTA is a multicentre, randomised, double-blind, placebo controlled trial designed to test the ability of tocilizumab to maintain disease remission in GCA and is currently ongoing[51].

Adjuvant therapies

Antiplatelet agents: The use of antiplatelet agents in GCA is controversial. There are no randomised controlled trials that have evaluated the use of aspirin as an adjuvant treatment in GCA. However, in addition to its antiplatelet effects, aspirin may have a disease modifying effect in GCA. One of the signature cytokines driving vascular inflammation in GCA is Interferon gamma (IFNγ). IFNγ is produced by Th1 cells and its production is relatively steroid resistant with very high doses of glucocorticoid required for effective suppression.

Using a SCID mouse chimera model, Weyand *et al*[52] have demonstrated that IFNγ production by T cells was suppressed by high dose aspirin. Nesher *et al*[53] in a retrospective review of 175 patients with GCA in 2004 found a significantly increased risk of ischaemic events in patients who were not on aspirin prior their diagnosis of GCA (29% *vs* 8%). Similar results were reported by Lee *et al*[54] with 16% of patients who were on aspirin at the time of their diagnosis having an ischaemic event *vs* 48% of those who were not on aspirin. Other studies have not demonstrated any clinical benefit from the use of aspirin[55,56]. Some of the discrepant findings may be explained by a higher burden of ischaemic heart disease in some cohorts, which is of itself associated with a higher risk of developing a subsequent ischaemic event. Nevertheless, the use of low-dose aspirin (75-150 mg/d) is routinely recommended for patients with GCA in the absence of contraindications[13].

Statins: Statins are inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A reductase, the most powerful class of lipid lowering drugs to date, widely used in medical practice. Apart from their lipid lowering effect, additional pleotropic effects have been discovered, which include anti-inflammatory and immunomodulatory properties. Statins are capable of the following actions: suppressing the expression of major histocompatibility complex class II antigen induced by IFNγ in various cells; decreasing T-cell activation and proliferation; down-regulating endothelial adhesion molecules; and reducing circulating inflammatory molecules and cytokines such as IL-6, IL-8, IL-1β, TNF-α, as well as acute phase proteins (CRP). Moreover they restore endothelial cell function and decrease muscle cell proliferation in the vessel wall, which in turn prevents intimal hyperplasia[57,58]. Given the pathophysiology of the disease, statins could influence the inflammatory process in GCA, since some of the inflammatory pathways may be shared with atherosclerosis. Narváez and colleagues conducted a retrospective follow-up study with 121 patients with GCA treated with or without statins, which found no significant benefit from their use[59]. By contrast, in another retrospective study of 594 patients (GCA and controls), patients receiving statins were less likely to develop GCA; however, these drugs did not appear to modify the clinical presentation or disease course in patients who actually developed GCA[60]. To date there are no formal recommendations on the use of statins in patients with GCA.

Bone protection: The treatment of GCA requires both long-term and high dose glucocorticoid therapy. Oral glucocorticoid treatment with the equivalent of > 5 mg prednisone daily can lead to a reduction in bone mineral density and a rapid dose-dependent increase in the risk of fracture[61,62]. Calcium in isolation appears to have little effect in preventing bone loss in patients starting glucocorticoids[63] although when combined with vitamin D, it is an appropriate adjunctive treatment[64]. Bisphosphonates are indicated in accordance with local guidelines. For example, the BSR advise weekly bisphosphonate therapy for all patients with GCA[13], but American College of Rheumatology recommends a stratified approach according to the FRAX score[65].

Gastrointestinal protection: Given the high doses and long term duration of glucocorticoid therapy in patients with GCA, gastrointestinal protection is recommended with proton pump inhibitors, especially if concomitant risk factors are present such as NSAID use, and older age[13,66]. However, in clinical practice it is often advisable to discontinue NSAID use (apart from low dose aspirin) whilst the patient is receiving glucocorticoids.

Future therapies

Advances in immunology have revealed that a number of molecules are important modulators in the pathophysiology of GCA. Patients with GCA, refractory to glucocorticoids, have a higher expression of pro-inflammatory cytokines such as s IL-1β, TNF-α, and IL-6. Mice lacking the interleukin 1 receptor antagonist (*IL-1ra*) gene developed large vessel vasculitis[67], suggesting that IL-1 inhibition could be a therapeutic option in patients with GCA. Ly *et al*[68] have reported

three patients with GCA, refractory to glucocorticoids, who were successfully treated with anakinra, showing improvement in clinical and/or inflammatory markers (two patients also showed radiologic improvement). However, randomized control trials are needed to determine the true efficacy and safety of this drug. Activated T-cells are believed to have a critical role in the development of large-vessel vasculitis. Abatacept, a signal modulator of T-cell activation, is being evaluated in a randomized study of patients with active GCA or Takayasu's Arteritis[69].

SURGICAL TREATMENT

Extracranial involvement in GCA, or large-vessel GCA (LV-GCA), has been described in 30%-80% of cases, varying according to the imaging modality performed[70,71]. However, most patients with LV-GCA improve with medical treatment alone, making the need for surgical interventions uncommon.

The risk of aortic aneurysm is higher in patients with GCA when comparing with the general population (twofold increased risk in the United Kingdom[72]), and the aneurysms are more likely to occur late in the disease course. Given there are no validated guidelines on surgical repair of aneurysms in patients with GCA, most strategies are based on the recommendations of atherosclerosis-related aneurysms. Surgical intervention should be considered in case of symptomatic aneurysm; ascending aorta aneurysm >5 cm in diameter; descending aorta aneurysm > 6 cm; abdominal aorta aneurysm > 5.5 cm; and an aneurysm which has grown > 0.5 cm within a 6 mo period[73].

In addition, revascularization procedures (*e.g.*, angioplasty, stenting or bypass surgery) due to artery stenosis are rarely required. Although narrowing of important arteries, such as the subclavian artery, may compromise distal tissue viability, the development of extensive collateral circulation over time is usually sufficient to maintain adequate tissue viability, even when ischaemic symptoms, such as limb claudication or loss of large vessel pulses, are observed. There have been some case reports of successful revascularization surgery, but with common restenosis[74-76]. When necessary, surgical treatment should be performed in the quiescent phase of the disease and in experienced centres[9].

Aortic structural damage in GCA is associated with a trend towards increased mortality (of any cause)[77]; however, the comparison between surgical outcomes in GCA and other causes of aortic disease has not been evaluated.

MANAGEMENT

Not all patients with GCA respond to therapy in the same way, but there are no valid biomarkers to assess treatment response. Several potential molecular and imaging biomarkers have been investigated.

Molecular markers

Changes in the conventional inflammatory markers (CRP and ESR) do not consistently reflect disease activity[78]; however, they are still the laboratory tests used routinely to monitor the effects of therapy. Serum levels of IL-6 have been found to be more sensitive than ESR for indicating disease activity in untreated and treated patients with GCA[79]. Additionally, circulating pentraxin 3 (PTX3) and vascular endothelial growth factor (VEGF) levels have been recognized to be significantly increased in patients with very recent optic nerve ischaemia[80], with VEGF levels responding well to treatment[81]. Antibodies against ferritin have also been suggested as potential activity markers for GCA, particularly in patients without cranial artery involvement[82]. However, further studies with larger series are warrant to understand the potential role of these serum markers in the assessment of GCA.

Imaging

Imaging techniques, especially for patients with extracranial involvement, have an important role in monitoring patients with GCA.

Ultrasound: Three meta-analyses have reported the high value and validity of ultrasound in diagnosing GCA[83-85], and we have recently completed patient recruitment for a large multicentre study looking at ultrasound as a diagnostic tool for GCA - TABUL study (Temporal Artery Biopsy *vs* ULtrasound in diagnosis of GCA)[86]; however, the role of ultrasound as a measure of disease activity is still unclear. In small case series and case reports, abnormal ultrasound appearances have been reported to resolve within 2 d of starting glucocorticoids[87] or alternatively, to persist for 11 wk despite treatment[88], allowing correlation of imaging changes with clinical response. In the TABUL study, we performed a cross-sectional analysis of 131 patients with GCA and positive ultrasound halo (dark area around arterial wall); the size of the halo was found to be smaller in patients who had received more days of glucocorticoid treatment, as well as correlating with the presence of ischaemic symptoms, supporting the early use of ultrasound as a potential prognostic marker and monitoring tool[89]. In addition, Czihal *et al*[90] documented that the clinical pattern of patients with extracranial GCA and cranial GCA, all identified by ultrasound, substantially differs, with visual impairment inversely correlated to the frequency of extracranial GCA (Figure 2).

Magnetic resonance imaging/magnetic resonance angiography: Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) can demonstrate the presence of increased wall thickness, oedema; mural contrast enhancement is highly

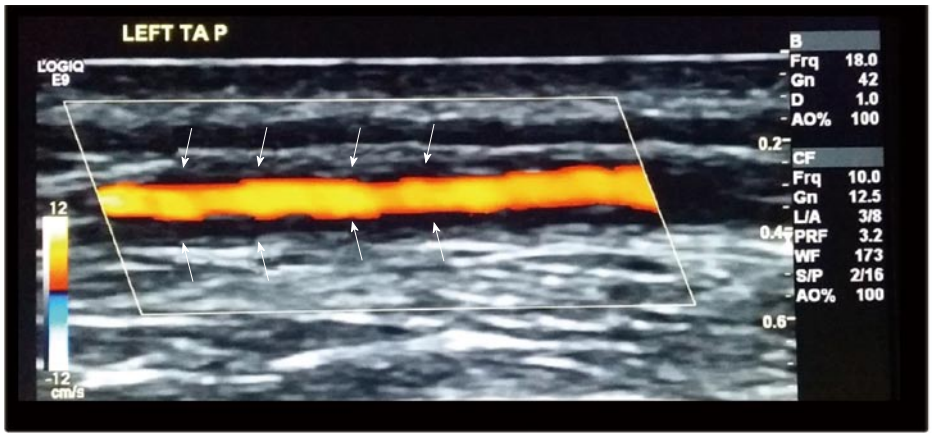

Figure 2 Ultrasound of the left temporal artery showing a dark halo (arrows) around the vessel wall of the parietal branch compatible with vascular inflammation.

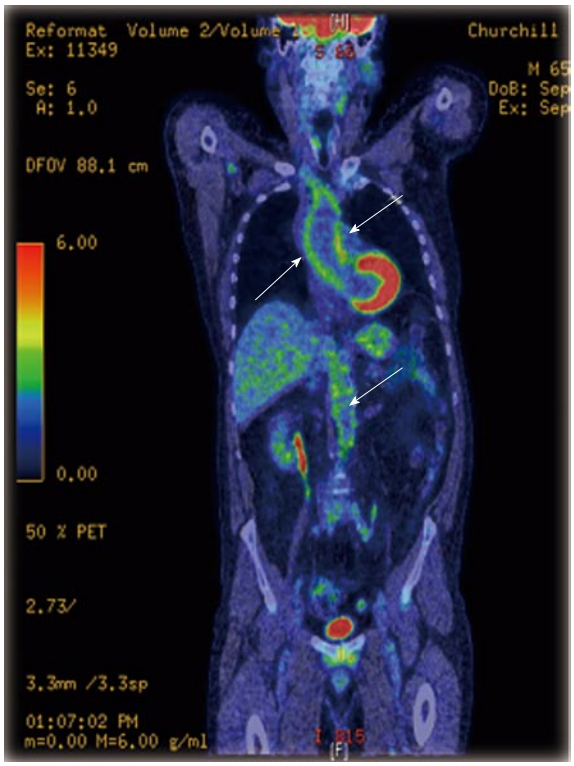

Figure 3 Whole body positron emission tomography-computerised tomography scan of a patient with large vessel vasculitis, showing increased fluorodeoxyglucose uptake in the ascending and abdominal aorta (arrows).

suggestive of vascular inflammation. These imaging modalities can be used in patients with GCA, not only to verify extra-cranial involvement, but also to evaluate temporal arteries. High-resolution MRI of the cranium has been reported to detect biopsy-positive GCA with high sensitivity[91,92], but future research is needed to validate this technique for diagnosis of cranial GCA.

There are still controversies regarding the use of MRI/MRA to monitor patients with extracranial GCA. Although it has great value for assessing aortitis and potential associated aneurysms and stenoses, MRI has failed to correlate well with clinical measures of disease activity[93-95]. In addition, false-positives may occur due to increased mural contrast enhancement as a result of vascular remodelling.

Because MRI/MRA are not invasive and do not involve ionizing radiation, they are widely used for monitoring GCA, despite their limitations.

18F-Fluorodeoxyglucose positron emission tomography: 18F-Fluorodeoxyglucose positron emission tomography (^{18}F-FDG PET) is a functional imaging technique which is very sensitive for diagnosing inflammatory changes in vessels with a diameter greater than 4 mm[96] (Figure 3). When compared to MRI, it appears to be more sensitive in detecting early vascular inflammation and correlates better with changes in disease activity over time[93,97,98]. However, like MRI, the relationship between PET findings and the prediction of disease activity or relapse is also inconsistent[93,97], which can be partly explained by the lack of standardized and validated criteria for disease activity in large vessel vasculitis.

The main limitations of this modality are: the lack of a uniform definition of vascular inflammation based on the FDG uptake; inability to provide information regarding wall structure or luminal flow; inability to visualize the temporal arteries; the use of large amounts of ionizing radiation (typically 15-20MSv per scan); and the limited access to this technique by most health institutions.

Computerised tomography/computerised tomography angiography: In GCA the main role of computerised tomography/computerised tomography angiography is to assess large vessel involvement or late complications of the disease, such as vessel stenosis, occlusions or aneurysms. This imaging modality has been proposed to evaluate response to treatment in Takayasu patients[99], but to our knowledge the same has not been considered in GCA.

Chest radiograph: The main use for regular chest

radiographs in patients with GCA is to monitor for potential aortic aneurysms. Although the BSR recommends its performance at least every 2 years[100], we have recently demonstrated that the risk of aneurysm development as a result of GCA is actually quite low[72]; if an aneurysm is suspected, more advanced imaging modalities (described above) should additionally be obtained in order to confirm the diagnosis and evaluate possible treatment measures.

Follow-up

The frequency for patient follow-up should be guided by their clinical manifestations and adverse advents. The BSR recommends follow-up during the first year at weeks 0, 1, 3, 6, then months 3, 6, 9, 12 and if new symptoms or adverse effects occur[13]. At each visit bloods tests for ESR, CRP, full blood count, glucose as well as monitoring relevant to any DMARD use should be performed. In practice, this is often not achievable in secondary care and therefore involvement by the patient's primary care physician is usually required. Screening for aortic aneurysms and monitoring bone density may be indicated in high risk individuals (*e.g.*, older male smokers have the highest risk of aortic aneurysm).

CONCLUSION

Despite the severe consequences of untreated GCA, such as blindness, there is no consensus on the optimal therapeutic strategies for this disease. Early initiation of glucocorticoid treatment is essential; however, the value of additional steroid-sparing synthetic or biologic agents to avoid the common glucocorticoid adverse effects or obtain quicker remission is still uncertain. We do not know how many and which synthetic DMARDs should be used before considering a biologic agent, because there are no valid and specific biomarkers to assess therapy response in GCA. Potential biomarkers which require further validation include circulating levels of IL-6 and VEGF as well as imaging assessments, such as ultrasound. Further investigation is needed to establish the role of these biomarkers, which can assist in the development and testing of innovative targeted therapies whose effects can be more reliably measured.

Abstract

A closed loop audit of the ear nose and throat (ENT) urgent referral clinic at a London hospital was conducted assessing the number of patients reviewed, referral source, appropriateness of referral, presenting complaint and assigned follow-up appointments. Data was sourced from clinic letters and the patient appointment system over a 3-mo period. The initial cycle analysed 490 patients and the subsequent cycle 396. The initial audit yielded clinically relevant and cost effective recommendations which were implemented, and the audit cycle was subsequently repeated. The re-audit demonstrated decreased clinic numbers from an average 9.8 to 7.2 patients per clinic, in keeping with ENT United Kingdom guidelines. A 21% decrease in patient follow-up and 13% decrease in inappropriate referrals was achieved. Direct bookings into outpatient clinics decreased by 8%, due to correct referral pathway utilisation. Comparisons of all data sets were found to show statistical significance $P < 0.05$. We reported a total financial saving of £32490 in a period of 3 mo (£590 per clinic). We demonstrated that simple guidelines, supervision and consultant-led education which are non-labour intensive can have a significant impact on service provision and cost.

Key words: Otorhinolaryngologic diseases; Quality of health care; Clinical audit; Practice guideline; Total quality management; Ambulatory care facilities

Core tip: The implementation of simple clinical guidelines, a transparent referral pathway to the ear nose and throat urgent referral clinic, and consultant led education to both juniors and referring specialties has demonstrated an improved service provision whilst being more cost effective and efficient.

INTRODUCTION

The ear nose and throat (ENT) urgent referral clinic is a fundamental and well established service provided by otolaryngology department. This service is heavily depended upon by primary care providers and emergency departments to avoid unnecessary admissions and inpatient reviews[1]. With Accident and Emergency presentations rising to 21.7 million in 2012/13, a fifty percent increase in the last decade, urgent referral clinics such as that provided by the ENT department are increasingly pressurised[2]. Improving the efficiency of these clinics whilst ensuring that standards are maintained is a necessary adaptation. The services provided in ENT urgent referral clinics can vary significantly from one trust to another with no gold standard or national guidelines[3]. However, historically, these clinics are booked beyond their capacity due to high service demand. This can lead to erroneous direct bookings into consultant led two week wait clinics. This has an evident threat to patient safety but also a significant financial implication. The inevitable result of this high demand is non-adherence to clinic appointments and to time, resulting in poor patient satisfaction which is a key indicator of quality of care[4]. The source of this extra demand cannot be attributed to the increasing pressures on the accident and emergency department alone. The ENT urgent referral clinic itself can generate unnecessary patient follow-up which is a well-recognised source of financial pressure as funding is typically only available for a limited number of follow up appointments.

AUDIT CYCLE

A closed loop audit was performed with implementation of new guidelines after the initial cycle, highlighting key areas of improvement. Local guidelines were constructed on the basis of our findings.

Data for each audit cycle was sourced from clinic letters, each over a period of 3 mo, conducted at Northwick Park Hospital. The initial audit analysed 490 patients and the subsequent re-audit 396 patients. The primary outcome measure of this study was the number of patients reviewed in each urgent referral clinic and whether these were in line with the standards set by ENT United Kingdom[5].

Data pertaining to the following was also evaluated: (1) the source of the original referral; (2) the presenting feature; (3) the number of follow up appointments for each patient; and (4) the appropriateness of the referrals and whether patients were diverted towards main outpatient clinics, ultimately causing a loss of funding.

Data was analysed using GraphPad prism v5.0 (San Diego, California, United States) with a P value of < 0.05 considered statistically significant.

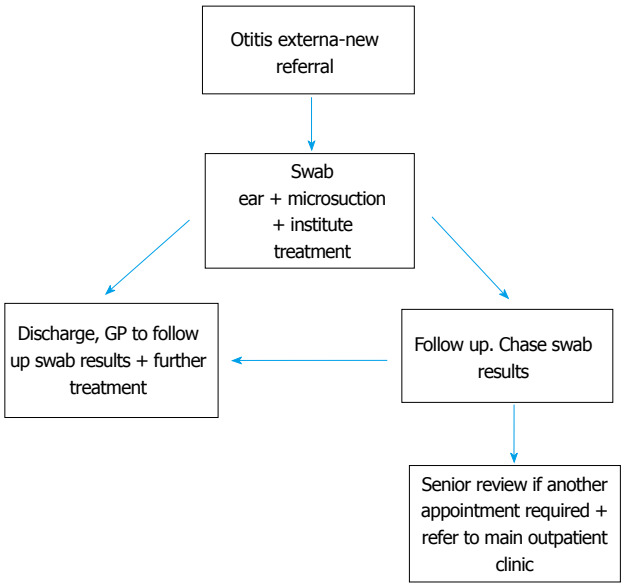

Figure 1 Otitis externa protocol.

SUMMARY OF DATA FROM INITIAL AUDIT CYCLE

All patients reviewed in the urgent referral clinic in a 3-mo period were analysed both in the initial and subsequent re-audit.

The initial audit analysed 490 patients during a 3-mo period from the urgent referral ENT clinic at Northwick Park Hospital. An average of 9.8 patients were reviewed in each clinic. Thirty-two percent (158 patients) were listed for follow up appointments after assessment in the urgent referral clinic. Twelve percent (59 patients) were direct outpatient bookings rather than registration through the "choose and book" service and therefore bypassed the appropriate referral and funding pathway. Re-referrals *via* the GP only consisted of 0.2% (1 patient) which is a source of income generation for the trust. Eighteen percent (89 patients) of referrals were deemed to be inappropriate for urgent referral review by a designated senior clinician and were suitable for either GP review or non-urgent ENT review. The most common presentation to the ENT urgent referral clinic was otitis externa consisting of 26% of patient reviews. The others included 16% nasal trauma, 15% removal of a foreign object and 11% with epistaxis which are consistent with similar audits conducted[3].

Based on the above findings from the initial cycle, the following guidelines were implemented: (1) clinical protocols were produced for ENT juniors regarding accepting, reviewing and organising subsequent follow up for patients; (2) clinical guidelines for the management of common ENT pathologies, *i.e.,* otitis externa were produced (Figure 1); (3) a safety net

Table 1 Summary of data including both initial and subsequent re-audit

Patients per clinic	First cycle 9.8		Re-audit 7.2	
	Percentage	No. of patients	Percentage	No. of patients
Follow ups	32%	158	11%	45
Direct outpatient bookings	12%	59	4%	15
Re-referrals	0.2%	1	4%	15
Inappropriate referrals	18%	89	5%	21
Total patients		490		396

Table 2 Estimated savings and income

Cost of follow up per patient	£190	
Income per clinic patient reviewed	£190 + tariffs for procedures performed (discontinued after 2 follow ups)	
Re-audit	Savings £29830	Income £2660
Overall	£32490 over 3 mo £590 per clinic	

system for earlier senior review of patients that had been followed up more than once and those who were immunocompromised[6]; (4) clear instructions to GPs on discharge paperwork from Accident and Emergency/wards requesting for an appropriate referral to a consultant led ENT clinic; (5) education regarding the follow up of patients more than once and deterrence from booking into main outpatient clinic appointments unless clinically indicated; and (6) education for local GPs and emergency department services regarding the referral pathway (combined contribute 95% of referrals received) by regular otolaryngology consultant led sessions.

SUMMARY OF DATA FROM SUBSEQUENT RE-AUDIT

The implemented guidelines overall had a significant effect on outcomes (Table 1). The number of patients per clinic decreased to 7.2. A significant decrease in the number of patient follow-ups from 32% to 11% (158 to 45 patients) was noted after the implementation of new clinical guidelines relating to common ENT presentations (Figure 2). This also led to a reduction in the number of referrals deemed to be inappropriate from 18% to 5% (89 to 21 patients). The booking of patients directly into main outpatient clinics decreased from 12% to 4% (59 to 15 patients); this was previously a significant source of financial loss. As a result of education regarding the referral system and clearer instructions to GPs, the number of re-referrals increased from 0.2% (1 patient) to 4% (15 patients).

The above results showed statistical significance between the initial audit and the re-audit in all comparisons ($P < 0.05$, Table 1).

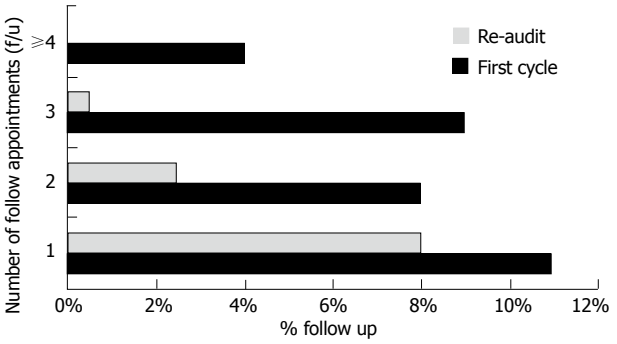

Figure 2 Comparison of number of follow up (f/u) appointments in first and second cycles of audit, $P < 0.0001$.

FINANCIAL IMPLICATION

The above results demonstrate a definite clinical significance, whilst simultaneously equating to a financial saving. The implemented changes described above and subsequent re-audit demonstrated a saving of £29830 over a 3-mo period. Income generated for example by re-referrals equated to £2660. Total savings amounted to £32490 over a 3-mo period, or £590 per clinic (Table 2).

ROLE OF THE URGENT REFERRAL CLINIC

The fundamental role of the urgent referral clinic is variable and each NHS trust provides a different service with no pre-determined gold standard. There are no specific national guidelines which outline the remit of service which should be provided by urgent referral clinic, nor the manner in which referrals should be accepted. Similar audits have been conducted which show an improvement in service provision with a shift from open access to rapid access clinics and the formation of robust criteria to avoid what are deemed to be inappropriate referrals[3,7]. The overall common denominator is that these clinics are heavily depended on by primary and secondary care with a significant referral number. This can lead to abuse of the service and subsequently poor patient satisfaction.

SYNOPSIS OF KEY FINDINGS

Clinical activity decreased from 9.8 to 7.2 patients per clinic between each audit cycle with 21% decrease in patient follow up and 13% decrease in the number of referrals deemed inappropriate for review in the urgent referral clinic. Direct bookings into outpatient clinics decreased by 8% with a greater number of referrals taking the correct pathway. The implemented changes resulted in a total financial saving of £32490 in a period of 3-mo or £590 per clinic.

CLINICAL APPLICABILITY/CONLUSION

Urgent referral clinics are historically serviced by junior members of the ENT team which can lead to a greater duration of patient consultations but also a tendency towards greater clinical caution and therefore follow-up. This study demonstrates that the implementation of simple changes such as an established protocol (Figure 1) for the management of otitis externa (the commonest presentation), guidance and education to general practitioners and emergency department staff regarding the referral pathway, can all translate to an improvement in the service provided, by reducing clinical activity. This has subsequently resulted in a financial saving whilst maintaining a high standard of clinical care.

The results of this audit have a 2 fold consequence. A reduction in the overall number needed to be seen in the urgent referral clinic (primary outcome), with patients seen by the correct services. This volume reduction is in keeping with ENT United Kingdom guidelines and has resulted in clinics running to time, a higher patient satisfaction whilst permitting juniors to seek advice for complex cases[5]. Secondly, we have demonstrated that service improvements are not mutually exclusive to financial saving/income and one may run in parallel with the other through the implementation of simple guidelines, supervision, education and frameworks which are non-labour intensive. More globally we have highlighted the importance of clinical governance in driving forward service provision with an awareness of the finite resources available within our National Health Service.

Abstract

Upper and lower airways can be considered as a unified morphofunctional unit. In this paper, nasobronchial interactions are evaluated based on literature.To discuss nasobronchial interactions, literature review from PubMed since 1982 is evaluated. Data base was including the terms "nasobronchial interaction, nasal and bronchial". Asthma and rhinosinusitis may be associated with environmental factors and immunological predisposition. Treatment of rhinosinusitis may decrease asthma exacerbations. It was concluded that "one airway, one disease"-concept may be accepted when considering naso-bronchial interaction. Asthma treatment should also mean treating the nose as good as treating patients with nasal symptoms. To reach the succesful results ıt should be associated with evaluation of lung functions.

Key words: Nasal; Bronchial; Nasobronchial interaction; Reflex; Airway

Core tip: Upper and lower airways may be accepted as unified morphofunctional unit. This concept is defined as nasobronchial interaction.

Cingi C, Muluk NB, Cobanoglu B, Çatli T, Dikici O. Nasobronchial interaction. *World J Clin Cases* 2015; 3(6): 499-503 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/499.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.499

INTRODUCTION

Upper and lower airways may be accepted as unified morphofunctional unit. Likewise rhinosinusal disorders and lower airway diseases have interrelation. Inflammatory cytokines may play a role for the interaction between cells[1].

During infections of upper respiratory tract such as rhinosinusiitis, asthma development may occur[2,3]. Atopic dermatitis in children, and also allergies to the

food may be the first sign for developing of allergic rhinitis (AR) and astma[4].

In this paper, nasobronchial interactions were evaluated thoroughly by the means of literature review from PubMed since 1982. Data base was depended on the terms of nasobronchial interaction, nasal and bronchial.

NASAL FUNCTON

Nose works as "air-conditioner". Cold air through induces bronchospasm in asthmatic patients. Nose humidifies the air which inhaled nasally. In allergic rhinitis patients, exposure to allergens increase bronchial hyper-reactivity[5-8].

MECHANISMS FOR NASO-BRONCHIAL INTERACTION

Impaired nasal function, pulmonary aspiration of nasal contents, the nasal-bronchial reflex and increased absorption of inflammatory mediators in the blood stream maybe responsible for lower airway dysfunction in AR[7]. They also cause the interaction between the nose and the lung. After nasal allergen application, no allergen deposition was shown in the lungs by radiolabeled allergen[6]. Cold and dry air exposure may cause immediate bronchoconstriction[8]. Nasal provocation with methacholine also increase lower airway resistance in asthma and AR patients[9].

Mast cells and eosinophils are the major effector cells in AR and asthma[10,11]. Eosinophils migrate to the tissues from the blood and this process is depend on the expression of cytokines and adhesion molecules[12]. Vascular cell adhesion molecule-1 and E-selectin increased after nasal provocation[13]. After bronchial provocation, mast cell degranulation and increase of of basophils occur in the nasal mucosa[14].

Impaired nasal function

In AR, mouth breathing was observed related to the nasal obstruction. Therefore, with the lower nasal filter function, increased allergen exposure develops. This process is resulted in hyperresponsivity of the airway. If additional chronic rhino-sinusitis and/or nasal polyposis were present, surgery help to improve nasal functions. In these patients, asthma control could be done better[15]. When nose blocked with a clip, response to cat-allergen was not detected in patients with cat allergy[16].

Aspiration of nasal contents

Inhale particles may be removed by the help of the mucociliary clearance. With this function and beat of the cilia, particles were carried toward the pharynx. In AR patients, secretions contain inflammatory mediators and cells[7,17]. When allergens inhaled, there was swelling of the nasal mucosa[18].

Nasobronchial reflex

The trigeminal nevre is responsible for afferent sensory innervation of the nose. Efferent parasympathetic fibers are carried in the Vidian nevre. Vagal nevre supports afferent and efferent innervation of the lower airways[19]. Sneezing, coughing or bronchoconstriction occur with the help of reflex mechanisms. The receptors were present in the nose, trachea, larynx and respiratory tract. The are sensitive to the mechanical or chemical factors. Cold dry exposure of nasal mucosa can cause immediate bronchoconstriction in asthmatic patients[6,20,21].

Nasobronchial reflex is another mechanism for interaction between upper and lower airways. Receptors are localize in the nose, sinuses and pharynx. The signals were transferred to the medulla by trigeminal, facial and glossopharyngeal nerves[22]. In the medulla, connections with vagal nevre were performed and bronchoconstriction occur[23].

Triggers of the reflex

In infectious conditions of the nose and lungs, virus and bacteria may trigger the reflex system. Smoking, pollutant agents in the work places and environment may cause chronic inflammation[24]. Beta-blockers or aspirin, cold dry air exposure, and physical exercise may also trigger the AR and asthma[25].

Increased absorption of inflammatory mediators in the blood stream

Increase in the eosinophil count is detected in AR and asthma patients in the blood[26]. Nasal provocation, performed with methacholine, also increases the lower airway resistance. It may be said that systemic mediators may induce lower airway resistance[9]. In AR and asthma, inflammatory cells and progenitors may play a role[27-29].

RHINOSINUSITIS AND ASTHMA

Symptoms of rhinosinusitis

Syptoms of rhinosinusitis are known as nasal congestion, discharge, purulence and postnasal drip; hyposmia, facial pressure, fever, halitosis, dental pain and headache. Chronic rhinosinusitis (CRS) may damage to the mucociliary clearance. CRS is an independent risk factor for asthma[2,3,30,31].

Epidemiology

Rhinosinusitis and asthma were coexistently detected in 34%-50% of patients. In asthmatic patients, concomitant rhinosinusitis were present up to 84%[24].

Clinical appearence

In rhinosinusitis patients, there is the possibility of having asthma. When nasal disease was treated, asthma control maybe easier due to the reducing of

bronchial hyperresponsiveness. Therefore, therapeutic approach to asthma and rhinosinusitis should be planned together[32].

Treatment

Medical treatments or surgery for rhinosinusitis help the reduce of respiratory symptoms and impove the asthma. Cold air inhalation causes the decrease FEV1 in asthmatic patients[5].

AR AND ASTHMA

AR is a risk factor for asthma development[33]. Whereas, in same cases, asthma starts first. Exercise induces bronchoconstriction in most asthmatic patients. It may be related to to alterations in the osmolarity of the liquid covering the epithelial layer. This process may be resulted release of chemical mediators originating in mast cells[34].

Epidemiology

In 19%-38% of AR patients, there are concomitant asthma. Moreover, 30%-80% of asthmatic patients also have AR. Rhinitis symptoms were reported in 98.9% of allergic asthmatics and in 78.4% of non-allergic asthmatics[35]. Bronchial hyperreactivity was observed in most of the AR patients[36]. In AR petients, 40% have involvement of the lower airways. Additionally, allergic asthma patients have concomitant rhinitis symptoms as a 80%[37,38].

Potential mechanisms

The allergic response starts with the uptake of the antigen by antigen presenting cells, in particular dendritic cells[39,40]. Dendritic cells present the antigen to T lymphocytes in the regional lymph nodes[41,42]. B cells recognize antigen with surface immunoglobulin (sIg) receptors. The T cell receptor recognizes antigens and activation of the it stimulates the naive T helper cell, a ThO cell. It differentiates to either a Th1 or a Th2 subset[43,44].

Activation of Thl cell causes the release of IL-2 and lNF-y. Additionally IL-4, IL-5, IL-1O and IL-13 are also produced by Th2 cells. Th2 cytokines are also involved in IgE synthesis (IL-4)[45,46].

Nerve growth factor (NGF) and NGF receptors are expressed in the nasal mucosa[47]. In patients with AR and allergic asthma, serum levels[48-50]; and nasal and bronchial fluid levels of NGF increase[51-53].

Microbial stimuli

Exposure to endotoxins reduces the risk of developing allergic rhinitis and asthma during the first years of life. Chlamydia pneumoniae infection has been suggested as a possible causative factor for asthma[54]. It was also reported as protective against the development of asthma in children[55]. In infancy, bacterial infection is associated with a reduced prevalence of atopic eczema, allergic rhinitis and asthma[56]. Viral respiratory infections stimulate nasal allergic inflammation in atopic patients; and virus-induced airway hyperresponsiveness develops[57].

Treatment

The medical treatment of AR reduces the risk of asthma-related events in asthmatic patients[58]. Nasal corticosteroids stabilize bronchial hyperreactivity in allergic rhinitis patients with seasonal asthma[37,59]. The leukotriene receptor antagonists are less effective than antihistamines and nasal steroids in upper airway disease[60,61].

Allergen immunotherapy reduces asthma symptoms. This therapy also improves nasal disease[62,63]. By immunotherapy, progression of allergic rhinitis to bronchial asthma may be prevented. Specific immuno-therapy with seasonal allergic rhinitis significantly reduced the asthma development risk[64,65].

UPPER AIRWAYS AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The correlation between chronic obstructive pulmonary disease and upper airway inflammation are reported. The relation between nasal and bronchial inflammation by estimating the IL-8 concentration were reported[66].

CONCLUSION

Upper and lower airways are thought as one functional entity. Local allergen exposure of the respiratory system induces mucosal inflammation. A "unified airway" concept suggests that the upper and lower airways function as a single unit[67]. The nasobronchial interaction may be suggested as present in airway. Trigger agents for naso-bronchial reflex are important to initiate the symptoms.

Abstract

Obesity and diabetes is a co-pandemic and a major health concern that is expanding. It has many psychosocial and economic consequences due to morbidity and mortality of this disease combination. The pathophysiology of obesity and related diabetes is complex and multifactorial. One arm of this disease process is the genetic susceptibility. Other arm is dependent on the intricate neuro-humoral factors that converge in the central nerve system. Gut hormones and the adipose tissue derived factors plays an important role in this delicate network. Bariatric surgery provides the only durable option for treatment of obesity and furthermore it provides a remission in the concomitant diseases that accompany obesity. This review provides a brief insight to all these mechanisms and tries to deduce the possible reasons of remission of type 2 diabetes after bariatric surgery.

Key words: Type 2 diabetes; Morbid obesity; Bariatric surgery

Core tip: Metabolic surgery in obese individuals results weight loss and beneficial effects on type 2 diabetes mellitus and metabolic syndrome.

INTRODUCTION

Obesity is considered as abnormal accumulation of

Table 1 World Health Organization classification of obesity

Classification	WHO class	BMI (kg/m^2)
Underweight		≤ 18.5
Normal		18.5-24.9
Overweight		25.0-29.9
Obesity	I	30.0-34.9
	II	35.0-39.9
Extreme obesity	III	40

Adapted from Aronne[4]. WHO: World Health Organization; BMI: Body mass index.

excess energy as fat tissue that results in major health problems and reduced life span of the individual[1]. Obesity is a major health problem and is now considered a worldwide pandemic. Its incidence increasing in an alarming rate and by 2015 around a million people is expected to be overweight worldwide[2]. Furthermore, it is considered as a government political problem for it results in economic, social losses due to morbidity and mortality during the course of the disease[3]. The risk stratification of obesity is made according to World Health Organization's proposed classification of obesity (Table 1)[4]. Increasing body mass index (kg/m^2) the morbidity and mortality rate of the patient increases. Obesity causes many concomitant systemic diseases. Among the diseases that occur with obesity are diabetes, hypertension, coronary artery diseases, dyslipidaemias, non-alcoholic fatty liver disease and metabolic syndrome are pronounced[5]. There are many problems when dealing with obese patient. For since it is a multifactorial disease the treatment is very hard furthermore there are many social security related problems when dealing with bariatric patient. There are also psychosocial implications against obese people such as job interview bias, unavailability of public bills and inability of social security coverage for obesity related diseases[6].

Obesity is multifactorial disease and many neuro-humoral factors are orchestrated in appetite control and energy haemostasis of the individual. Detailed review of these factors is out of the scope of this text. Here we will examine briefly the central nervous system related and gut humoral factors related control mechanisms of the appetite of the individual and furthermore we will give detailed information regarding type 2 diabetes mellitus (T2DM) and obesity pandemic. Later on, we will try to summarize the effects of bariatric surgery on humoral factors of obesity and diabetes.

Role of central nervous system in control of appetite

Central nervous system as a pivotal point in orchestration of anorectic and orexigenic signals received from the periphery. Mainly the arcuate nucleus of the central nervous system integrates all the input[7]. This area of the brain contains neuropeptide YY rich neurons. The main orexigenic stimulus comes from Ghrelin and the anorectic stimuli come from the Glucagon like peptide-1 (GLP-1), plasma peptide tyrosine tyrosine 3-36 (PYY3-36), cholecystokinin and *etc*. All these stimuli integrate at the arcuate nucleus and this causes the individual to seek food in discrete time points between daily activities[8-10]. This is one of the main points that is deranged in the obese individual and a continuous eating behaviour occurs in the obese patient.

Peripheral axis

Peripheral axis consists of gut related hormones with vagus and the adipose tissue related humoral factor; namely the adipokines. These are all potent short and long terms stimuli for the control of energy haemostasis in the individual and as a result of this there is the food seeking behaviour characteristics of humans (and most vertebrates) ae determined.

Role of gut related hormones in obesity

Several factors secreted from the gastrointestinal tract regulate the caloric intake and the food seeking behaviour of the individual[7,8]. There are factors that increase the adipogenesis and there are counteracting factors that reduce the appetite and reduce adipose tissue formation. Main orexigenic factors secreted from the gastrointestinal system are ghrelin and insulin. The counteracting mechanisms on the other hand are GLP-1, NYY3-36, *etc*[9,10]. Furthermore vagus and the autonomic system are important afferent inputs of the gastrointestinal system to the arcuate nucleus forming the gut-brain feedback mechanisms[11,12].

Ghrelin is a 28-amino acid peptide. It has been shown to be produced from the fundic mucosa. In animal models, it was shown that ghrelin increased feeding and weight gain and had an orexigenic role in energy balance. The clock genes *PER1* and *PER2* ghrelin levels peak before meals and quickly decrease following meals. Arcuate nucleus in the central nervous system exhibits ghrelin receptors[13,14].

Insulin has many roles in energy balance. Serum glucose levels elevated after a meal stimulate insulin release by pancreatic beta cells. Additional secretagogues of insulin are amino acids such as alanine, glycine, and arginine, acetylcholine produced from vagal nerve endings, and incretins such as GLP-1 and glucose-dependent insulinotropic polypeptide[7,8]. Although central effects of insulin is reduced appetite and weight loss in preclinical studies in obese individuals show higher basal insulin levels[8].

GLP-1 has an important role in increasing secretion of insulin from the pancreas[7]. Both *in vivo* and *in vitro* researches have showed that GLP-1 increase insulin secretion in the beta cell. Moreover, glucagon secretion is inhibited by GLP-1 while insulin sensitivity is increased[7,15].

PYY3-36 is an anorectic factor on the arcuate nucleus through the Y2 receptors expressed at the neuronal level. It shows peak levels 1-2 h following the meals and the rise in serum levels are observed within 15 min following eating[8,16]. PYY3-36 anorectic effect is possibly facilitated by the vagus nerve[16].

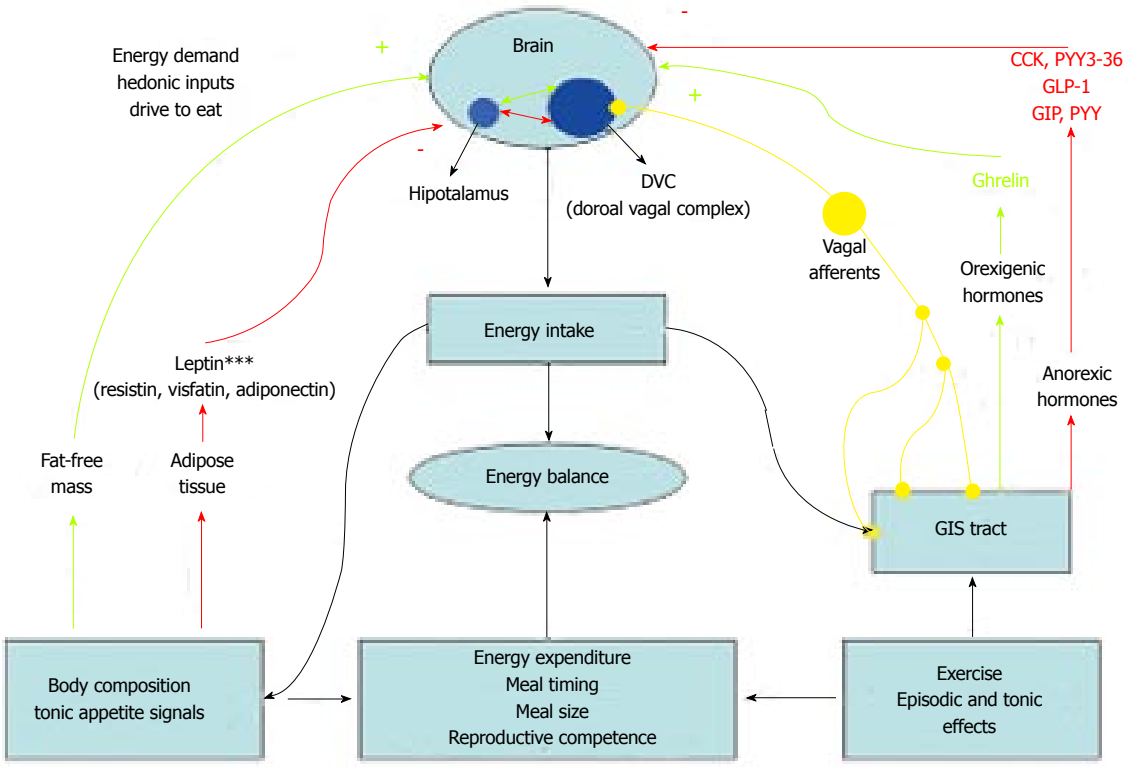

Figure 1 Factors produce a tendency towards insulin resistance and diabetes in the obese patients. DVC: Dorsal vagal complex; CCK: Cholecystokinin; GLP-1: Glucagon-like peptide-1; PYY: Peptide YY; GIP: Gastric inhibitory polypeptide.

Role of adipose tissue in obesity

Leptin and adiponectin are the two main humoral factors secreted from the adipose tissue and that play a role in the energy haemostasis of the individual. They all together form the adipose-brain feedback axis[8].

Leptin is produced in white and brown adipose tissue, placenta, ovaries, skeletal muscle, stomach, breast, bone marrow, pituitary, and liver[8]. Engineer and Garcia have showed that leptin affects hypothalamus, where it inhibits NPY/AgRP receptor neurons while stimulates α-MSH neurons[17]. In contrast to ghrelin, leptin acts on appetite and energy balance[7,18]. Harvey *et al*[8] has reported leptin resistance in obese patients.

Adiponectin is secreted from white adipose tissue[8]. Serum adiponectin levels are negatively correlated to serum insulin and glucose levels, body fat mass, and waist-to-hip ratio. It has been shown that fasting adiponectin levels have been reduced in the obese individuals[19]. Nevertheless, the response to a meal appear to be exaggerated in obese subjects.

Relationship between obesity and diabetes

Obesity is associated to many medical conditions, probably the most disturbing may be T2DM. Both obesity and T2DM are mainly related with insulin resistance[3]. The nonesterified fatty acids (NEFAs) secreted from adipose tissue in obese population may lead to the theory that insulin resistance and β-cell dysfunction are probably related[20,21]. Adipose tissue affects body metabolism by secreting hormones, glycerol, leptin, cytokines, adiponectin, proinflammatory substances, and NEFAs. Increased NEFA secretion is detected both in obesity and T2DM, and it is related with insulin resistance in both situations. In humans, insulin resistance starts to develop shortly after an acute increase of plasma NEFA levels.

Intra-abdominal fat is linked to the genes that secrete specific types of proteins responsible for the production of energy[22,23]. Omental adipocytes secrete larger amount of adiponectin than the subcutaneous-derived adipocytes[24,25]. Furthermore, adiponectin secreted from omental adipocytes is negatively associated with weight gain. The excretion of NEFAs to different tissue may be affected by their source. Abdominal fat is considered more lipolytic than subcutaneous fat, and it does not respond simply to the antilipolytic action of insulin, which makes intra-abdominal fat more significant in causing insulin resistance and diabetes[26]. All these factors produce a tendency towards insulin resistance and diabetes in the obese patients (Figure 1).

Fecal fat, and fecal biliary acids in obesity

The cytotoxicity of fecal bile acids is associated with their concentration in fecal water, and particularly is related to the concentration of secondary bile acids[27,28]. Total bile acid levels in fecal water were decreased meaningfully in the course of orlistat treatment. The decrease in fecal water bile acids during orlistat treatment mainly was caused by a large reduction in deoxycholic acid. Small reductions were observed in fecal water with both the orlistat and placebo groups for all the other bile acids. This is relevant in that the

secondary bile acids, which include deoxycholic acid, are the bile acids most frequently associated in colonic cell hyperproliferation[29,30].

BARIATRIC SURGERY AND OBESITY RELATED METABOLIC CHANGES

Bariatric surgery consists of various interventions which can be divided as restrictive, malabsorptive, or combined restrictive and malabsorptive. The number of bariatric interventions (*i.e.*, metabolic surgery) for the treatment of obesity is in exponential increase. This is partially due to effective and long-lasting weight loss; in addition, a good deal of improvement of co-morbidities after surgery compared with diet and physical activity[7]. In this subsection we will briefly evaluate the changes in the levels of above mentioned factors with respect to various bariatric procedures and at the end try to draw certain conclusion regarding the metabolic effects of bariatric (metabolic) surgery. We will briefly summarize the effect of bariatric surgery on each of the adipose and gut humoral factors.

In the case of ghrelin there are many report regarding Roux-en-Y gastric bypass (RY-GBP) and the serum ghrelin levels detected in various set points starting from ranging between 14 d postoperatively to 2 years[31,32]. Most of the researchers have found decreased ghrelin levels postoperatively and these results have been compared to non-resectional restrictive procedures such as adjustable gastric banding (AGB). Therefore we can say that the final effect of procedures involving gastric transection reduces the serum ghrelin levels[33,34].

The changes in ghrelin after sleeve gastrectomy (SG) were measured in different studies. Shak *et al*[35] stated that fasting ghrelin levels are decreased up to 5 years of follow-up. Moreover, some studies tried to evaluate and compare the effects of RY-GBP or AGB with the SG on fasting ghrelin levels, which showed to be decreased[36]. These studies showed that the ghrelin suppression after both SG and RY-GBP may be part of the mechanism that contributes to diabetes remission[35,36].

Serum insulin levels sow rapid drop with RY-GBP, biliopancreatic diversion and duodenal switch and SG however with AGB although insulin drops the incretin effect is not observed[7,35-38].

A strong GLP-1 response was reported 10 years after RY-GBP, suggesting a long-lasting effect. Furthermore, in T2DM patients, an improved GLP-1 response to meal intake is not enough to preserve normal glucose tolerance in the long term after RY-GBP. Similarly, some studies have shown unaffected fasting GLP-1 and a noteworthy increase in response to a glycemic challenge[39,40]. Studies have shown a significantly increased fasting level of PYY3-36 following RY-GBP. Following the AGB, fasting PYY3-36 or meal-stimulated response is variable and inconclusive[41,42]. Data regarding the effects on leptin are inconclusive and therefore research regarding area is urgently needed. Furthermore, adiponectin studied in RY-GBP in only one study and was found be increased following surgery[43]. This study is not enough to draw conclusions and therefore multi-centric high patient volume studies are needed to evaluate the role of metabolic surgery on adipose-brain axis in obesity.

Clinically all these changes in the humoral effects that the bariatric surgery produces is seen as remission of diabetes in obese individuals postoperatively. Even in patients who continue to have diabetes postoperatively have a better quality of life due to reduced medications and a better glycaemic control. This has been extensively studied and currently here even meta-analysis regarding this subject showing very good results in almost all procedure types[44-47].

CONCLUSION

Metabolic surgery in obese individuals results weight loss and beneficial effects on T2DM and metabolic syndrome.

Abstract

Hypertensive emergencies and hypertensive urgencies in children are uncommonly encountered in the pediatric emergency department and intensive care units, but the diseases are potentially a life-threatening medical emergency. In comparison with adults, hypertension in children is mostly asymptomatic and most have no history of hypertension. Additionally, measuring accurate blood pressure values in younger children is not easy. This article reviews current concepts in pediatric patients with severe hypertension.

Key words: Hypertensive crisis; Hypertensive urgency; Hypertensive emergency; Blood pressure

Core tip: Hypertensive crisis in children is a disease easily mismanaged in the emergency department. The physician should carefully search for evidence of end organ injury to distinguish between hypertensive emergency and hypertensive urgency. Only patients with hypertensive emergency require immediate reduction in markedly elevated blood pressure to prevent and arrest progressive end organ damage. In all other patients, the elevated blood pressure can be lowered slowly using oral agents, *i.e.*, esmolol, nicardipine, labetalol and fenoldopam. All young children should receive complete examinations to look for the underlying cause of secondary hypertension.

Yang WC, Lin MJ, Chen CY, Wu HP. Clinical overview of hypertensive crisis in children. *World J Clin Cases* 2015; 3(6): 510-513 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/510.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.510

DEFINITIONS OF HYPERTENSION IN CHILDREN: HYPERTENSIVE CRISIS AND HYPERTENSIVE ENCEPHALOPATHY

Hypertension in children older than 12 mo was defined as blood pressure (BP) level > 140/90 mmHg, as in adults, until the updated definition of "The fourth report on the diagnosis, evaluation and treatment of high blood pressure in children and adolescents" in 2004[1]. Hypertension is identified when the systolic BP (SBP) or diastolic BP (DBP) is greater than or equal to the 95th percentile for gender, age and height: stage 1 hypertension is SBP or DBP within the range of the 95th percentile to the 99th percentile plus 5 mmHg; stage 2 hypertension is greater than the 99th percentile plus 5 mmHg. Height and gender revealed no statistical difference from the previous study[2-4].

Hypertensive crisis is defined as a severe elevation in BP, classified as hypertensive emergencies and hypertensive urgency[5]. Hypertensive encephalopathy is a hypertensive emergency and characterized by an abrupt or prolonged elevated BP that overcomes the autoregulatory capacity of the cerebral vasculature. It appears as severe hypertension associated with headache, altered mental status, seizure, visual disturbances or stroke, and the lesion may be revealed as reversible posterior leukoencephalopathy[6-11].

EPIDEMIOLOGY

Although the prevalence of hypertension tends to be increasing today, pediatric hypertension still accounts for about 0.5%-1% in children and its incidence is obviously less in younger children and infants[12,13]. Until now, data of the incidence of hypertensive crisis in children have not been analyzed enough to give a definite result, but in adults, approximately 1% of hypertensive individuals have been reported to have hypertensive crisis[14].

ETIOLOGY

Generally, primary hypertension is identifiable in children and adolescents, whereas secondary hypertension is more common in younger children. In primary hypertension, there is a strong association of high BP with being overweight and BMI should be calculated as part of physical examination, with the marked increase in the prevalence of overweight children.

In newborn infants with hypertension, the most likely definable causes are renal artery thrombosis or stenosis, congenital renal malformation, or coarctation of the aorta[15]. In children between infancy and 6 years of age, coarctation of the aorta, renal parenchymal diseases and renal artery stenosis are the three most common causes of secondary hypertension. In children older than 6 years, renal artery stenosis and renal parenchymal diseases are the leading causes of diastolic BP over 90-100 mmHg. Primary hypertension accounts for 90% of the causes of hypertension in patients aged over 15 years[16-19].

PATHOPHYSIOLOGY

In the long term in children, high BP levels could be associated with the early development of cardiovascular changes[20]. In the acute phase of hypertensive crisis, rapid increases in systemic vascular resistance could be precipitated as a result of increases in the circulating vasoconstrictor substances, including norepinephrine, angiotensin Ⅱ, or anti-natriuretic hormone[21]. Arteriolar fibrinoid necrosis may induce a consequence of the severely elevated BP, precipitating endothelial damage with resultant end organ ischemia. Ischemia could trigger the further release of vasoactive substances, causing further vasoconstriction and myointimal proliferation[21]. This may appear to be an important part[22]. Activation of the renin-angiotensin system could also be highly involved[23-25].

CLINICAL MANIFESTATIONS

Compared to adults, the clinical presentations of hypertensive crisis in children are more likely asymptomatic[26]. Our previous study reported that no specific clinical manifestation correlated with the age factor[27]. Patients with hypertensive crisis in different age groups did not have specific different clinical presentations in this study[27]. In addition, the signs of end organ dysfunction are hypertensive encephalopathy, acute left ventricular failure and acute myocardial ischemia, papilledema, elevated liver function tests, *etc.* For children with complaints of any symptoms such as persistent headache, nausea/vomiting and altered mental status, hypertensive crisis should be ruled out immediately to prevent further damage. According to some clinical analyses, the related risk factors for hypertensive encephalopathy were male gender, stage 2 hypertension and some clinical symptoms. In pediatric patients with hypertensive crisis caused by essential hypertension, symptoms of chest tightness and no family history of hypertension may show a lower risk for hypertensive encephalopathy[27]. Moreover, the recurrence was 29.1%[27].

EVALUATION

Detailed medical history taking and complete physical examinations are both required in children presenting with suspected hypertensive crisis. In laboratory tests, serum electrolytes, complete blood counts, blood urea nitrogen, creatinine and urinalysis should be considered for children with suspected hypertensive crisis. Chest radiograph and electrocardiogram may be also performed in patients with chest pain and tachypnea. A brain computed tomography scan may be needed in

hypertensive children with neurological signs[28].

MANAGEMENT

Pediatric patients with hypertensive crisis require immediate and appropriate reduction in BP levels, whereas patients with hypertensive urgency require a slower rate of reduction in BP levels over 24 to 48 h. However, rapidly decreasing BP levels may result in decreasing the blood flow of organs, causing ischemia and infarction[29-31]. In patients with hypertensive encephalopathy combined with chronic hypertension, it is important to reduce the mean arterial pressure gradually during the first hour[32]. Accordingly, patents with hypertensive emergency should be treated in an intensive care unit. The drugs of choice should depend on the end organs involved and the monitoring environment. Once the reductions in mean arterial pressure to less than 20% or to a DBP of 100 mmHg have been reached, oral maintenance therapy may be given instead of the intravenous agent. Another important part of BP control in hypertensive crisis is volume depletion. Adequate fluid replacement will restore organ perfusion.

The agent of choice should depend on the clinical presentation and the severity of the hypertensive crisis. The preferred agents include esmolol, labetalol, fenoldopam and nicardipine, but phentolamine and trimethaphan camsylate may be less commonly used today. Nevertheless, they appear to be useful in some particular situations, such as catecholamine-induced hypertensive crises, such as pheochromocytoma[33,34]. Sodium nitroprusside could be used in patients with acute pulmonary edema and/or severe left ventricular dysfunction and in patients with aortic dissection. However, this agent has some limitations for application in the pediatric ED because of the requirement of intra-arterial BP monitoring and protection from light[35]. Short-acting, immediate-release oral nifedipine and sublingual nifedipine have been used for effective reduction of severe elevated BP, but some studies cautioned against it as being potentially dangerous in patients with hypertensive crises. Clonidine and angiotensin-converting enzyme inhibitors are long acting and difficult to titrate, but these agents may be still useful in some clinical conditions[36].

CONCLUSION

Hypertensive crisis in children is a rare but important disease easily mismanaged in the ED. Pediatric patients with hypertensive emergencies need immediate reduction of BP levels to arrest further end organ damage. For patients with hypertensive urgency, BP may be lowered slowly.

Abstract

Lymphangiomas are a group of benign malformations of the lymphatic system, and hemolymphangioma (or hemangiolymphangioma) is a rare congenital malformation of the lymphatic system with vascular involvement. These benign malformations are most commonly diagnosed at an early age, and may be present as a part of an associated syndrome. In this case report, we describe the first case of adolescent scoliosis associated with a large, paraspinous hemolymphangioma. A 15-year-old girl with an incidental finding of a paraspinous hemolymphangioma is presented along with her history, physical exam, radiographic findings, and operative course. The possible pathogenesis, treatment approach, and clinical dilemmas are also discussed. Given the well-known relationship between tumors and scoliosis, a benign paraspinous vascular and lymphatic tumor may be responsible for the presence of scoliosis in a small number of patients.

Key words: Case report; Scoliosis; Etiology; Hemolymphangioma; Tumor

Core tip: This case report describes the first case of adolescent scoliosis associated with a large, paraspinous hemolymphangioma. Given the relationship between tumors and spinal deformity, a benign paraspinous vascular and lymphatic tumor may be responsible for scoliosis in a small number of patients.

INTRODUCTION

The association between paraspinous tumors and scoliosis is well recognized in clinical orthopaedics. To our knowledge, there are no reports in the current literature of an association between paraspinous hemolymphangioma and scoliosis. A lymphangioma is a congenital or post-traumatic malformation of the lymphatic system that is inherently benign, and typically found by palpation or with symptomatic compression of nearby anatomic structures. This entity has been classified into four types: capillary lymphangioma, cavernous lymphangioma, cystic lymphangioma (hygroma), and hemolymphangioma[1]. However, it may also be classified by cyst size as microcystic, macrocystic, or mixed[2].

Hemolymphangioma is the least common subtype, and has been found in the genitalia[3,4], gastrointestinal tract[5,6], head and neck[7,8], and extremities[9,10]. In the literature, there is also one report of a retroperitoneal hemolymphangioma without associated scoliosis[5], as well as a case series of bone lymphangioma associated with spinal deformity in the international literature[11]. Secondary transformation of lymphagioma to lymphangiosarcoma is rare, and when present, it is most often due to radiation therapy[12]. Treatment for symptomatic tumors includes marginal excision, aspiration and drainage, cryotherapy, injection of sclerosing agents, and radiotherapy[12]. However, recurrence is common, even after meticulous excision[10]. For asymptomatic lesions, a conservative approach may be taken in the form of serial imaging.

In this case report, we describe the first case to our knowledge of adolescent scoliosis associated with a large, paraspinous hemolymphangioma. The diagnosis and operative course of this patient is presented, in addition to a discussion of the pathogenesis and clinical management of this condition. We discuss various clinical dilemmas associated with this case, and we suggest a modification in the work-up of adolescent scoliosis in the setting of a strong family history of lymphatic tumors.

CASE REPORT

A 15-year-old girl presented for consultation regarding her scoliosis. Several years ago, the patient had been prescribed a brace for a 26-degree curve, but she admitted to non-compliance with this regimen. The patient was born at full-term by vaginal delivery. She had delayed puberty, and at the age of 15, she was 145 cm tall and weighed 34 kg. The patient was active in sports and did not complain of back pain. She had no family history of scoliosis or spine surgery. However, her maternal heritage was significant for several relatives with "hemangiomas," including her mother who had a large and irregular lesion of the left upper extremity (Figure 1).

On physical exam, the patient demonstrated a right thoracic rib prominence of 10 degrees on Adams forward bending test. There were no cutaneous lesions present, and the remainder of her physical exam including neurological exam was unremarkable. Routine scoliosis radiographs were obtained (Figures 2 and 3), and demonstrated a right thoracic curve. No additional imaging was indicated at that time[13]. At this point, the patient's presentation and curve pattern seemed consistent with adolescent idiopathic scoliosis (AIS), and given the severity of disease, the patient was indicated for a posterior spinal fusion from T2 to L1.

In the operating room, a standard posterior approach to the spine was performed, and the posterior elements were exposed. A Lenke probe was used to instrument the right pedicle of T11 (Figure 4), at which point, an immediate flow of thin, white fluid was noted through the tract. As a result, cultures were obtained, a drain was placed, and a decision was made to postpone the definitive procedure until the etiology of this fluid was determined.

The intra-operative Gram stain and microscopic analysis demonstrated moderate white blood cells without the presence of bacteria. Similarly, AFB, fungus, aerobic and anaerobic cultures were negative for any organisms. An magnetic resonance imaging (MRI) was also obtained that demonstrated a multilobulated, prominently vascularized lesion in the retroperitoneum from T7 to L5 (Figures 5 and 6). These pathologic and radiographic findings were reviewed with an expert pediatric surgical oncologist at a leading cancer center, and based on the patient's strong family history, intraoperative finding of lymph, and the lesion's characteristics on advanced imaging, a diagnosis of hemolymphangioma was made by the specialist. At that point, there was no indication for acute oncologic management, and there were no contraindications to proceeding with spine surgery. After discussion with the patient and her family, the decision was made to move forward with the definitive procedure. The patient underwent an uncomplicated posterior spinal fusion from T2 to L1 as previously planned (Figure 7). Care was taken to avoid the left pedicles of T7 to T9, as these levels corresponded to the largest portion of the hemolymphangioma seen on MRI. The patient recovered uneventfully, and was discharged without further incident. She was advised to follow-up with a pediatric oncologist for further surveillance and management. At one-year follow-up, the patient reported no symptoms, and her most recent radiographs revealed a stable correction with intact hardware.

DISCUSSION

At the patient's initial presentation, the curve pattern and clinical behavior of her spinal deformity seemed consistent with AIS. However, the immediate proximity of this large malformation to the spine suggests an association with the patient's spinal deformity, and warrants further discussion regarding the etiology and

Figure 1 Vascular malformation, left upper extremity of mother.

Figure 3 Pre-operative lateral X-ray.

Figure 2 Pre-operative AP X-ray.

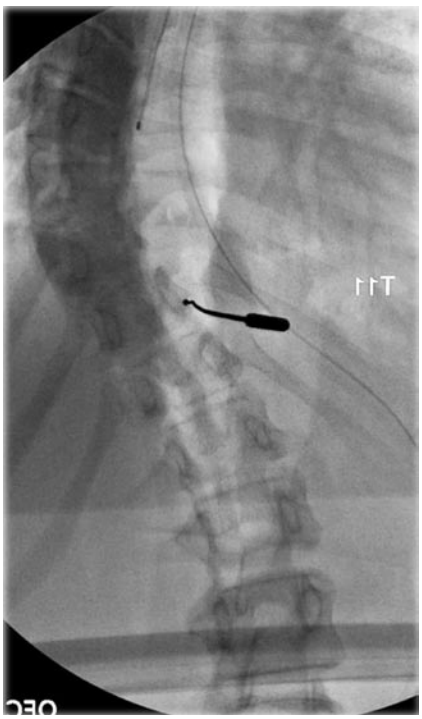

Figure 4 Intraoperative X-ray from initial procedure at right T11 pedicle.

management of this patient's scoliosis.

Several tumors within the spine have been shown to be associated with scoliosis and spinal deformity, most commonly osteoid osteoma and osteoblastoma[14,15], but also astrocytoma, ependymoma, epidermoid cyst[16], and bone lymphangioma[11]. However, there have been no reports of spinal deformity associated with paraspinous hemolymphangioma. In the case of osteoid osteoma and osteoblastoma, the tumor is more commonly located on the concavity of the curve. As a result, the deformity is caused by an asymmetric inflammation of the paraspinal muscles leading to asymmetric spasm[17]. In the case of bone lymphangioma, the spinal deformity is thought to result from a loss of spinal stability[11]. This patient's tumor was also predominantly located on the concavity of

Figure 5 Coronal T2-weighted magnetic resonance imaging.

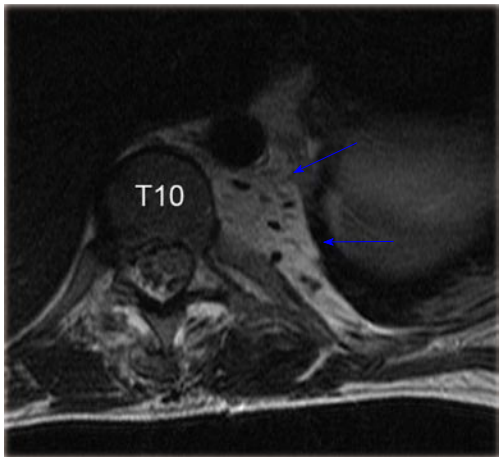

Figure 6 Axial T2-weighted magnetic resonance imaging.

the curve and her spinal stability was compromised suggesting a similar pathogenesis. In addition to an asymmetric inflammatory response and loss of spinal stability, unilateral disruption of growth or alteration of soft tissue dynamics may also have played a role in the pathogenesis of this patient's spinal deformity.

This case also presents several interesting clinical dilemmas. The first dilemma is whether an MRI should have been obtained pre-operatively. Since this patient was healthy and lacked any neurological signs or atypical features, a pre-operative MRI did not appear to be indicated[13]. However, given the findings of this case report, it is reasonable to obtain a pre-operative MRI in patients with a strong family history of lymphatic tumors. Secondly, the unexpected intra-operative finding of a thin, whitish fluid from the pedicle raises an important dilemma regarding surgical decision-making. In this instance, a drain was placed and the etiology was further investigated. The staged procedure allowed the surgeon to review the patient's case with experts

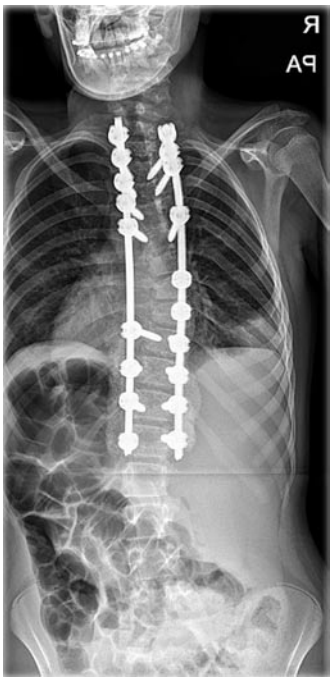

Figure 7 Post-operative AP X-ray.

and colleagues, and proceed when malignancy and infection were ruled out. Once the clinical diagnosis of a benign lesion was made, the surgeon was able to safely proceed with the planned procedure. Ultimately, this patient's treatment was similar to the originally prescribed surgical management, with the exception of fewer pedicle screws being included in her instrumentation. Lastly, it is unclear whether the patient will benefit from treatment of her hemolymphangioma, since the natural history of this condition is benign and there are several risks associated with treatment, including malignant transformation and a high likelihood of recurrence[10,12]. Nevertheless, it is clear that this patient will require close follow-up to monitor for symptoms as well as recurrence of her deformity.

Overall, this case report describes the first case of a paraspinous hemolymphangioma associated with adolescent scoliosis. The natural history of hemolymphangioma is typically benign, however, it may be associated with the development of scoliosis in a small number of patients. The diagnostic work-up and surgical management of scoliosis may need to be modified in patients with a known history or strong family history of lymphatic tumors.

ACKNOWLEDGMENTS

We would like to thank Michael P La Quaglia, MD, for his expertise in the oncologic diagnosis and management of this patient.

COMMENTS

Case characteristics

A 15-year-old girl presented with scoliosis.

Clinical diagnosis

On physical exam, the patient had a right thoracic rib prominence of 10 degrees on Adams forward bending test, she had no cutaneous lesions, and her neurological exam was unremarkable.

Differential diagnosis

The possible diagnoses included adolescent idiopathic scoliosis or pathologic scoliosis.

Imaging diagnosis

The patient's initial radiographs demonstrated a right thoracic curve, and magnetic resonance imaging (MRI) demonstrated a multilobulated, prominently vascularized lesion in the retroperitoneum from T7 to L5.

Pathological diagnosis

The intra-operative Gram stain and microscopic analysis demonstrated moderate white blood cells without the presence of bacteria, and AFB, fungus, aerobic and anaerobic cultures were negative for any organisms.

Treatment

After consultation with an expert pediatric oncologist, the patient underwent a posterior spinal fusion from T2 to L1. However, care was taken to avoid the left pedicles of T7 to T9 as these levels corresponded to the largest portion of the hemolymphangioma seen on MRI.

Related reports

There have been no previous reports of adolescent scoliosis associated with a large, paraspinous hemolymphangioma, however there have been several reports of spinal deformity associated with spinal tumors.

Term explanation

Hemolymphangioma is a rare congenital malformation of the lymphatic system with vascular involvement.

Experiences and lessons

This case report presents the diagnostic work-up and surgical management of adolescent scoliosis associated with a large, paraspinous hemolymphangioma. Several clinical dilemmas are also discussed such as the need for advanced imaging, surgical decision-making, and post-operative management. An MRI may be indicated in patients with a strong family history of lymphatic tumors, and close collaboration with a surgical oncologist and other colleagues is required to ensure an optimal surgical outcome.

Peer-review

The case is rare, and the correction is well done. It is a nice paper.

Abstract

A 54-year-old female with Anderson-Fabry disease (AFD)-R342Q missense mutation on exon 7 in alpha-galactosidase A (*GLA*) gene - presented with sustained ventricular tachycardia. Imaging confirmed the presence of a new left ventricular apical aneurysm (LVAA) and a significantly reduced intra-cavitary gradient compared to two years prior. AFDcv is an X-linked lysosomal storage disorder caused by GLA enzyme deficiency. The phenotypic expression of AFD in the heart is not well described. Cardiac involvement can include left ventricular hypertrophy (LVH), which is typically symmetric, but can also mimic hypertrophic cardiomyopathy (HCM). Left ventricular apical aneurysm is a rare finding in HCM. We suggest a shared mechanism of LVAA formation in AFD and HCM, independent of the underlying cardiomyopathy. Mechanisms of LVAA formation in HCM include genetic predisposition and long-standing left ventricular wall stress from elevated intra-cavitary systolic pressures due to mid-cavitary obstruction. Both mechanisms are supported in this patient (a brother with AFD also developed a small LVAA). Screening for AFD should be considered in cases of unexplained LVH, particularly in patients with the aneurysmal variant of HCM.

Key words: Anderson-Fabry disease; Sustained ventricular tachycardia; Left ventricular apical aneurysm; Hemodynamic compensation; Transthoracic echocardiography; Magnetic resonance imaging; Hypertrophic cardiomyopathy

Core tip: Left ventricular apical aneurysm (LVAA) is a very rare phenomenon in patients with Anderson-Fabry disease (AFD); however, this patient with genetically confirmed AFD presented with a new LVAA. The authors believe that formation of the LVAA is the result of long-

standing elevated intra-cavitary systolic pressures and possibly genetic predisposition, similar to what can be seen in hypertrophic cardiomyopathy.

Poulin MF, Shah A, Trohman RG, Madias C. Advanced Anderson-Fabry disease presenting with left ventricular apical aneurysm and ventricular tachycardia. *World J Clin Cases* 2015; 3(6): 519-524 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/519.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.519

INTRODUCTION

Anderson-Fabry disease (AFD) is an X-linked lysosomal storage disorder caused by alpha-galactosidase (GLA) enzyme deficiency. The phenotypic expression of AFD in the heart is not well described. Cardiac involvement can include left ventricular hypertrophy (LVH), which is typically symmetric, but can also mimic hypertrophic cardiomyopathy (HCM). We report the case of a middle-aged female previously diagnosed with AFD who developed a left ventricular apical aneurysm (LVAA), which has been rarely reported in AFD. We suggest a shared mechanism of LVAA formation in AFD and HCM, independent of the underlying cardiomyopathy.

CASE REPORT

A 54-year-old female with AFD and well controlled hypertension presented with chest pain, palpitations and dizziness after missing two doses of metoprolol. Her initial electrocardiogram (ECG) displayed sustained monomorphic ventricular tachycardia (VT) with a cycle length of 214 ms. The VT had a right bundle, superior axis morphology suggesting a left ventricular (LV) apical origin (Figure 1)[1]. She initially received a bolus of amiodarone that failed to terminate the VT. Post direct current cardioversion, serial ECGs showed atrial fibrillation with persistent ST segment elevation in the inferior leads (Figure 2). A coronary angiogram demonstrated non-occlusive coronary artery disease. Transthoracic echocardiogram (TTE) revealed that her ejection fraction was newly reduced from 75% to 40% and identified a thin-walled LVAA that was not seen on TTE two years prior (Figure 3A and B). The mid and basal segments of the LV still had marked concentric hypertrophy with systolic mid-cavitary obliteration; however, the intra-cavitary gradient at rest was significantly lower than on the prior study; it had decreased from 71 to 16 mmHg (Figure 4). Contrast-enhanced cardiovascular magnetic resonance (CMR) confirmed these findings and demonstrated late gadolinium enhancement (LGE) of the aneurysmal LV apex extending to the lateral and inferolateral walls, consistent with myocardial scarring (Figure 5). The patient was restarted on metoprolol and had no further episodes of VT. A defibrillator (ICD) was implanted prior to discharge.

DISCUSSION

AFD is a rare, X-linked lysosomal storage disorder caused by GLA enzyme deficiency, which results in an abnormal accumulation of sphingolipid catabolites in multiple organs, including the heart. Although the prevalence of AFD is likely underestimated, mutations are present in 1:6000 to 1:40000 females. Clinical manifestations in heterozygous females vary widely from no apparent clinical disease to full expression of the disease[2]. Cardiac involvement can lead to myocardial hypertrophy, restrictive cardiomyopathy, coronary artery disease, arrhythmias (atrial and ventricular) as well as aortic and mitral valvulopathy[3]. Our patient's disease manifested in childhood with acroneuropathy and hypohydrosis, and subsequently progressed to include cutaneous lesions, lacunar infarcts and LVH. A few years prior to presentation she was diagnosed with hypertension, but there was no manifest renal involvement from AFD. Her blood pressure was well controlled with a combination of an angiotensin converting enzyme inhibitor and a beta blocker. The diagnosis of AFD was established at age fifteen by genetic testing with a R342Q missense mutation on exon 7 in the *GLA* gene. A brother had the same mutation. The R342Q mutation has been shown to lead to a complete loss of the GLA activity, and to be associated with a classical phenotypic presentation of AFD[4,5].

Despite a relatively early diagnosis, our patient had been reluctant to initiate AFD therapy until her symptoms worsened. Enzyme replacement therapy with Agalsidase beta (Fabrazyme®, Genzyme, Cambridge, MA, United States) had been initiated eighteen months prior to presentation. She received monthly infusion of 65 mg for one year, followed by an infusion of 60 mg every 2 wk. Despite being compliant with the treatment, her disease slowly progressed, with worsening of her neuropathy, cutaneous lesions, development of cerebral vasculopathy and formation of the LVAA.

LVH is a relatively common finding in AFD and has been shown to correlate with severity of the disease. LVH in AFD can mimic HCM and has been identified among the causes of late onset HCM in women. In addition, women tend to present at a later age than men, and often have milder symptoms, making the diagnosis of AFD more challenging in female patients[6,7]. The pattern of hypertrophy in AFD is typically symmetric, as opposed to asymmetric with preferential septal involvement in HCM. Contrast-enhanced CMR typically demonstrates evidence of LGE, particularly in the LV subepicardial and mesocardial inferior and inferolateral segments. The LGE is believed to be the result of both intra-myocyte accumulation of sphingolipids and fibrosis[8]. Development of a LVAA is uncommon in HCM (reported in only 2% of patients) but portends a poor prognosis with a high adverse event rate, including sudden death,

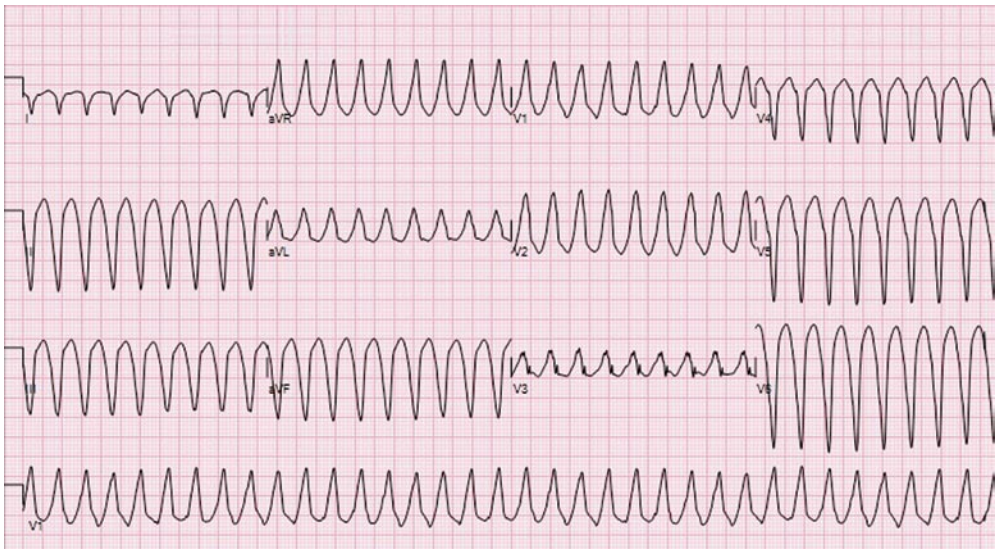

Figure 1 12-lead electrocardiogram (5 mm/mV) during ventricular tachycardia. The QRS shows a right bundle morphology with superior axis, suggesting a left ventricular apical source.

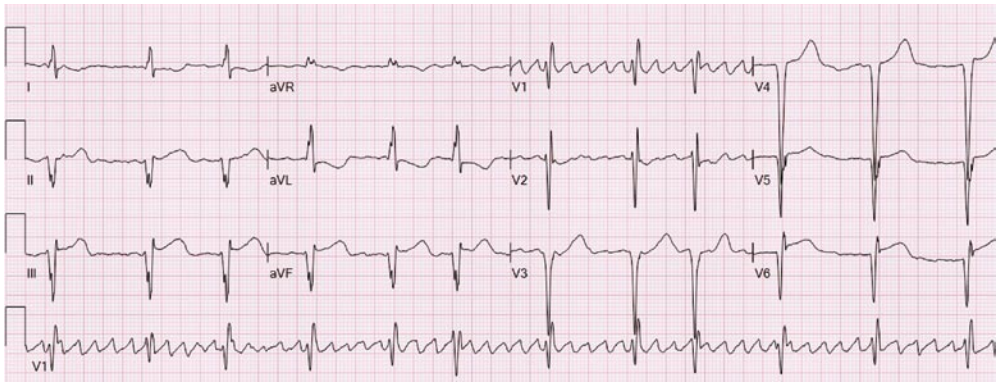

Figure 2 12-lead electrocardiogram (10 mm/mV) following direct current cardioversion. ST segment elevation is seen in the inferolateral leads.

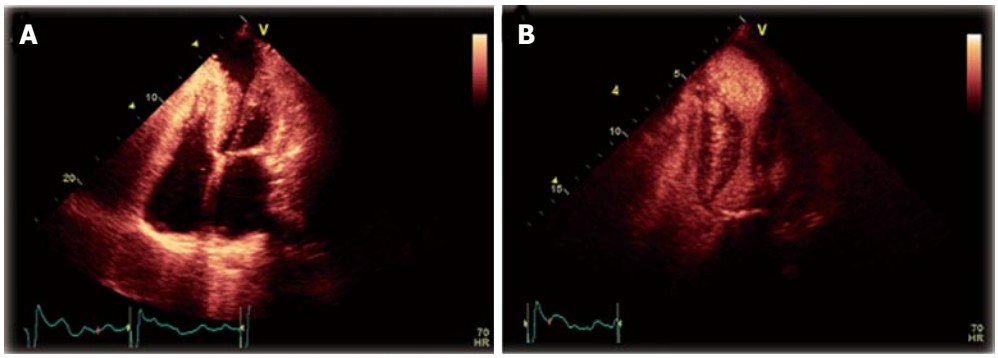

Figure 3 Transthoracic echocardiogram. A: Transthoracic echocardiogram (TTE), apical four-chamber view, demonstrating concentric left ventricular hypertrophy with mid-cavitary obliteration at end-systole, as well as a large left-ventricular apical aneurysm (LVAA); B: TTE apical two-chamber view, with ultrasound contrast demonstrating stasis within the LVAA with a circular flow pattern, as well as decreased perfusion of the apex.

appropriate ICD discharges, thromboembolic stroke, and progressive heart failure[9].

In contrast to AFD, HCM is a relatively common genetic disease and is the most common cause of sudden cardiac death in young people. Its estimated prevalence is 1 in 500. In HCM, the inheritance pattern is autosomal dominant. The mutant proteins that cause HCM are incorporated into intact filaments of the sarcomere and have been described as "poisonous peptides". Local environmental factors such as pressure, protein defect and modifier genes interact to induce the subsequent phenotype[10]. In HCM, development of ST

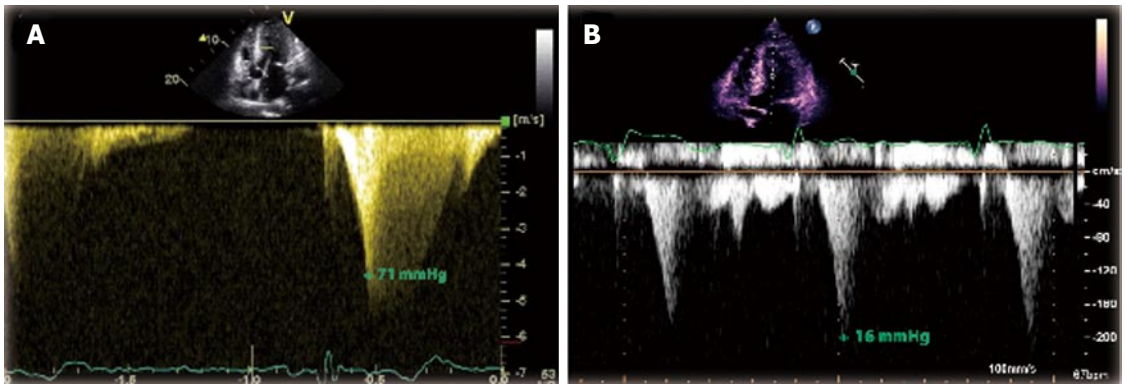

Figure 4 Transthoracic echocardiogram continuous Doppler. A: Transthoracic echocardiogram continuous Doppler flow across the left ventricle. The mid-cavitary gradient at rest from two years prior to the left-ventricular apical aneurysm (LVAA) formation (71 mmHg) is shown; B: Over time, flow across the mid-cavitary obliteration decreased and the peak pressure declined after the formation of the LVAA (16 mmHg).

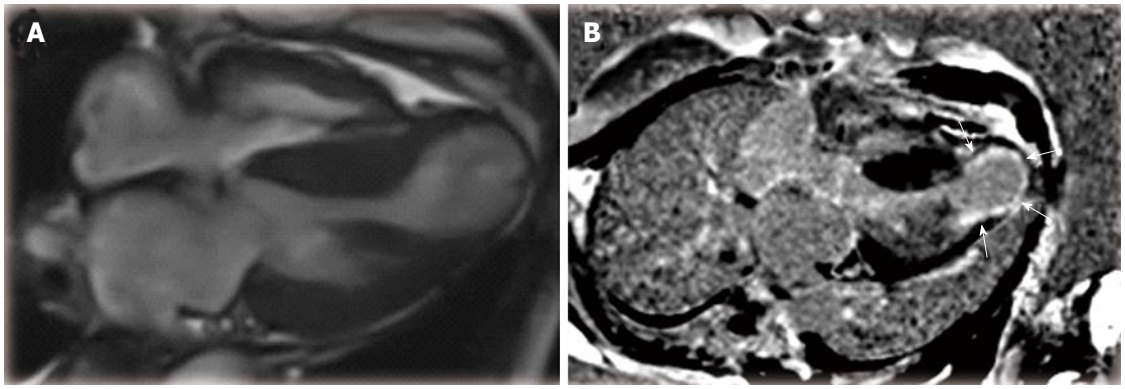

Figure 5 Contrast-enhanced cardiovascular magnetic resonance. A: Long-axis four-chamber cardiovascular magnetic resonance in systole showing concentric left ventricle hypertrophy with mid-cavitary obstruction and large apical aneurysm; B: Late gadolinium enhancement (LGE) image of the left-ventricular apical aneurysm consistent with myocardial scarring (arrows) with extension of LGE into the inferolateral segments (a pattern typically seen in Anderson-Fabry Disease).

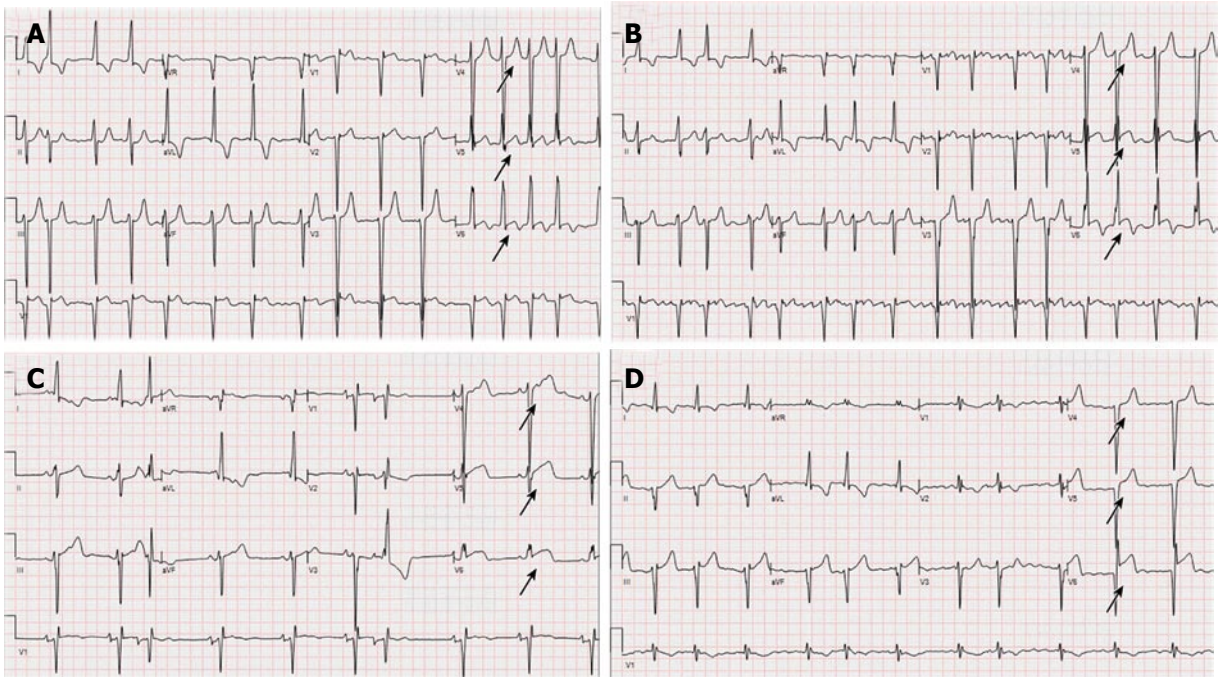

Figure 6 Serial electrocardiograms from this patient (A) 4 years prior, (B) 2 years prior, (C) 1 year prior, and (D) 3 mo prior are presented. The development of ST elevation in leads V4-V6 (arrows) can be seen, and correlates with the formation of the left ventricular apical aneurysm.

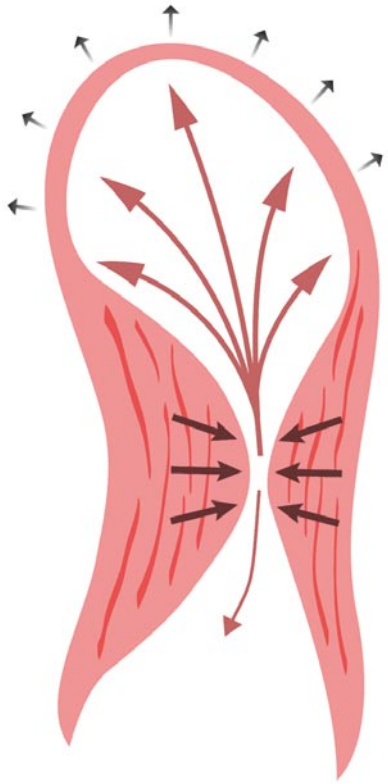

Figure 7 Illustration of blood flow direction during left ventricular systole. While some blood is ejected towards the outflow tract (single arrow), the flow is initially greater towards the apex, which is the area of least resistance (arrows from mid-cavity to the left-ventricular apical aneurysm), resulting in a lower gradient across the mid-cavitary obliteration as the aneurysm size increases.

elevation in leads V4 through V6 has been associated with LVAA formation[11]. Similar findings were seen upon reviewing our patient's serial ECGs (ranging from 4 years to 3 mo) prior to her presentation (Figure 6). To the best of the authors' knowledge, the development of LVAA has only been previously described once in AFD. In a recent report, the case of a middle-aged female diagnosed with HCM and LVAA is described. That patient was later found to have a missence mutation in the *GLA* gene (p.R118C) confirming the diagnosis of AFD[12].

The proposed mechanisms for LVAA formation in HCM are genetic predisposition and long-standing LV wall stress from elevated intra-cavitary systolic pressures as a result of mid-cavitary obstruction[8]. Both mechanisms are potential contributors in our patient, as a brother with AFD also developed a small LVAA prior to his death. We hypothesized that the formation of an apical aneurysm may be considered a hemodynamic adaptation to sustained elevation of systolic intra-cavitary LV pressure. The apex can dilate in response to the chronically elevated wall pressures during systole, with some blood flow directed towards the aneurysm, which offers less resistance than the mid-cavitary obliteration (Figure 7). Over time, this results in decreased flow across the mid-cavitary obstruction and a concordant smaller peak pressure gradient[13]. This phenomenon is exhibited in our patient by the considerable fall in her peak intra-cavitary gradient after the LVAA developed. Of note, our patient had chronic atrial fibrillation and it could be speculated that the LVAA formation was the result of a thromboembolic event. However, this scenario seems unlikely given that she had been appropriately anticoagulated with coumadin for years and had no other evidence of (non-cerebral) systemic embolization.

The phenotypic expression of AFD in the heart is not well described and can mimic even rare forms of HCM. The findings in this case suggest a shared mechanism(s) of aneurysm formation in AFD and HCM, independent of the underlying cardiomyopathy. Screening for AFD should be strongly considered in cases of unexplained LVH, particularly in patients with the aneurysmal variant of HCM. As previously demonstrated in HCM, it is likely that LVAA formation in AFD portends a poor prognosis.

COMMENTS

Case characteristics

A middle-aged female with Anderson-Fabry disease (AFD) presented with chest pain, palpitations and dizziness for a few hours after missing two doses of her beta-blocker.

Clinical diagnosis

She was found to have sustained ventricular tachycardia originating from the left ventricular (LV) apex, and further imaging confirmed the presence of a new LV apical aneurysm (LVAA).

Differential diagnosis

The differential diagnosis included aneurysm from hypertrophic cardiomyopathy (HCM), aneurysm from prior infarct, apical diverticulum and Takotsubo cardiomyopathy.

Laboratory diagnosis

The diagnosis of AFD was established by genetic testing with the presence of R342Q missense mutation on exon 7 in the *GLA* gene.

Imaging diagnosis

A transthoracic echocardiogram revealed that her intra-cavitary gradient had significantly decreased from two years prior and identified a new LVAA, which was confirmed by a cardiovascular magnetic resonance imaging.

Pathological diagnosis

The findings in this case suggest a shared mechanism(s) of aneurysm formation in AFD and HCM: genetic predisposition and long standing LV wall stress from elevated intra-cavitary systolic pressures as a result of mid-cavitary obstruction.

Treatment

She was placed back on her beta blocker and a defibrillator was implanted prior to discharge.

Related reports

Left ventricular hypertrophy in AFD can mimic HCM, however the pattern of hypertrophy is typically symmetric in AFD as opposed to asymmetric with preferential septal involvement in HCM. Development of a LVAA is uncommon in HCM (reported in only 2% of patients) and has only been (recently) reported once in AFD.

Term explanation

Development of a LVAA is a very rare phenomenon in patients with AFD.

Experiences and lessons

The findings in this case suggest a shared mechanism(s) of aneurysm formation in AFD and HCM, independent of the underlying cardiomyopathy. Screening for AFD should be strongly considered in cases of unexplained LVH, particularly in patients with the aneurysmal variant of HCM.

Peer-review

Authors showed a case of AFD complicated by apical aneurysm and ventricular

tachycardia. This report is written and presents well.

Abstract

We describe an unusual clinical and diagnostic feature of a patient with multiple sclerosis (MS). A 25-year-old woman was admitted to the Neurology department (December 2009) with one month history of rapid cognitive deterioration. She had poor cognition, dysphasia, reduction in visual acuity and temporal pallor of the optic discs. She had prolonged latencies of P100 component of visual evoked potentials (VEPs). Magnetic resonance imaging (MRI)-brain showed multifocal large (⩾ 3 cm) white-matter hypointense lesions in T1W and hyperintense in T2W and fluid-attenuated inversion recovery images and patchy enhancement. A diagnosis of tumefactive MS was given. She received two consecutive 5-d courses of 1 g daily intravenous methylprednisolone for 2 mo and oral prednisolone in dose of 80 mg twice/daily in between. At the 3rd month, Mini Mental State Examination and VEPs returned to normal but not the MRI. Patient continued oral steroids after hospital discharge (March 2010) for 9 mo with significant MRI improvement after which tapering of steroids started for a year. The patient refused immunomodulation therapy due to her low socioeconomic status. Neither clinical relapse nor new MRI lesions were observed throughout the next 4 years. In spite of the aggressive course of tumefactive MS variant, good prognosis may be seen in some patients.

Key words: Tumefactive multiple sclerosis; Acute dementia

Core tip: Multiple sclerosis (MS) is the most common cause of progressive neurologic handicap in young adults. MS is typically presented by sensory, motor and visual dysfunctions, abnormal visual, auditory brainstem, somatosensory and motor evoked potentials, elevated cerebrospinal fluid proteins and oligoclonal bands, and abnormal neuroimaging of the brain and spinal cord. In the literature, atypical clinical and radiological presentations or variants have been described in adults with MS which may pose diagnostic difficulties. However

and in spite of the aggressive course of its tumefactive variant, good prognosis may be seen in some patients on corticosteroids.

Hamed SA. Variant of multiple sclerosis with dementia and tumefactive demyelinating brain lesions. *World J Clin Cases* 2015; 3(6): 525-532 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/525.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.525

INTRODUCTION

Multiple sclerosis (MS) is a chronic immunologic disease in which inflammation, demyelination and axonal damage are the main pathologic features. The exact etiology of MS is unknown, however genetic susceptibility may be contributed[1]. MS has a prevalence of more than 30 cases per 100000 people[2,3]. Typically, the majority of patients with MS (approximately 70%) are young adults with an age range between 20-40 years particularly females (75%), while the remaining 10% and 30% of cases occur before the age of 20 years and after the age of 40 years, respectively[3]. MS has often nonspecific initial symptoms; however, typically, MS is presented by sensory, motor and visual dysfunctions. MS is usually diagnosed by demonstrating evidence of clinical and/or radiographic dissemination of the disease in time and space[4,5]. The typical MS plaques appear in magnetic resonance imaging of the brain (MRI) as multiple periventricular homogenous ovoid lesions ranged in size from 3 to 16 mm, often oriented perpendicular to the long axis of the ventricular system and have no mass effect. Other locations include the optic nerves, corpus callosum, centrum semiovale, pons, cerebellar peduncles or hemispheres, brainstem and spinal cord[5]. Nearly 85% of cases with MS develop relapsing-remitting MS (RRMS) course in which relapses usually occur on average once every other year. Nearly 50%-90% of cases with RRMS develop secondary progressive MS within 10-25 years, 10% develop primary progressive MS and 5% develop acute attacks on top of steadily progressive neurologic decline[6]. Pharmacologic treatment of MS include immunosuppressants and immunomodulators[7].

Some cases of MS may pose a diagnostic difficulty due to atypical clinical and neuroimaging manifestations which mimic other fulminant central nervous system (CNS) conditions as inflammatory/infective conditions and intracranial neoplastic and non-neoplastic space occupying lesions (SOLs).

This paper describes an adult woman who presented for the first time with mental confusion and rapid deterioration in different cognitive functions. She also had atypical imaging features.

CASE REPORT

At December 2009, a 25-year right handed woman was admitted to our department with a one month history of mental confusion and rapid cognitive deterioration without previous history of systemic infection or a stress-related factor. Her family reported that the patient was unable to do her daily home duties, neglected care for herself and her children and looked blind and had poverty of speech. She was referred by a neurologist who reported abnormal computed tomography (CT) of the brain with large multifocal hypodense lesions (Figure 1). On neurological evaluation upon admission, she looked apathetic, had mixed dysphasia and had marked diminution of visual acuity (hand movement) with bilateral dilated pupils which were less reactive to light and bilateral temporal pallor of the optic discs. She had normal motor and peripheral sensory examination and bilateral flexor planter responses. She had bilateral prolonged P100 component of the visual evoked potentials (VEPs) indicating demyelinating optic neuropathy (Figure 2). Conventional magnetic resonance imaging of the brain (MRI-brain) showed bilateral multiple subcortical superficial and deep white-matter large (≥ 3 cm) lesions in the frontal, parietal, temporal and occipital lobes which were hypointense in T1-weighted and hyperintense in T2-weighted and fluid-attenuated inversion recovery (FLAIR) images with minimal perifocal edema and mass effect in spite of large sizes and bilaterally of the lesions. They demonstrated incomplete or patchy contrast enhancement with gadolinium (Figure 3). Spinal MRI was normal. The patient had normal routine laboratory blood testing which included complete blood count, blood sugar, serum electrolytes, liver and kidney function tests, erythrocytic sedimentation rate, rheumatoid factor, antinuclear antibodies and anti-double stranded DNA (anti-ds DNA) antibodies. The patient was given a diagnosis of tumefactive MS. After admission, she received 1 g daily intravenous methylprednisolone for 5 d. Oral prednisolone in a dose of 80 mg twice daily was given for 1 mo. As no clinical improvement was observed, another dose of pulse steroid therapy was given which was also followed by

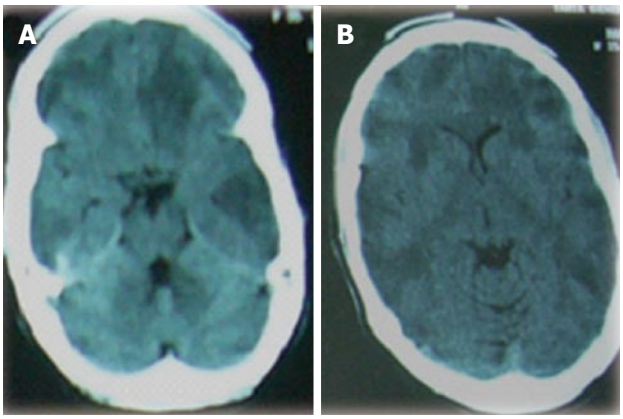

Figure 1 Cranial computed tomography brain showing axial views (A, B) with bilateral multifocal large hypodense lesions in the frontal, parietal, temporal and occipital lobes.

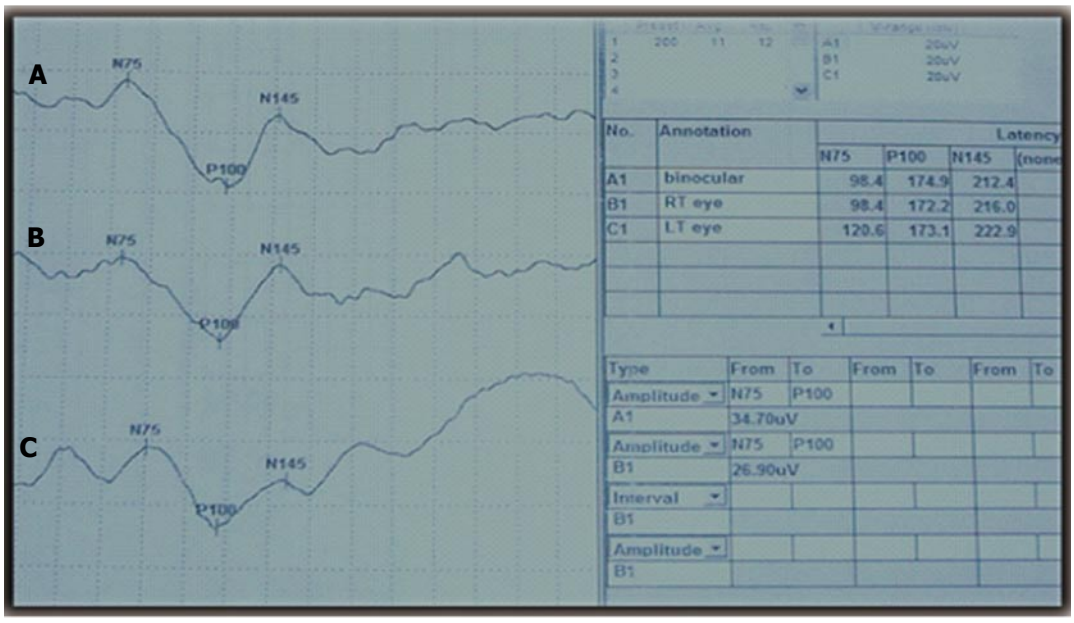

Figure 2 Visual evoked potentials showing prolonged absolute latencies of the P100 component of the right eye (A), left eye (B) and binocular (C).

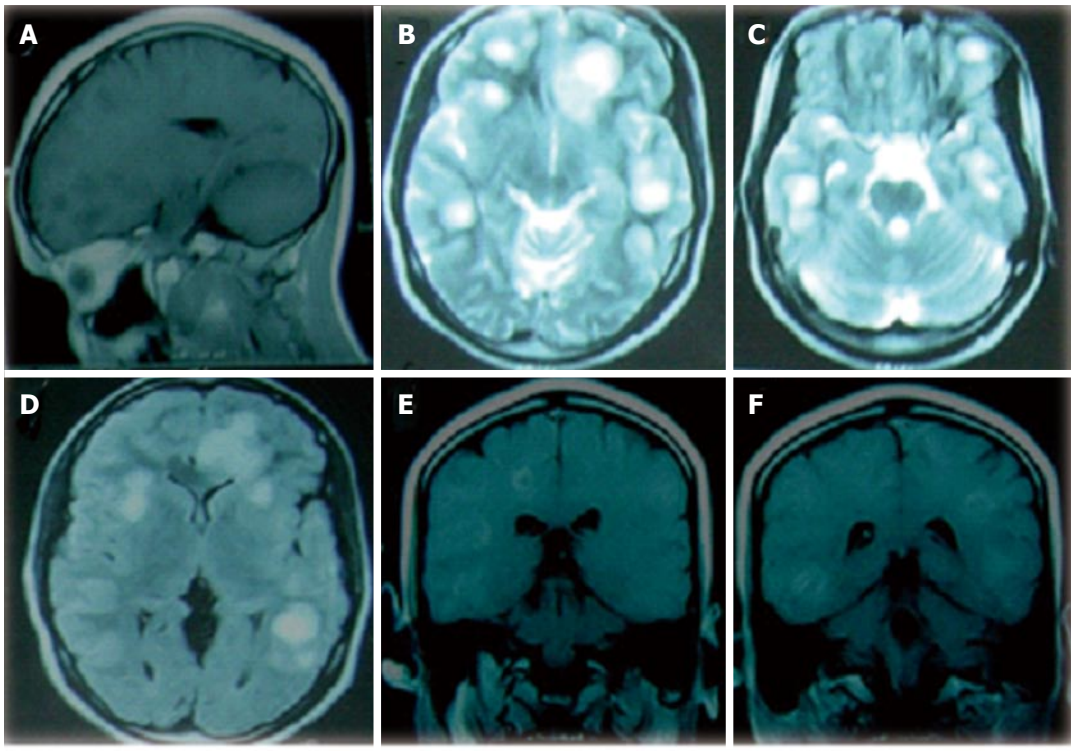

Figure 3 Cranial magnetic resonance imaging brain (on admission) showing (A) sagittal T1-weighted view with multiple hypointense lesions in the frontal and parietal regions, (B, C) axial T2-weighted images showing multifocal large hyperintense lesions in the frontal, parietal, temporal and occipital lobes, (D) axial fluid-attenuated inversion recovery-weighted image showing hyperintense lesions with minimal perifocal hypointense rim (edema), (E, F) coronal T1-weighted contrast enhanced views with patchy enhancement of the hypodense lesions in the temporal, parietal and frontal lobes bilaterally.

80 mg twice daily oral prednisolone. Near the end of the 3rd month of treatment, improvement started with rapid regression of patients symptoms in the form of improvement of cognition and vision, after which the patients was discharged from the hospital (March 2010). Clinical and MRI follow ups were done every 3 mo. We observed lack of significant MRI improvement in spite of the clinical improvement (Mini Mental State Examination = 30/30) after 6 mo from the onset of the condition (Figure 4). The patient was informed that she is in need for a disease modifying therapy to optimize therapy and prevent relapses (as IFNβ-1a/b, glatiramer acetate, mitoxantrone and natalizumab which are available in our country) but she refused due to the

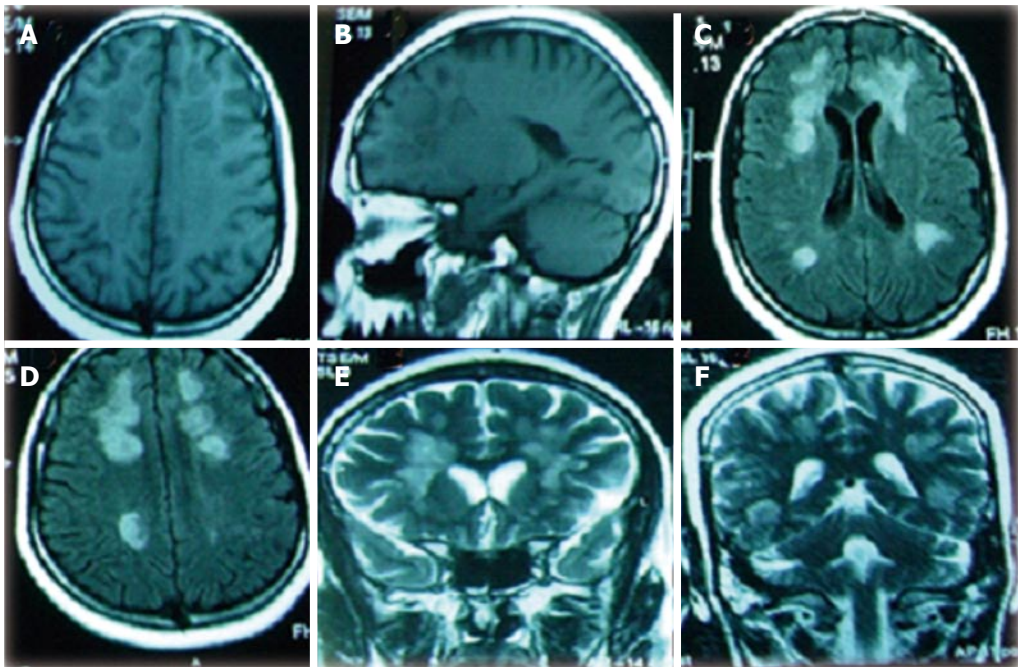

Figure 4 Cranial magnetic resonance imaging brain (after 6 mo of follow up) showing (A, B) axial and sagittal T1-weighted views with multiple hypointense lesions in the frontal, parietal, temporal and occipital regions, (C, D) axial fluid-attenuated inversion recovery-weighted images showing multifocal hyperintense lesions, (E, F) coronal T2-weighted images showing multifocal bilateral hyperintense lesions.

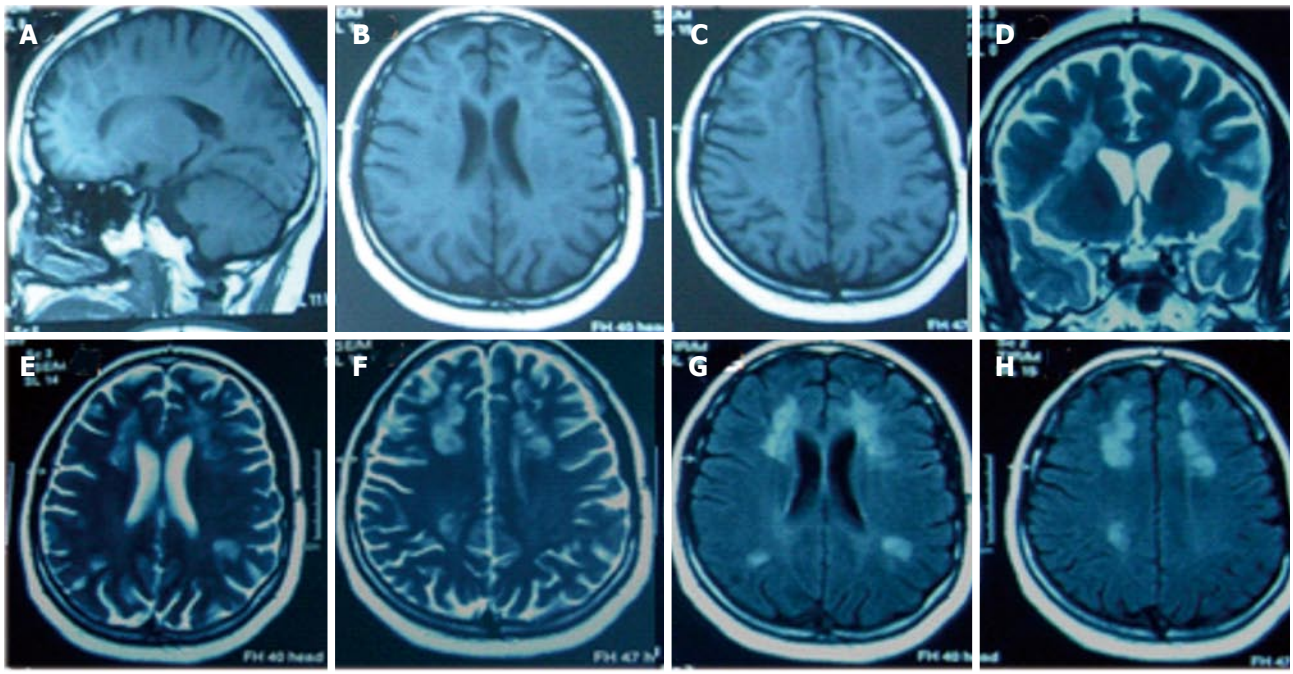

Figure 5 Cranial magnetic resonance imaging brain (after one year of follow up) showing (A, B, C) sagittal and axial T1-weighted views with bilateral multiple hypointense lesions in the frontal, parietal, temporal and occipital regions, (D, E, F) coronal and axial T2-weighted images showing multifocal bilateral hyperintense lesions, (G, H) axial fluid-attenuated inversion recovery-weighted images showing multifocal hyperintense lesions. In all views, lesions had reduced sizes compared to those at 6 mo follow up.

low socioeconomic status and she had no insurance to cover the cost of such expensive course of treatment. Significant reduction of the sizes of the MRI lesions was observed after one year of onset of the condition (Figure 5). Neither clinical relapse nor new MRI lesions were observed throughout the following 4 years of follow up.

The protocol of the study was approved by the local ethical committee of Assiut University Hospital which was in accordance of the principles of Helsinki and informed consent was obtained from the patient to publish her detailed clinical, laboratory and imaging data.

DISCUSSION

For our patient, tumefactive MS (or a tumor like demyelination) was established as diagnosis. Tumefactive MS is one of the atypical clinical and radiological presentations or variants described in adults with MS. It nearly represents 7% of cases with MS[8]. These variants are collectively named central nervous system inflammatory demyelinating diseases (CNS IDD) and include tumefactive MS[8-14], acute disseminated encephalomyelitis (ADEM)[15,16], Marburg's MS[17], Balo Disease (or Balo concentric sclerosis)[18] and Devic's disease or neuromyelitis optica[19]. In general, these variants have monophasic presentations and commonly aggressive or fulminant clinical course and do not show dissemination in time and space which is a typical feature for MS. Most commonly, these atypical aggressive attacks of variants of MS may present as the first demyelinating event in the course of MS. The management of these variants often prompts hospital admission and intensive care monitoring.

The diagnosis of tumefactive MS was done based on the acute onset (developed over days or weeks) of the condition, the predominance of cognitive impairment[8-14], the radiological evidence of multiple bilateral large rounded white matter lesions, absence of cortical involvement, absence of mass effect[9], patchy enhancement with gadolinium[14], regression with corticosteroids and lack of MRI evidence of new lesions on follow ups[8]. The severe cognitive impairment was due to great burden imposed by the large bilateral multifocal brain lesions. This also could explain the presence of aphasia and/or agnosia and/or apraxia (bilateral superficial and deep subcortical lesions). The marked diminution of vision in the patient was due to the presence of demyelinating optic neuropathy as evidenced by the VEPs, however, the possibility of the presence of field defects due to the involvement of the optic radiations in the temporal, parietal and occipital lobes of the cerebral hemispheres could not be excluded as additional cause of diminution of vision although visual field was not tested due to marked cognitive impairment. The enhanced lesions represented the areas of active inflammation, while the unenhanced lesions represented the chronic phase of the inflammatory process[20].

In general, tumefactive MS represents 1-2/1000 of cases of MS[21] with high frequency in adult females[14]. It is defined by the presence of single (frequent) or multiple large sized brain masses ($\geqslant$ 2.0 cm in diameter)[9], associated with perilesional edema and mass effect[14]. The common clinical presentations of tumefactive MS include headache, cognitive abnormalities, mental confusion, impaired consciousness, aphasia, apraxia, cerebellar symptoms, visual field defects and/or seizures. With contrast, tumefactive demyelinating lesions usually appear as open-ring (directed toward the cortical surface or to the basal ganglia) or closed rings[14,20] or have diffuse, homogeneous, punctate, or concentric enhancement[14]. The CSF may have high levels of immunoglobulin G (IgG) index and oligoclonal bands. CSF may also be normal in fulminant conditions and short duration of the disease[22]. Abnormal visual (VEPs) and somatosensory-evoked potentials may present in 33%-60% of cases with tumefactive MS[14]. Acute treatments of tumefactive MS include intravenous methylprednisolone and/or plasma exchange, rituximab and natalizumab followed by immunomodulatory agents[12,23,24]. The prognosis and course of tumefactive MS remain controversial. Some studies reported clinical and radiological improvement of tumefactive demyelinating lesions with no future development of typical recurrent relapsing MS[8]. In contrast, few reported development of clinically definite MD[14,25,26].

The differential diagnosis related to the presented case may include: (1) other variants of MS as ADEM, Marburg's MS and Balo concentric sclerosis; (2) CNS vasculitis; (3) intracranial infection/abscess or granuloma as tuberculoma; and (4) intracranial neoplastic SOLs as multifocal glioma, metastasis and primary CNS lymphoma (PCNSL).

ADEM is an acute multifocal monophasic inflammatory demyelinating disorder of the brain and spinal cord which should not progress beyond 3 mo. Although ADEM often occurs in the pediatric population, however adult cases have been reported. ADEM is often preceded by viral upper respiratory tract infection. ADEM is typically presented by encephalopathy. Other features may include vomiting, fever, headache, motor, sensory, and cerebellar symptoms, optic neuritis, seizures and aphasia[15,16]. Characteristic MRI features of ADEM include multifocal and diffuse hyperintense lesions in the gray and white matter of the brain and spinal cord in T2-weighted and FLAIR images and have no gadolinium enhancement[15,27]. Marburg's MS is a very rare form of atypical MS which rapidly progress and often leads to rapid disability followed by death[17]. It is caused by the severe axonal loss. Balo concentric sclerosis is a rare and rapidly progressive variant of MS. It usually first appears in adulthood. Symptoms may progress rapidly over several weeks or more slowly over 2-3 years. Symptoms may include headache, seizures, gradual paralysis, involuntary muscle spasms , and cognitive loss. Balo concentric disease is so named because of the pattern of concentric layers formed by the damaged myelin tissues. Some patients have been known to spontaneously recover from this disease[18]. CNS vasculitis is inflammatory disease of the blood vessels of the brain or spinal cord. It is often secondary to connective tissue diseases or systemic autoimmune diseases as systemic lupus erythematosis (SLE), polyarteritis nodosa and rheumatoid arthritis and Behçet's syndrome[28,29], but it can occur without associated systemic disease. Symptoms of CNS vasculitis may include headache, delirium, disorientation, forgetfulness

or confusion, recurrent focal or generalized seizures, aphasia, apraxia, motor and sensory abnormalities, gait disorder, optic atrophy and encephalopathy. The MRI brain picture consistent with vasculitis include multiple ischemic brain lesions which appear as periventricular hyperintense dot-like areas in T2-weighted, FLAIR- and diffusion-weighted MRI imaging, multiple subcortical white matter hyperintense lesions in the frontal, temporal, parietal and occipital lobes, and abnormal enhancement of the leptomeninges. Magnetic resonance angiography may show string-of-beads stenosis of the carotid and vertebro-basilar arteries. Treatment of CNS vasculitis include immunotherapy as methylprednisolone, methotrexate, cyclophosphamide and intravenous immunoglobulins (IVIGs)[30]. Patients with intracranial infection/abscess/granulomas commonly have history of risk factors as immunocompromised state, dental abscess, pulmonary abscess, intravenous drug use, etc. Fever and abnormal labs (as high erythrocytic sedimentation rate or C-reactive protein) are clues for presence of infection. Presentation is usually of acute onset and secondary to symptoms of increased intracranial pressure (ICP), and seizures and focal neurological deficits are common. MRI-brain usually show ring enhancement which is often complete with regular margin[31]. Intracranial tuberculomas are relatively common in developing countries. It represents about 10%-30% of all intracranial masses of cases of infective intracranial SOLs. Seizures and focal neurological deficits are common clinical presentations. Systemic tuberculosis may be absent in up to 70% of cases. MRI-brain may show multiple intracranial enhancing SOLs particularly ring enhancement or target sign[32]. Intracranial neoplastic SOLs which mimic tumefactive MS include multifocal glioma, metastasis and PCNSL. Multifocal glioma usually presents insidiously with progressive neurologic deficit. Seizures are the common presentation in nearly one fourth of the patients of supratentorial lesions. Increased ICP is the common presentation of posterior fossa lesions[33]. Nearly fifteen percent of cases with cerebral metastasis have no previously known cancer. The primary cancers commonly involve the lung, breast, kidney, and gastrointestinal tract. Increased ICP, seizures and focal neurological deficits are common presenting manifestations[34]. PCNSL is a rare brain tumor that comprises only 1% of all intracranial neoplasms. Nearly 80% of cases of PCNSL have single supratentorial lesions. In one-third of the cases, PCNSL lesions are located deeply in the white matter while 10% are present in the posterior fossa. PCNSL is characterized by varied nonspecific neurologic deficits. The most common and early presenting manifestations are mental change, somnolence and paresis. Nearly 90% of cases with PCNSL have hyperdense or isodense lesions in CT brains and hypointense or isointense in T1-weighted MRI images. Only 40% have hyperintense lesions in T2-wighted images with mild edema and mass effect. Ring enhancement is more frequent in solitary lesions but meningeal enhancements is rare[35].

The atypical clinical and radiological presentations of MS may sometimes pose a considerable diagnostic difficulty. However and in spite of the aggressive course of its tumefactive variant, good prognosis may be seen in some patients.

ACKNOWLEDGMENTS

I would like to thank the patient and her mother for their approval to publish the results of this case presentation.

COMMENTS

Case characteristics

A 25-year-old woman with history of acute dementia and blindness.

Clinical diagnosis

The patient had marked cognitive impairment, dysphasia, reduction in visual acuity and temporal pallor of the optic discs.

Differential diagnosis

Other variants of multiple sclerosis (MS) as ADEM, Marburg's MS and Balo concentric sclerosis; central nervous system (CNS) vasculitis; intracranial infection/abscess/granuloma and neoplastic lesions as primary CNS lymphoma.

Imaging diagnosis

Magnetic resonance imaging-brain showed multifocal large ($\geqslant$ 3 cm) white-matter hypointense lesions in T1W and hyperintense in T2W and fluid-attenuated inversion recovery images and patchy enhancement.

Pathological diagnosis

A demyelinating disease.

Treatment

Intravenous methylprednisolone in a dose of 1 g/d for 5 d was administered for two consecutive months followed by oral prednisolone in a dose of 80 mg twice daily was given for 1 mo. As no clinical improvement was observed, another dose of pulse steroid therapy was given which was also followed by 80 mg twice daily oral prednisolone for 9 mo followed by tapering of the steroid dose over the next year.

Related reports

Usually acute treatments of tumefactive MS include intravenous methylprednisolone and/or plasma exchange, galatiramer acetate, mitoxantrone and natalizumab followed by immunomodulatory agents as IFNβ-1a/b.

Term explanation

MS is a chronic immunologic disease in which inflammation, demyelination and axonal damage are the main pathologic features.

Experiences and lessons

In this case report, in spite of the fulminant presentation, good prognosis was seen with corticosteroids.

Peer-review

Interesting article on the scientific and practical level, text is well wrote and easily comprehensible with clear figures.

Abstract

A 75-year-old male presented with difficult defecation and increasing urinary frequency over a few months. He had a significant history of previous partial gastrectomy for gastric carcinoma 20 years prior. Computed tomography of the abdomen and pelvis showed extensive lymphadenopathy, a gastric mass and rectal as well as bladder wall thickening with bilateral ureterohydronephrosis. Normal looking serosal surfaces of the bladder and bowel were seen on laparoscopy and a defunctioning ileostomy was created. Gastroscopy revealed a malignant mass while cystoscopy and sigmoidscopy found extensive tumour growth lining the mucosal surfaces. Biopsies from all sites were compatible with intestinal type adenocarcinoma of gastric origin with few signet ring cells. Metabolic response to palliative chemotherapy was good and the patient's symptoms have improved on follow-up four months post ileostomy. We discuss the immunohistochemical profile of the tumour and review the literature.

Key words: Gastric adenocarcinoma; Intestinal-type; Metastasis; Colorectum; Bladder

Core tip: Although exceedingly rare, metastases to the colorectum and bladder can occur with primary gastric adenocarcinoma. Unusual sites of spread are more often associated with diffuse type or signet ring cell gastric carcinoma but can occur with intestinal type as well. Site specific symptoms should alert the clinician to the possible locations of spread so as to allow prompt diagnosis. CK7 and CK20 profiles may help to establish the origin of the metastatic tumour if in doubt.

Seow-En I, Seow-Choen F. Intestinal type gastric adenocarcinoma with unusual synchronous metastases to the colorectum and bladder. *World J Clin Cases* 2015; 3(6): 533-537 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/533.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.533

INTRODUCTION

Gastric adenocarcinoma commonly spreads to the peritoneum, liver, lungs and intra-abdominal lymph nodes. Multiple as well as unusual sites of metastases have been described more often with diffuse type or signet ring cell gastric cancer. We describe the first case of intestinal type gastric adenocarcinoma with few signet ring cells presenting with synchronous colorectal and vesical metastases. Laparoscopic findings were also unusual as the serosal surfaces looked grossly normal but extensive intraluminal masses were found on endoscopy. Metabolic response to palliative chemotherapy was good and the patient's symptoms have improved on follow-up four months post defunctioning ileostomy.

CASE REPORT

A 75-year-old Indonesian male presented to our clinic with the complaints of difficult defaecation and increasing frequency of micturition for a few months' duration. He had a history of previous partial gastrectomy for gastric cancer in Indonesia more than 20 years prior. Full histology from the initial surgery was unavailable. Abdominal examination was unremarkable apart from mild abdominal distension. On rectal examination, extra-anal nodular masses were felt causing tight stricturing of the anal canal extending proximally. The anal mucosa felt intact.

Serum CEA and CA 19-9 were markedly elevated at 31.6 μg/L (normal 0-5 μg/L) and 30523 U/mL (normal 0-37 U/mL) respectively. AFP level was normal. Contrast enhanced computed tomography of the abdomen and pelvis revealed extensive retroperitoneal lymphadenopathy including para-aortic and aortocaval nodes as well as bilateral iliac lymphadenopathy. In addition a gastric mass was suspected. Rectal wall thickening causing luminal constriction and bladder wall thickening with bilateral ureterohydronephrosis were noted. The liver appeared normal.

During diagnostic laparoscopy, the transverse colon down to the visualised rectum was found to be thickened and rigid. The bladder appeared normal externally (Figure 1) but was thickened with intravesical masses palpable *via* laparoscopic manipulation. The appendices epiploicae of the transverse colon and the median umbilical ligament also appeared thickened (Figure 1) and biopsies were taken from both sites. Moderate greenish ascites was noted. No peritoneal or serosal nodules were seen and the small intestine and stomach were grossly unremarkable on laparoscopy. The previous gastrojejunostomy anastamosis site looked normal. A defunctioning ileostomy was created to alleviate intestinal obstruction.

As no definite intra-abdominal masses were found on laparoscopy, oesophago-gastroduodenoscopy (OGD) and sigmoidoscopy were performed at the same sitting. OGD showed a mass at the lesser curve of the stomach and sigmoidoscopy revealed anal stricturing and extensive tumour lining the rectal mucosa (Figure 1). The scope was unable to pass beyond 8 cm from the anal verge due to the tight intraluminal growths. A cystoscopy was done which showed the entire bladder mucosa to be covered by mucosal tumour growth.

Biopsies from all sites including the gastric, rectal and bladder tumours as well as the appendices epiploicae and median umbilical ligament were compatible with adenocarcinoma of gastric origin (Figure 2). This was of intestinal type based on both the Lauren as well as world health organization (WHO) classification. In view of the length of time between the patients's initial gastric tumour and the current primary lesion occurring in the remnant stomach it was not felt to be a recurrence. Immunohistochemical studies revealed the tumour cells to be positive for CK7, CK19 and CDX2 while negative for CK20 and CK5 (Figure 3). Mucicarmine staining showed intracytoplasmic mucin positivity in only few tumour cells (Figure 4). Uroplakin and HER2/neu were negative. *KRAS* and *BRAF* gene mutations were not detected. No features of a second primary tumour were found.

F-18 fluorodeoxyglucose positron emission tomography coupled with a multi-slice low-dose computed tomography scan (FDG PET/CT) was performed with FDG uptake at the site of gastric tumour and retroperitoneal lymph nodes. Additionally, hypermetabolic para-oesophageal, anterior mediastinal, paratracheal and left supraclavicular lymph nodes were seen. There were also foci of increased FDG uptake in the T2 and T3 vertebrae consistent with bone metastasis. There was no significant FDG uptake seen in the liver.

The patient underwent initial chemotherapy with 5-FU and bevacizumab. Three further cycles of chemotherapy was given using 5-FU, bevacizumab and oxaliplatin with paclitaxel added to the second cycle.

FDG PET/CT prior to the third cycle showed good metabolic response with interval decreased FDG uptake in the stomach. Previously noted FDG avid nodes in the neck, thorax, abdomen and pelvis all showed interval resolution, metabolic resolution or decreased uptake. Interval resolution was also observed in T2 and T3 vertebrae. Serum CA 19-9 also came down to 3900 U/mL.

The patient showed clinical improvement with resolution of urinary symptoms and decrease in abdominal distension with good ileostomy output 4 mo from surgery at the time of writing. He has been on regular follow-up and is planned for further chemotherapy.

DISCUSSION

Gastric adenocarcinoma is the fourth most common cancer worldwide, accounting for 8% of the 12.7 million new cases of cancer diagnosed in 2008[1]. More than 50% of these patients present with unresectable locally

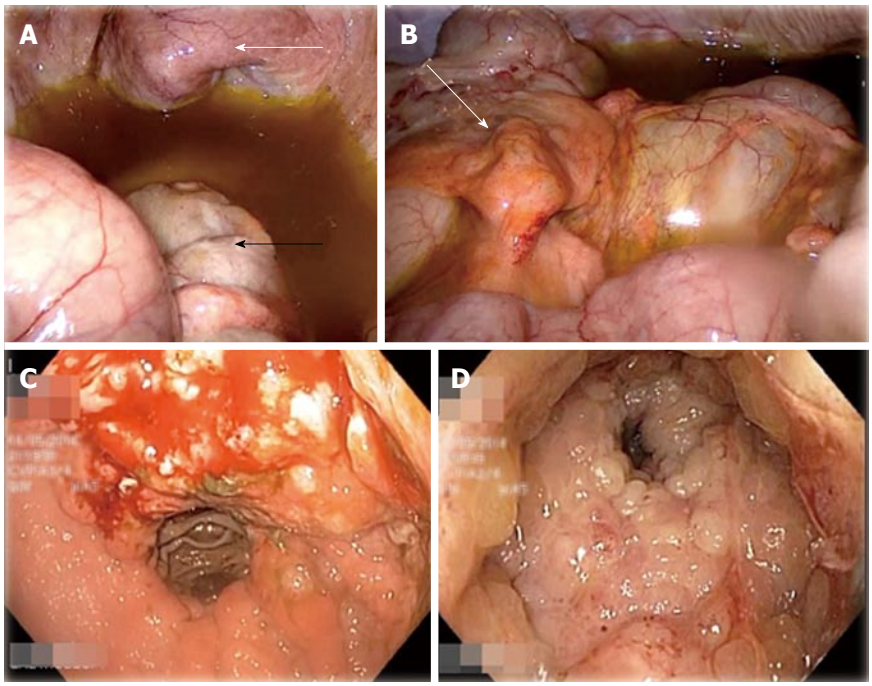

Figure 1 Laparoscopy examination. A: Laparoscopic view of the pelvic organs; Bladder (white arrow) and rectum (black arrow) look grossly normal. Moderate amount of greenish ascites seen; B: Transverse colon serosa normal looking except for thickened appendices epiploicae (white arrow); C: Gastric tumour seen at lesser curve on EGD; D: Extensive circumferential rectal mucosal tumour with luminal narrowing.

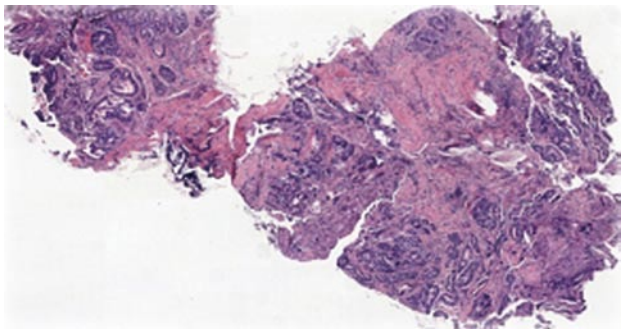

Figure 2 Gastric biopsy showing intestinal type gastric adenocarcinoma.

advanced or metastatic cancer[2], and out of those resected with curative intent, 40%-65% of cancers will recur[3]. Seventy-nine percent of recurrences occur within the first 2 years of resection, 94% within 4 years and rarely after[4].

Patterns of gastric metastasis have been well studied. The most common sites of metastasis include the liver due to portal drainage, the lungs due to lymphatic drainage, the peritoneum, and the intra-abdominal lymph nodes. Reports of spread to colonic or bladder mucosa have been rare in literature. 39 cases of gastric linitis plastica with metastases to the colon were described from 1936 to 1989; the bladder was involved in three cases[5]. To our knowledge, only four cases of gastric cancer with colorectal metastases[6-9] and five cases with vesical metastases[10-13] were described in the English language literature in the past 10 years. No other reports of concomitant colorectal and vesical metastases were found.

Six out of these nine recent cases of gastric adenocarcinoma with colorectal or vesical metastases were poorly differentiated diffuse type based on the Lauren classification with predominant signet ring cells. Two of the remaining cases were well differentiated intestinal type[6,10], while the last was an undifferentiated type with signet ring and intestinal differentiation[8]. Diffuse type adenocarcinoma have been shown to have an increased propensity for disseminated spread to multiple organs, in particular to the peritoneum, while intestinal type carcinoma more frequently spreads to the liver. Frequency of abdominal lymph node involvement was similar for both types[14]. In a 2001 radiological study of 23 patients with intestinal metastases from gastric adenocarcinoma, 70% were linitis plastica and 74% were poorly differentiated or signet ring cell type[15]. It is clear that an association exists between linitis plastica/diffuse type or signet ring type histology and unusual sites of metastases.

This report is the first described with synchronous colorectal and vesical metastases from intestinal type gastric adenocarcinoma. Few signet ring cells were present in the histological specimens and less than the required 50% to be labelled as signet ring carcinoma as per the WHO classification. This case was also unusual as the rectal and bladder metastases were only obvious intraluminally and initially suggestive of *de novo* carcinoma. While the serosal biopsies were positive for cancer, no obvious masses were visible on the serosal aspect during laparoscopy.

Immunohistochemical analysis can be useful in establishing location of the primary tumour if in doubt. In this case the $CK7^{+}/CK20^{-}$ profile of the tumour was

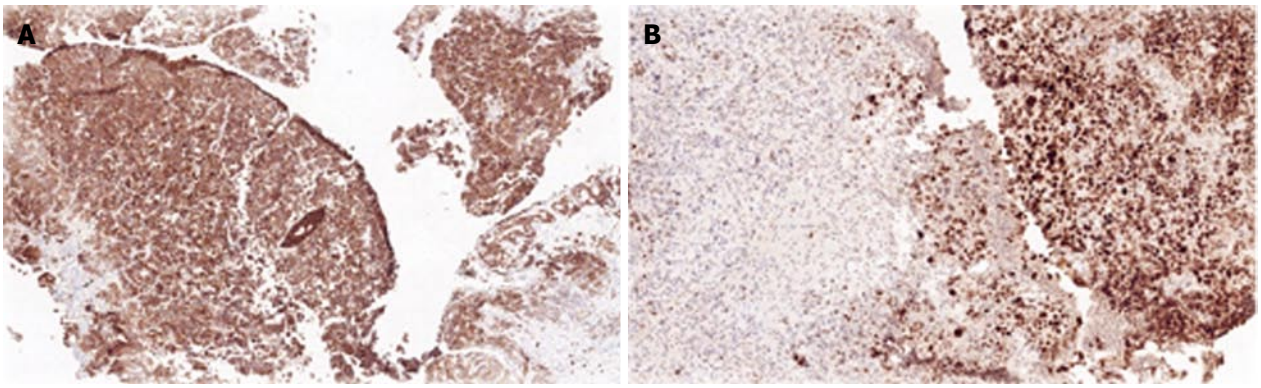

Figure 3 CK7 with strong cytoplasmic positivity (A) and CDX2 with diffuse and strong nuclear positivity (B).

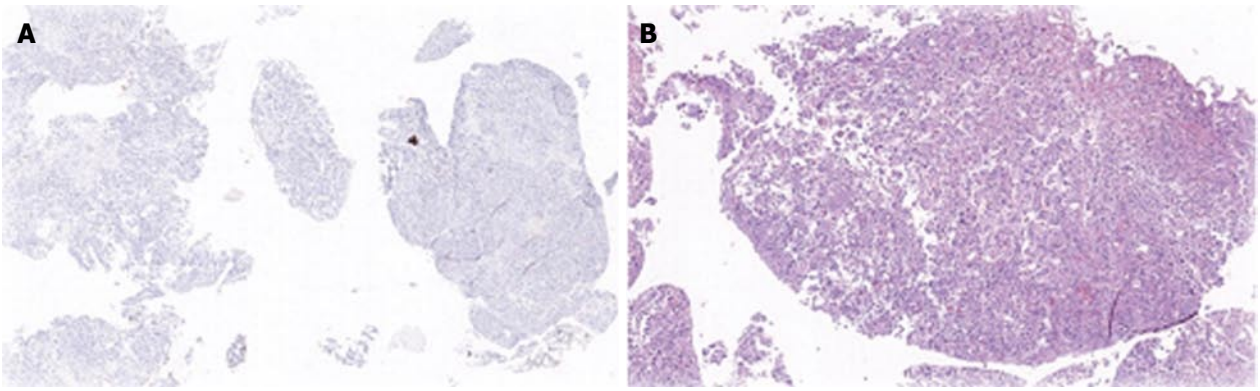

Figure 4 CK20 negative (A) and few signet ring cells seen with mucicarmine staining (B).

indicative of a primary gastric carcinoma as opposed to a colorectal origin, with more than 90% of rectal primaries expressing CK20[16]. CDX2 is a sensitive and specific marker for adenocarcinoma of the gastrointestinal tract, and is associated with both gastric intestinal metaplasia and intestinal type gastric carcinoma. CDX2 positive gastric adenocarcinoma have been demonstrated to have better outcomes and prognosis as compared to CDX2 negative tumours[17]. A $CK7^{+}/CK20^{-}/CDX2^{+}$ profile was compatible with adenocarcinoma of pancreaticobiliary origin as well; this was ruled out by PET/CT.

In conclusion, albeit very rare, colorectal and vesical metastases can occur from a primary gastric adenocarcinoma. Although previously more significantly associated with linitis plastica, diffuse type or signet ring cell carcinoma, multiple sites of metastases to unusual locations can also occur with intestinal differentiation. Further studies can be done to shed light on the mechanism of such spread and may likely be derived only from analyses of isolated case reports. Site specific symptoms should alert the clinician to the possible locations of spread so as to allow prompt diagnosis and appropriate treatment.

COMMENTS

Case characteristics

A 75-year-old male presented with difficult defecation and increasing urinary frequency over a few months.

Clinical diagnosis

Rectal examination revealed nodular masses causing tight stricturing of the anal canal while endoscopy showed a gastric mass and intravesical tumour growth.

Differential diagnosis

Metastatic gastric adenocarcinoma *vs de novo* rectal or bladder carcinoma.

Laboratory diagnosis

Serum CEA and CA 19-9 were markedly elevated at 31.6 μg/L (normal 0-5 μg/L) and 30523 U/mL (normal 0-37 U/mL) respectively.

Imaging diagnosis

Computed tomography showed a gastric mass, rectal and bladder thickening as well as extensive lymphadenopathy.

Pathological diagnosis

Histological analyses of all biopsy specimens were compatible with metastatic gastric adenocarcinoma of intestinal type differentiation based on Lauren classification.

Treatment

A defunctioning ileostomy was performed to relieve impending obstruction and the patient underwent palliative chemotherapy with good response.

Related reports

Incidences in literature of colorectal or bladder metastases from a primary gastric adenocarcinoma are rare. Most reported cases are associated with diffuse type adenocarcinoma or linitis plastica rather than intestinal type.

Term explanation

Cytokeratins are intermediate filament proteins found in normal epithelium, which have preserved expression in neoplastic cells. This allows the detection of specific cytokeratins to be useful tools in determining the origin of metastatic carcinoma.

Experiences and lessons

Multiple sites of metastases to unusual locations can occur with intestinal type gastric adenocarcinoma and site specific symptoms should alert the clinician to

the possible locations of spread.

Peer-review

It is a very unsual case of gastric Ca. with long time distal relapse in colon, bladder and huge abdominal lymph nodes. Specially remarkable is that primary tumor ocurred 20 year ago.

Abstract

Primary adenocarcinoma of the appendix is a rare malignancythat constitutes < 0.5% of all gastrointestinalneoplasms. Moreover, primary signet ring cell carcinomaof the appendix is an exceedingly rare entity. In the present report, we describe a rare case of primary signet ring cell carcinoma of the appendix with ovarian metastasesand unresectable peritoneal dissemination occurring in a 45-year-old female patient. She was clinically misdiagnosed as torsion of ovarian cyst. She underwent appendicectomy and unilateral salpingo-oophorectomy.Histopathology revealed signet ring cell carcinoma and a right hemicolectomy was done. She then received palliative systemic chemotherapy with 12 cycles of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX-4). The patient is doing well till today on follow up without progression of disease 10 mo after beginning chemotherapy.

Key words: Appendix; Primary; Signet ring cell carcinoma; Ovarian metastasis

Core tip: Meticulous histopathological evaluation along with clinical correlation is strongly recommended in such unusual circumstances. The clinician and surgical pathologist should keep in mind this rare entity as a differential diagnosis.

Kulkarni RV, Ingle SB, Siddiqui S. Primary signet ring cell carcinoma of the appendix: A rare case report. *World J Clin Cases* 2015; 3(6): 538-541 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i6/538.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i6.538

INTRODUCTION

Primary adenocarcinoma of the appendix, first invented in 1882, and constitutes 0.12 cases per one million

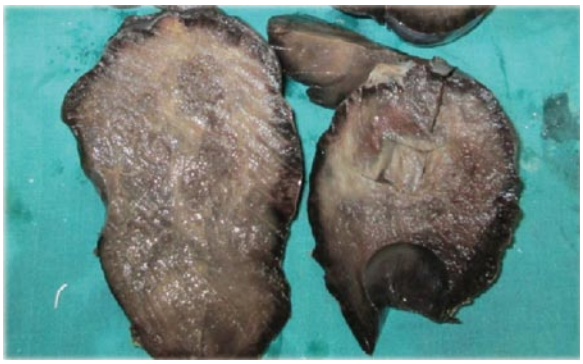

Figure 1 Showing twisted ovarian cyst.

Figure 2 Showing appendix.

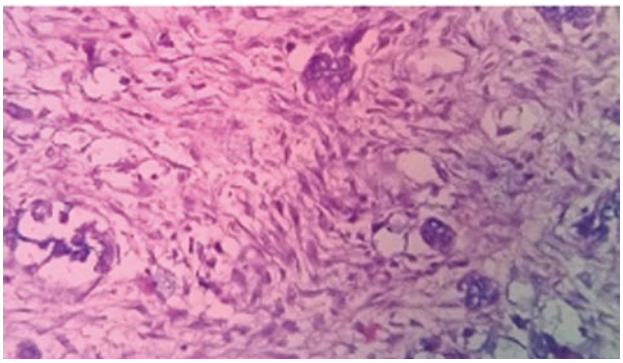

Figure 3 Signet ring cells in left ovary.

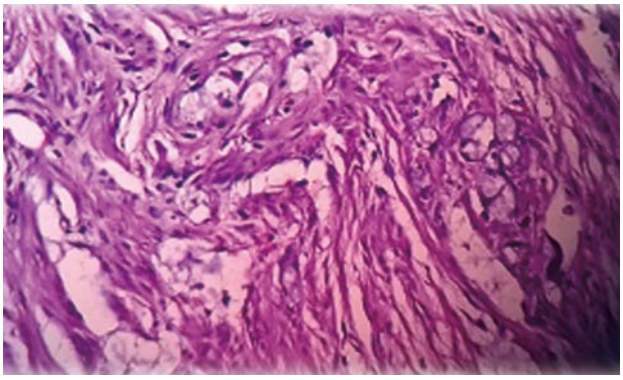

Figure 4 Showing signet ring cells in the appendix.

people per year[1]. Primary signet ring cell carcinoma is an extremely unusual event in surgical practice[2]. Clinically it simulates acute appendicitis and difficult to distinguish from it[3,4]. So, it is a difficult task to diagnose it on clinical grounds. Usually the diagnosis is confirmed on histopathology of a surgically-removed inflamed appendix[5].

CASE REPORT

A 46-year-old female admitted in YCR Hospital Latur with persistent right lower quadrant abdominal pain. Baseline blood tests showed neutrophilic leukocytosis. Per abdominal examination revealed right abdominal distension. The patient was misdiagnosed as twisted ovarian cyst and emergency laparotomy was planned and performed. At laparotomy, the appendix appeared severely inflamed so the patient underwent an appendectomy and unilateral salphingo-oopherectomy. On gross examination, left large encapsulated, dark brown and smooth ovarian mass measuring 16 cm × 13 cm × 9.5 cm was found. The cut surface showed large hematoma with grey white visible areas. Attached fallopian tube measured 5 cm in length (Figure 1).

Appendix measured 6 cm in length. External surface was thickened and congested. Cut section showed obliterated lumen filled with gelatinous material (Figure 2). Microscopic examination of both left ovarian mass revealed signet ring cells showing an intracellular mucin to vacuolated cytoplasm shifting the nuclei towards periphery (Figure 3). Some extracellular mucin was seen infiltrating the stroma.Large areas of hemorrhage and necrosis are noted. In appendix the signet ring cells and extracellular mucin was seen invading the mucosa, submucosa and muscularis propia (Figure 4). Thus the case was finally diagnosed as infiltrating adenocarcinoma of the appendix with "signet ring cells" differentiation, with signs of infiltration of peri-appendicular fat. The tumor cells were immunopositive for CEA, cytokeratin 20 (Figure 5), MUC2, and CDX-2 (Figure 6). The patient underwent colonoscopy for the evaluation of synchronous disease, which was negative. Later computed tomography (CT) scan was done and an 8 cm × 5 cm lesion in right adnexal region was noted so the patient subsequently underwent right hemicolectomy with total abdominal hysterectomy and unilateral salphingo-oopherectomy and no residual carcinoma with negative lymph nodes was found.

DISCUSSION

Appendiceal adenocarcinoma is an unusual malignancy[1]. The reported prevalence rate is 0.3%[6]. Signet ring carcinoma constitutes only 4% of all neoplasms of appendix[2]. Malignant carcinoids are mainly found in younger age group (mean age, 38 years)[1]. The mean age of occurrence of mucinous adenocarcinoma is 60 years, while that of signet ring cell carcinoma is 62 years with male: female ratio 1:1[1].

According to International Classification of Diseases

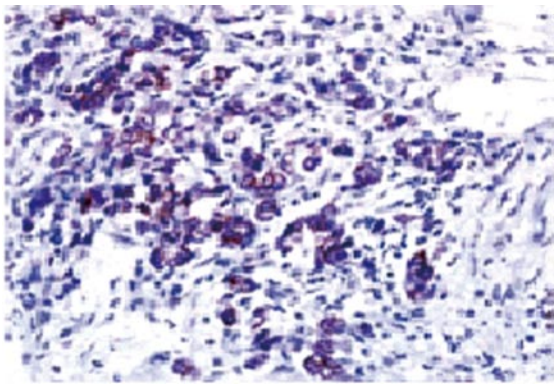

Figure 5 CK20 positive tumor cells.

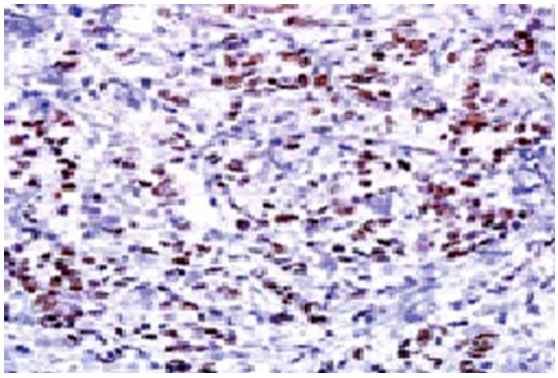

Figure 6 Presentations of CDX positivity by tumor cells.

for Oncology appendiceal tumors are divided in to five classes: Mucinous adenocarcinoma, colonic type adenocarcinoma, goblet cell carcinoma, signet ring cell carcinoma and malignant carcinoid/adenocarcinoid[1,7]. Adenomas are the premalignant lesions[8,9]. The signet ring cell carcinomas are usually frequent in the stomach and intestine. In our case, the tumor cells were immunopositive for cytokeratin 20, CDX-2, MUC-2, and CEA. The CDX-2 marker is the key to confirm the final diagnosis[10].

Most of them are clinically low-grade tumors with indolent behavior. The overall 5-year survival rate is 20.5%. As per previous workers except for signet ring cell carcinoma and malignant characinoid, the histopathological variant does not affect the survival rate[11]. In fact the extent of the disease at the time of diagnosis is an important determinant of prognosis of patient. As per previous studies, the prognosis of patients with diffuse, peritoneal metastases is worse, with a 5-year survival rate of 6.7%-14%[12,13]. However, according to some workers signet ring cell carcinoma and poorly differentiated adenocarcinoma of the appendix had high propensity for development of metastasis with a 5-year survival rate of only 7%. So, signet ring cell carcinoma is considered as a separate tumor type in the appendix in view of its poor prognosis. Right hemicolectomy is the treatment of choice for all microscopic types of appendiceal carcinoma, even in cases with perforation. In case of metastasis treatment modalities are systemic chemotherapy along with intraoperative intraperitoneal chemotherapy, peritonectomy and cytoreductive surgery[1,5].

To conclude, meticulous histopathological examination of appendix is mandatory during exploratory laparotomy for ovarian masses and for diagnostic procedure. Exclusion of signet ring cell carcinoma from other carcinoma subtypes is of particular importance as it has an extremely poor prognosis and is usually diagnosed in advanced stages.

COMMENTS

Case characteristics

A 45-year-old woman presented to the Emergency Department of YCR Hospital Latur with persistent right lower quadrant abdominal pain.

Clinical diagnosis

Clinically diagnosed as twisted ovarian cyst.

Differential diagnosis

Twisted ovarian cyst was the clinical differential diagnosis and signet ring carcinoma of either colon, stomach or appendix were the histological differential diagnosis.

Laboratory diagnosis

Primary signet ring carcinoma of appendix with secondaries in the ovaries.

Imaging diagnosis

Computed tomography (CT) scan was done and an 8 cm × 5 cm lesion in right adnexal region was noted so the patient subsequently underwent right hemicolectomy with total abdominal hysterectomy and unilateral salphingo-oopherectomy.

Pathological diagnosis

Primary signet ring carcinoma of appendix with secondaries in the ovaries.

Treatment

Right hemicolectomy.She then received palliative systemic chemotherapy with 12 cycles of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX-4). The patient is doing well till today on follow up without progression of disease 10 mo after beginning chemotherapy.

Experiences and lessons

Meticulous histopathological examination of appendix is mandatory during exploratory laparotomy for ovarian masses and for diagnostic procedure.

Peer-review

The authors have performed a good study, the manuscript is interesting.

Abstract

The term phantom sensations (PS) refers to sensations in a missing body part. They are almost universal in amputees and can be both painful and not painful. Although PS have been frequently described in limb amputees, they can also occur in other clinical conditions and several pathophysiological interpretations have been proposed, with a predominance of theories based on a central origin. Actually, different mechanisms are able to create a phantom sensation. After an amputation, PS are frequently generated by the genesis of ectopic action potentials in the interrupted nerve fibers but the PS generator can also be more proximal. Sometimes PS are not created by the stimulation of somatosensory fibers with a missing territory, but they can be the result of central sensitization or neuroplastic changes that allow for the convergence of impulses coming from different body parts (referred sensations), one of which is missing. In conclusion, PS can be generated by both neuropathic and non-neuropathic mechanisms developed in the amputated body part or in other parts of the nervous system. Since these mechanisms are not pathognomonic of amputation there are no hidden ghosts to look for in phantom sensations. The only interpretative rule is just to follow the pathophysiological principles.

Key words: Phantom sensations; Phantom pain; Neuropathic pain; Referred pain; Pain pathophysiology

Core tip: The term phantom sensations (PS) refers to sensations in a missing body part. They are almost universal in amputees and can be both painful and not painful. Several pathophysiological interpretations have been proposed, with a predominance of theories based on a central origin. Actually, PS can be generated by both neuropathic (ectopic) and non-neuropathic (referred) mechanisms developed in the amputated body part or in other parts of the nervous system. Since these mechanisms are not pathognomonic of amputation there are no hidden ghosts to look for in phantom sensations. The only interpretative rule is just to follow the pathophysiological principles.

Buonocore M. Where is hidden the ghost in phantom sensations? *World J Clin Cases* 2015; 3(7): 542-544 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i7/542.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i7.542

The term phantom sensations (PS) refers to sensations in a missing body part, phenomena that obviously appear paradoxical (but also intriguing) for the most part of the people. A literary example is in the very famous book "Moby Dick, or the whale" (1851) by Herman Melville, who describes in a short sentence the PS of the Captain Achab who had a leg amputated by the whale: "here is only one distinct leg to the eye, yet two to the soul".

PS are almost universal in amputees and can be both painful and not painful[1-3]. More precisely, patients can describe their PS in several ways, according to the anatomical and pathophysiological characteristics of the amputation: burning[4], tingling[3] or painful[3] sensations, illusory limb movement[5], visual hallucinations[6], and so forth.

Although PS have been frequently described in limb amputees, they can also occur in other clinical conditions such as after orchiectomy[7], mastectomy[8], tooth' s root canal treatment[9], penis amputation[10], ocular evisceration or enucleation[6].

Several pathophysiological interpretations have been proposed for PS, with a predominance of theories based on a central origin, including psychiatric explanations[11]. Actually, different mechanisms (neuropathic or non-neuropathic) are able to create a phantom sensation in a missing body part.

It is largely accepted that any neuropathic mechanism is characterized by the ectopic generation of action potentials in somatosensory afferent fibers[12]. In amputees, neuropathic pain mechanisms of PS can be localized at the level of amputation or more proximally. Sometimes they are strictly linked to the amputation, sometimes not.

After an amputation, PS are frequently generated by the genesis of ectopic action potentials in the interrupted nerve fibers, as demonstrated by human microneurographic recordings[13].

Nevertheless, several studies suggested that the PS generator can be proximal to the amputation site. On a pathophysiological point of view, this is not at all strange. In physiology, it is well known that the direct (ectopic) stimulation of a sensory nerve fiber induces a sensation localized in the territory of the stimulated fiber, *i.e.*, in the body part where the receptors are located. When Penfield and Rasmussen described for the first time the sensory homunculus, they reported patients' sensations evoked in different body parts during the electrical stimulation of the somatosensory cortex[14]. All that considered, when the territory of the stimulated nerve fibers is missing, the adequate ectopic stimulation of somatosensory nerve fibers always creates a phantom sensation, wherever the stimulation is applied.

Several examples can be given. For instance, in a recent paper, selective peripheral nerve blockades suggested a major role played by dorsal root ganglia in the generation of PS in a group of amputees[15].

Very interesting is also the recently described case of a patient with an old hip disarticulation amputation due to a malignant sarcoma[16]. After 1.5 years from amputation, this patient started to complain a severe phantom limb pain, mainly localized at the right phantom thigh. Computed tomography and magnetic resonance imaging showed the presence of a metastatic spinal mass involving the L3 vertebra with stenosis of the right lateral recess. Importantly, the resection of the vertebral mass completely resolved the phantom limb pain, demonstrating that the pain generator was in the sensory nerve fibers compressed at the lateral recess of the lumbar spine and not at the site of amputation.

Moving proximally in the central nervous system, the electrical stimulation of the thalamus during functional stereotactic mapping constantly evoked various PS, including pain, in a group of amputees[17].

Sometimes PS are not created by the stimulation of somatosensory fibers with a missing territory, but they can be the result of central sensitization or neuroplastic changes that allow for the convergence of impulses coming from different body parts (referred sensations), one of which is missing. All that happens because the conscious representation of the body lies in the activation of one or more parts of the sensory cortex, independently from what really occurs in the periphery. This seems to be clearly confirmed in patients with arm amputation where the stimulation of face and trunk can evoke a phantom sensation. Since face and trunk are close to the hand in the cortical representation of the human body, the interpretation for this referred sensation was again the change of cortical representation after the amputation[18].

On a neurobiological point of view, great importance has been attributed to the rearrangement of the central nervous system in response to the loss of inputs coming from the periphery[19], but it is important to underline that any injury can induce a change in the cortical body representation, independently from PS occurrence[20].

It is also worth highlighting that referred sensations are not neuropathic per se and can also be observed in healthy subjects, although only in special situations[21]. Since the beginnings of the 20th century it was clear that a painful sensation can be complained in a part of the body as a consequence of a disease in another[22]. This is confirmed by several studies on experimental pain demonstrating how the intense stimulation of some tissues is able to evoke a painful sensation not only in the stimulation site, but also at a distance from it[23,24]. Nowadays referred pain is truly considered a rather common complaint in several clinical conditions.

Moreover, the (traumatic) amputation of a body part is not necessary for the development of PS as demonstrated by the evidence that patients with congenital limb absence can experience PS after minor trauma or minor surgery[25,26].

Interestingly, cortical representation changes can also explain other quasi-phantom phenomena. For instance, in patients with complete spinal cord injury the stimulation of body parts above the lesion can evoke a

sensation below the injury level[27].

All that considered, referred sensations can thus represent an additional pathophysiological basis of PS in amputees.

In conclusion, PS can be generated by both neuropathic and non-neuropathic mechanisms developed in the amputated body part or in other parts of the nervous system.

Since these mechanisms are not pathognomonic of amputation there are no hidden ghosts to look for in phantom sensations. The only interpretative rule is just to follow the pathophysiological principles. In this respect, since PS are generally very stressful for patients, according to Sherman[4], physicians have an important role in easing the patients' suffering by educating them about the PS pathophysiology in order to explain that their sensations are not so strange as they appear.

Abstract

Multiple sclerosis (MS) is a chronic inflammatory condition of the central nervous system determined by a presumed autoimmune process mainly directed against myelin components but also involving axons and neurons. Acute demyelination shows as clinical relapses that may fully or partially resolve, while chronic demyelination and neuroaxonal injury lead to persistent and irreversible neurological symptoms, often progressing over time. Currently approved disease-modifying therapies are immunomodulatory or immunosuppressive drugs that significantly although variably reduce the frequency of attacks of the relapsing forms of the disease. However, they have limited efficacy in preventing the transition to the progressive phase of MS and are of no benefit after it has started. It is therefore likely that the potential advantage of a given treatment is condensed in a relatively limited window of opportunity for each patient, depending on individual characteristics and disease stage, most frequently but not necessarily in the early phase of the disease. In addition, a sizable proportion of patients with MS may have a very mild clinical course not requiring a disease-modifying therapy. Finally, individual response to existing therapies for MS varies significantly across subjects and the risk of serious adverse events remains an issue, particularly for the newest agents. The present review is aimed at critically describing current treatment strategies for MS with a particular focus on the decision of starting, switching and stopping commercially available immunomodulatory and immunosuppressive therapies.

Key words: Multiple sclerosis; Disease-modifying therapy; Treatment start; Treatment switch; Treatment stop; Interferon beta; Glatiramer acetate; Azathioprine; Natalizumab; Fingolimod

Core tip: Disease-modifying therapies for multiple sclerosis (MS) modulate or suppress with different mechanisms the autoimmune process that underlies the

disease. Patients with relapsing MS may benefit from treatment but individual response to a given therapy and adverse events occurrence are largely unpredictable and many cases need to change several drugs to stabilize their disease. Nevertheless, a high proportion of patients evolve to a progressive phase, which is not responsive to any existing therapy. As opposed, some cases have a benign course without treatment. A critical review of strategies for starting, switching and stopping disease-modifying therapies for MS is here presented.

INTRODUCTION

Multiple sclerosis (MS) is a chronic neurological disease of unknown cause sustained by a widespread inflammatory process within the central nervous system (CNS) leading to multifocal demyelination and axonal loss mostly in the white matter but importantly also in the grey matter of both brain and spinal cord[1]. Clinical manifestations are heterogeneous depending on the anatomical location of inflammatory lesions, and are expression of acute demyelination which can fully or partially resolve, of chronic demyelination and neuroaxonal injury, that are generally irreversible, or both. Based on the predominance of episodic acute demyelinating events or of the chronic neurodegenerative process, the clinical course is defined either relapsing-remitting, which represents around 60% of prevalent cases, or progressive (primary if progression starts from onset or secondary if it begins after a preceding relapsing-remitting phase). About 10% of MS cases have a primary progressive (PP) course, while transition to the secondary progressive (SP) phase occurs in around half of RR MS patients, generally decades after clinical onset. An initial acute episode of neurological disturbance that is suggestive of MS but does not fulfill diagnostic criteria is defined clinically isolated syndrome (CIS), which is the typical presentation of relapsing forms of MS, although many patients may remain asymptomatic and free of disease-defining brain/spinal cord MRI activity for several years after a CIS has occurred[2,3].

MS predominantly affects young adults of female sex (female to male ratio 2.5:1 or greater), although the disease may begin in children and subjects over the age of 60. Caucasians are more frequently affected and the prevalence of the condition varies profoundly across different areas of the world, roughly following an increasing gradient from the equatorial zone - where it is below 5 cases per 100000 inhabitants - to the poles, reaching rates over 130 cases/100000 in several regions of Northern America, Europe and Australia[4-6]. Epidemiological studies indicate that genetic susceptibility, infections (particularly Epstein-Barr virus), reduced sun light exposure/blood levels of vitamin D, cigarette smoking, obesity, and increased dietary salt intake are risk factors for developing the disease but have not yet a completely established causative role[7]. Although the etiology of MS remains unknown, there is strong biological evidence of an autoimmune pathogenesis sustained by migration of peripheral T and B cells - reactive against one or more unidentified myelin or neuronal antigens - into the CNS, in which lymphocytes induce and maintain inflammation also through persistent microglia activation among other mechanisms that cause demyelination, axonal loss, and ultimately neuronal death[8].

Currently disease-modifying therapies (DMTs) for MS approved by the European Medicine Agency (EMA) and Food and Drug Administration (FDA) include interferon beta (IFNB) 1-a and 1-b, glatiramer acetate (GA), mitoxantrone, natalizumab, fingolimod, teriflunomide, dimethyl fumarate, and alemtuzumab. In addition, azathioprine and cyclophosphamide are used off-label or approved in some countries for MS treatment as a consolidated indication not initially registered (Table 1). Also methotrexate and rituximab are used as an off-label option in some cases. All mentioned agents act by modulating and/or suppressing the immune system at various levels and with different mechanisms of action, the description of which is beyond the scope of this review[9]. As a general rule, available DMTs have a favorable impact on relapsing-remitting MS, while they have no significant benefit in progressive MS in which neurological disability continues to worsen over time[10]. Even in relapsing-remitting MS, the efficacy, tolerability and safety profile vary greatly across treatments, ranging from combinations of modest effect and excellent safety to options that are highly effective but at increased risk of serious adverse events, which may be fatal in rare cases[11]. These include but are not limited to: cardiomyopathy and acute leukemia after long-term treatment with mitoxantrone; natalizumab-associated progressive multifocal leukoencephalopathy (PML); bradyarrhythmias, macular edema, and varicella-zoster virus infections occurring with fingolimod therapy; autoimmune thyroiditis, thrombocytopenia, and glomerulonephritis induced by alemtuzumab. Ideally, optimal treatment responders should be free from relapses, disability worsening and adverse events, outcomes that are difficult to assess experimentally in the long term given the relatively short duration of clinical trials for a lifelong condition such as MS. As a consequence, surrogate outcomes - mainly represented by brain MRI measures - have been increasingly used in trials for the last 20 years to demonstrate the biological activity of MS therapies[12,13]. However, the precise correlation between short-term effect on MRI measures and long-term clinical changes remains to be fully elucidated[14-16]. In addition, MS may have an extremely

Table 1 Main characteristics of available disease-modifying therapies for multiple sclerosis

Agent	Indication and line of therapy	Dosage, route and frequency	Clinical efficacy in placebo-controlled phase III trials	Tolerability issues	Safety issues
Interferon beta 1b	RR MS; SP MS with relapses; CIS First line	250 mcg *s.c.* every other day	34% reduction of ARR over two years (RR MS) 50% risk reduction of conversion to CD MS at two years (CIS) No statistically significant effect on disability progression	Flu-like syndrome; injection site reactions	Hepatotoxicity; myelotoxicity; autoimmune thyroiditis; microangiopathy; epileptic seizures (rare)
Interferon beta 1a	RR MS; CIS First line	30 mcg *i.m.* once a week	18% reduction of ARR over two years (RR MS) 44% risk reduction of conversion to CD MS at two years (CIS) No statistically significant effect on disability progression	Same as above	Same as above
Interferon beta 1a	RR MS; CIS First line	44 mcg *s.c.* three times a week	32% reduction of ARR over two years (RR MS) 45% risk reduction of conversion to CD MS at two years (CIS) 30% reduction of progression of disability at two years (RR MS)	Same as above	Same as above
Peginterferon beta 1a	RR MS First line	125 mcg *s.c.* every two weeks	36% reduction of ARR over one year	Same as above	Same as above
Glatiramer acetate	RR MS; CIS First line	20 mg *s.c.* every day	29% reduction of ARR over two years (RRMS) 45% risk reduction of conversion to CDMS at three years (CIS) No statistically significant effect on disability progression	Injection site reactions; post-injection reaction (chest pain, flushing and dyspnea)	Cutaneous necrosis; anaphylaxis (rare)
Mitoxantrone	RR MS; SP MS; PR MS Second or third line	12 mg/m^2 *i.v.* every three months or 8 mg/m^2 *i.v.* every month	65% reduction of relapse risk over two years (mostly in RR MS)[98] 66% reduction of risk of disability progression at two years (mostly in RR MS)[98]	Nausea/vomiting; amenorrhea/infertility; alopecia; blue discoloration of sclera and urine	Infusion site tissue necrosis; myelotoxicity; infections; cardiotoxicity; acute leukemia
Natalizumab	RR MS Second line	300 mg *i.v.* every four weeks	68% reduction of ARR over two years 42% reduction of progression of disability at two years	Headache	Infusion associated reactions; anaphylaxis; infections; hepatotoxicity; progressive multifocal leukoencephalopathy
Fingolimod	RR MS Second line (first line in the United States)	0.5 mg per *os* every day	48%-54% reduction of ARR over two years 30% reduction of progression of disability at two years	Fatigue; headache	Bradyarrhythmias after first dose; lymphopenia; viral infections (VZV); macular edema; hepatotoxicity; hypertension
Teriflunomide	RR MS First line	14 mg per *os* every day	31%-36% reduction of ARR over one year or more 26%-32% reduction of progression of disability at one year or more	Nausea; diarrhea; alopecia	Myelotoxicity; hepatotoxicity; infections; peripheral neuropathy; pancreatic fibrosis; teratogenicity (requires accelerated elimination procedure)
Dimethyl fumarate	RR MS First line	240 mg per *os* twice a day	44%-53% reduction of ARR over two years 38% reduction of progression of disability at two years	Flushing; gastrointestinal symptoms; pruritus	Lymphopenia; progressive multifocal leukoencephalopathy
Alemtuzumab	RR MS Second or third line	12 mg/d *i.v.* for five days followed by 12 mg/d *i.v.* for three days one year after the first course	49%-55% reduction of ARR over two years compared to *s.c.* interferon beta 1a 42% reduction of progression of disability at two years compared to *s.c.* interferon beta 1a	Infusion associated reactions; myalgia; arthralgia; irregular menstruation	Infusion associated reactions; cytokine release syndrome; lymphopenia; infections; autoimmune thyroiditis; thrombocytopenic purpura; glomerulonephritis
Azathioprine[1]	MS of all types First or second line	2.5 mg/kg per *os* every day	23% relative risk reduction of the frequency of relapses over two years No statistically significant effect on disability progression at two and three years[98]	Gastrointestinal symptoms; photosensitivity; irregular menstruation/reduced fertility	Myelotoxicity; hepatotoxicity; lymphopenia; infections; acute pancreatitis; increased toxicity in subjects with thiopurine methyltransferase deficiency; malignancies (cumulative dose > 600 g)
Cyclophosphamide[1]	SP MS; PP MS Third line	1 g *i.v.* over three days or 500 mg *i.v.* over five days	No statistically significant effect on disability progression at two and three years[98]	Nausea/vomiting; amenorrhea/infertility; alopecia	Myelotoxicity; hepatotoxicity; infections; hemorrhagic cystitis; bladder cancer

[1]The use of these drugs for the treatment of multiple sclerosis is off-label in most countries. ARR: Annualized relapse rate; CD: Clinically definite; CIS: Clinically isolated syndrome; PP: Primary progressive; PR: Progressive-relapsing; RR: Relapsing-remitting; SP: Secondary progressive.

Table 2 Critical factors affecting the decision of starting disease-modifying therapies for multiple sclerosis

Factors suggesting not to start a DMT	CIS with favourable prognostic factors
	RR MS with no relapses in previous two years, no disability, and no evidence of MRI activity (potential "benign" case)
	Progressive forms of MS with no relapses or evidence of MRI activity
	Pregnancy planning
	High risk of low adherence to treatment
Factors suggesting to start a first line DMT	CIS with unfavourable prognostic factors
	RR MS with at least one relapse in previous two years but less than two relapses in the last year, low residual disability, and/or active MRI
Factors suggesting to start a second line DMT	RR MS with at least 2 disabling relapses in the last year
	Progressive forms of MS with relapses and/or active MRI

DMT: Disease-modifying therapy; CIS: Clinically isolated syndrome; MS: Multiple sclerosis.

variable clinical course both within and between subjects, who may show extremely active and break-through disease despite treatment or, on the contrary, very mild forms or phases not necessarily requiring a potentially harmful and costly pharmacological therapy[17].

Here we will discuss current and potential strategies to start, change and stop disease-modifying MS therapies in the clinical practice.

WHEN TO START TREATMENT FOR MS?

Primum non nocere

To avoid overtreatment, it is important to start on a DMT MS patients who carry the highest probability of optimal therapy response, making decisions based on multiple factors, including evidence of efficacy and safety profile of drugs, disease course and activity, expected adherence and preferences of the individual case (Table 2)[18-20]. Placebo-controlled randomized trials of IFNB and GA in patients with CIS have shown that active treatment significantly delays conversion to definite MS and prevent accumulation of new brain lesions on MRI[21-25]. However, there is little or no significant benefit of early *vs* delayed therapy on worsening of neurological disability in the open-label extension phase of these trials up to 10 years after study initiation[26-28].

Randomized trials of DMTs for relapsing-remitting MS included patients who had experienced at least one or two relapses in the previous one or two years prior to randomization and showed that all therapies significantly reduce relapse rate over 2-3 years of treatment with largely different effect size depending on the specific drug considered (Table 1)[29-45]. Comparisons between old and new drugs or between pivotal and recent trials are limited by the changed profiles of MS subjects enrolled in clinical trials who are now generally in earlier phases of disease and with much lower clinical and MRI activity compared to patients included in studies between 1988 and 2000[46].

When taking the decision of treating a patient with MS for the first time, clinicians choose either an escalation or an induction approach[10]. The first consists of starting with a first-line medication - intended as a moderate-efficacy high-safety drug - and switching to a second-line treatment (more effective but also with more safety risks) in case of unsatisfactory response to the first line: this is reasonable in most patients seen in the clinical practice who present with mildly or moderately active disease. The induction approach is the initial use of a highly effective second-line treatment in order to obtain the rapid remission of a very active disease, which justifies the risk of serious adverse events. This strategy is intended for MS cases with frequent (*i.e.*, two or more per year) and severe relapses who are at increased risk of rapid accumulation of disability.

IFNBs, GA, teriflunomide, and dimethyl fumarate are considered first-line therapies, while natalizumab, alemtuzumab, are mitoxantrone are second-line or third-line drugs. Fingolimod is approved as a second-line treatment in the EU and as first-line in the United States, Canada and other countries[47]. Azathioprine and cyclophosphamide, which are not registered for MS treatment, are used by clinicians as first-line and second-line medications, respectively. Among first-line drugs, differences exist in terms of efficacy and tolerability, although direct comparison data are limited. Existing evidence indicates that high dose IFNB (particularly IFNB 1-a 44 mcg subcutaneously three times a week) is more effective than low dose IFNB, *i.e.,* IFNB 1-a 30 mcg intramuscular once a week[48,49]. However, high dose IFNB and GA have similar efficacy on clinical parameters, while they slightly differ in terms of impact on MRI measures, that is greater for IFNB than GA, and tolerability profile[50-53]. There is less experience worldwide with dimethyl fumarate given its recent introduction to the market. One of the pivotal studies included a group of GA-treated patients as reference arm: MS subjects receiving the experimental drug or GA had similar statistically significant reductions of relapse rate, while differences in disability progression at 2 years were not significant, compared to placebo[42]. Teriflunomide has shown a similar efficacy to high dose IFNB and, as dimethyl fumarate, has the advantage of being an oral medication[54]. Recently, an independent comparative study has shown that azathioprine is not inferior to IFNBs in relapsing-remitting MS in terms of relapse rate and disability progression reduction, confirming the utility of an old and safe drug as a low cost and oral administration treatment option for this

Table 3 Critical factors affecting the decision of changing current disease-modifying therapy for multiple sclerosis

Factors suggesting to switch from a first line DMT to another	Tolerability/safety issues Suboptimal efficacy with disease activity not suitable for escalation to a second line DMT Persistent high-titre neutralizing antibodies in patients treated with interferon beta
Factors suggesting to switch from a first line to a second line DMT	RR MS patients experiencing at least one relapse and with an active MRI during the previous year on treatment RR MS patients transitioning to the secondary progressive phase with evidence of relapses or MRI activity
Factors suggesting to switch from a second line DMT to another or to a third line DMT	RR MS patients continuing to experience relapses Progressive forms of MS with relapses and/or active MRI despite treatment Safety issues (*e.g.*, patients on natalizumab at high risk of developing progressive multifocal leukoencephalopathy)
Factors suggesting to switch from a second line to a first line DMT	Tolerability/safety issues Risk perception of patient

DMT: Disease-modifying therapy; RR: Relapsing-remitting; MS: Multiple sclerosis.

condition[55].

Natalizumab, fingolimod, and mitoxantrone are consolidated second-line DMTs, which can be used as initial treatment in patients with aggressive MS requiring an induction approach. In addition, EMA and FDA recently approved alemtuzumab with the indication for "active" MS. In patients not previously treated with other medications, all the mentioned drugs strongly reduce the frequency of attacks compared to standard first-line therapy (around 50% relapse rate decrease *vs* IFNB) and have a profound effect on MRI activity measures[44,56-58]. However, the benefit on disability progression appears less robust and consistent across studies.

There are no approved DMTs for the PP form of MS[59-61], which carries the worst prognosis. For this reason, some patients - particularly in presence of rapid neurological worsening, superimposed relapses and evidence of inflammatory activity on brain/spine MRI - are treated off-label with immunosuppressants such as cyclophosphamide or mitoxantrone, based on the possible efficacy on disability progression suggested by some randomized trials[36,62].

WHEN TO CHANGE TREATMENT FOR MS?

Evidence-based data and guidelines on criteria and timing for DMT change in MS are limited and choices of clinicians on this matter are often based on observational reports and guided by good clinical practice (Table 3). In fact, MS patients who start a DMT discontinue it in a proportion ranging from 30% to 80% for various possible reasons[63]. One of the biggest challenges is the definition of treatment response/failure. An easy-to-apply and fairly validated tool is the Rio score, which combines clinical and MRI parameters to predict disability progression over five years[64,65]. In any case, MS patients receiving a first-line DMT who continue to have a similar relapse rate compared to the pre-treatment phase, have persistent MRI activity, and/or show irreversible neurological disability worsening, have a sub-optimal response and a therapy switch needs to be considered[66]. Second-line options for these cases are natalizumab, fingolimod and alemtuzumab, considering potential differences across drugs in efficacy and safety profiles[37-39,56,57,67,68].

For patients on first-line DMT with evidence of partial response but not fulfilling requirements for escalation to a second-line treatment (*e.g.*, isolated persistent MRI activity) or with adverse reactions/tolerability issues that affect patient safety or quality of life, a so called "lateral" switch to another first-line DMT is justified, *e.g.*, shifting from low-dose to high-dose IFNB (or the reverse in case of side effects), from GA to IFNB or *vice versa*[69,70]. In the near future switching from IFNB or GA to one of the newest oral agents such as teriflunomide and dimethyl fumarate will likely become very common. An additional option is switching from IFNB or GA to azathioprine.

Some authors suggest that patients treated with IFNB should be monitored for the serological status of neutralizing antibodies (NABs) both in cases in which suboptimal efficacy is suspected and with stable disease: persistent high-titer NABs positivity reflects IFNB biological activity loss, is associated with a higher risk of disease activity, and indicates the need of switching to a non-IFNB therapy[71]. Although NABs assay is not routinely performed in all IFNB-treated patients in all Centers, positivity is currently reported in less than 10% of cases on IFNB 1-a and over 30% of subjects receiving IFNB 1-b[72].

Finally, one has to consider the possibility or necessity of changing a second-line or third-line treatment in a patient with MS. If a patient continues to experience relapses and - more importantly - shows disability progression, a DMT change is needed as well as in case safety concerns arise during treatment. MS patients on fingolimod with break through disease will typically switch to natalizumab if this is safe, or to "rescue-therapy" with cyclophosphamide, which is also a possible option for cases not responsive to natalizumab, although this rarely occurs and should raise the suspicion of NABs presence[73]. Anyway, this scenario will likely change in the next future as the use of alemtuzumab catches on as a third-line or earlier therapeutic strategy. A debated issue in the community of MS neurologists is changing therapy in patients treated with natalizumab and at risk of developing PML,

since treatment discontinuation is associated with a high risk of disease reactivation[74]. However, also switching to another DMT, including fingolimod, does not prevent relapse occurrence and MRI worsening in many cases, particularly if new therapy start is delayed[75-77]. Other strategies, such as continuing natalizumab with a strict surveillance of early PML signs[78], or shifting to a third-line option such as cyclophosphamide or alemtuzumab are being adopted in some Centers, although it is not excluded that PML risk could be carried over by prolonging immunosuppression after natalizumab[79].

WHEN TO STOP TREATMENT FOR MS?

Effective DMTs are essential to guarantee the highest possible well-being to people with MS. For the same reason there are circumstances in which ongoing DMT should or must be stopped to avoid that risks or costs overcome benefit. Given the nature of MS, DMT discontinuation is usually temporary but in some cases it can be permanent[19,80].

First, DMT must be stopped when a serious adverse event potentially correlated to treatment occurs or is suspected, in particular if it is life threatening since MS itself does not lead to a meaningful increase of mortality. Several MS therapies, especially among the newest, expose patients to the risk of infectious, hematologic, cardiac, and neoplastic complications that are potentially lethal and must be monitored carefully[81]. If a DMT is discontinued for this reason, a treatment change has to be considered with caution since other drugs with similar mechanism of action may interfere with recovery of the adverse event or even aggravate it. In some cases a precautionary interruption of treatment, which may be temporary or prolonged, is dictated by factors that are known to increase the risk of certain adverse events. This is the case of PML risk during natalizumab in patients with anti-JCV antibodies positivity, previous immunosuppressive exposure, and treatment duration of 2 years or more[68]. Other examples include: risk of opportunistic infections in patients treated with fingolimod or dimethyl fumarate and persistently low lymphocyte count in the peripheral blood[82,83]; risk of cardiotoxicity and leukemia for patients treated with mitoxantrone[84]; increased risk of cancer with immunosuppressive cytotoxic therapies prolonged for more than 3 years in the case of cyclophosphamide or more than 10 years for azathioprine[85,86]. Beside serious adverse events, DMTs may cause "minor" side effects and tolerability issues that disrupt patient quality of life[87]. Cases not obtaining a satisfactory management of such symptoms or not perceiving treatment benefit that justifies undesired effects generally have low adherence to the prescribed medication. This is known to be a risk factor for poor control of disease activity and progression: if lack of adherence to treatment cannot be improved DMT has to be discontinued[88].

Pregnancy is another event that requires immediate DMT interruption in women with MS who, however, must be carefully informed of the need of adequate contraception prior to and during treatment, of the possibility that some DMTs may reduce fertility, and of the importance of becoming pregnant when the disease is as stable as possible[89]. Treatment cannot be resumed during breast-feeding meaning that nursing mothers should be advised of stopping breast-feeding and (re)starting therapy only in presence of disease activity or in case of aggressive course prior to treatment interruption. Pregnancy planning requires DMT discontinuation with the appropriate timing according to the pharmacokinetic of the specific drug[90]. IFNB and GA may be continued until few weeks in advance or even up to conception; natalizumab, fingolimod and dimethyl fumarate should be stopped at least two months prior to planned conception; cytotoxic agents, such as mitoxantrone and azathioprine, need to be discontinued at least three months in advance. In addition to therapy interruption, patients on teriflunomide are required to undergo an accelerated elimination procedure with colestyramine or activated charcoal at least two months before conception (in case of unexpected pregnancy the procedure must be started immediately)[91]. For patients on alemtuzumab pregnancy program appears more complex as the effects of a single five-days course of the drug may last up to four years; however, based on pharmacokinetic data, maintaining contraception for at least four months after last alemtuzumab administration is currently recommended[92]. Data and guidelines regarding paternity planning for men with MS receiving DMT are lacking. Treatment interruption is generally not recommended for IFNB and GA, since the outcome of pregnancies fathered by patients receiving those drugs does not differ from general population[93]. However, male patients receiving therapies with mutagen potential that could lead to an increased risk of fetal malformations should be encouraged to avoid conception while on treatment.

Although it might be difficult to establish, MS patients who gradually accumulate irreversible disability without experiencing relapses and MRI inflammatory activity - *i.e.,* have transitioned to the SP phase of the disease - do not benefit significantly from any of currently available DMT, which should be therefore discontinued in this group of subjects[94]. On the other hand, for treated patients with prolonged stable disease and no apparent side effects DMT discontinuation is not recommended because the disease could reactivate. However, available data have been obtained from few patients treated for less than three years who had high pre-treatment MS activity and were not selected according to an a priori definition of stable disease[95]. In this context, patients treated with natalizumab represent an exception because it has been consistently reported that treatment interruption even in cases with no sign of MS activity for several years, frequently leads to disease reactivation - with a very severe clinical

picture in some cases - soon after stopping therapy[96].

CONCLUSION

General consensus and detailed guidelines on starting, changing and stopping DMTs for MS are lacking. Recently, an effort to guide the use of DMTs based on evidence from the literature with the aim of improving access to therapies for MS patients, led to a consensus paper by the MS coalition[97].

Based on current evidence and good clinical practice principles, we suggest the following.

When to start treatment for MS?

First-line DMT should be started in patients with a diagnosis of relapsing MS (according to 2010 McDonald's criteria) and at least one documented attack in the previous two years; as for the choice of the specific drug, high dose IFNB 1-a and GA are the preferred options among established injectable therapies, although oral therapies such as azathioprine, teriflunomide and dimethyl fumarate have at least comparable efficacy.

First-line DMT may be initiated in patients with a CIS or MS with a single attack and dissemination in space and time according to 2010 McDonald's criteria in presence of factors known to be associated with poor prognosis, such as male sex, incomplete recovery from attack, prominent neurological efferent systems involvement, and more than nine lesions on brain MRI (good clinical practice point - there is no evidence that subgroups of patients with such features are significantly protected by DMTs against long-term disability progression).

DMT-naïve MS patients experiencing at least two disabling relapses in the last year and with an active MRI scan should be treated with a second-line regimen, such as fingolimod or natalizumab; also alemtuzumab may be considered for patients with aggressive disease from onset.

Available DMTs are of no utility in PP MS, although cases with rapid progression, superimposed relapses and active MRI might benefit from immunosuppressants such as mitoxantrone, cyclophosphamide, or methotrexate.

When to change treatment for MS?

Given the current availability of multiple options, a DMT change needs to be considered in any MS patient with suboptimal response: in case of one or more relapses during the previous year on a first-line DMT, particularly in case of incomplete recovery, switching to a second-line medication is appropriate, while isolated MRI activity and/or increased relapse frequency not qualifying for second-line escalation are conditions for switching to another first-line DMT; patients relapsing while on fingolimod may be switched to natalizumab, or the reverse (although natalizumab is expected to reduce relapse rate more than fingolimod based on indirect comparison); alternatively, these cases may be shifted to a third line of treatment such as alemtuzumab or intravenous cytotoxic immunosuppressants.

Patients on IFNB who develop persistent high-titer NABs need to change treatment even if disease is stable.

Subjects with intolerable side effects from their current medication need to be switched to another DMT within the same line of treatment.

Patients receiving natalizumab for more than two years who are anti-JCV antibody positive and previously received cytotoxic immunosuppressants should be switched to another DMT due to the significantly increased risk of PML; possible options include fingolimod, alemtuzumab, cyclophosphamide, and less convincingly first-line DMTs; to minimize the risk of disease reactivation the wash-out interval should be shortened as much as possible.

When to stop treatment for MS?

DMT must be stopped in case a serious adverse event potentially related to the drug occur or is likely to occur, in patients becoming pregnant, and in subjects who are not adherent to treatment.

DMT should be also discontinued in patients with confirmed disability progression over one year in the absence of relapses and new/enhancing lesions on MRI; these subjects have progressive MS, which does not respond to any DMTs, and priority should be given to symptomatic treatment, physical therapy, and management of disability.

Abstract

Ectopic mineralization - inappropriate biomineralization in soft tissues - is a frequent finding in physiological aging processes and several common disorders, which can be associated with significant morbidity and mortality. Further, pathologic mineralization is seen in several rare genetic disorders, which often present life-threatening phenotypes. These disorders are classified based on the mechanisms through which the mineralization occurs: metastatic or dystrophic calcification or ectopic ossification. Underlying mechanisms have been extensively studied, which resulted in several hypotheses regarding the etiology of mineralization in the extracellular matrix of soft tissue. These hypotheses include intracellular and extracellular mechanisms, such as the formation of matrix vesicles, aberrant osteogenic and chondrogenic signaling, apoptosis and oxidative stress. Though coherence between the different findings is not always clear, current insights have led to improvement of the diagnosis and management of ectopic mineralization patients, thus translating pathogenetic knowledge (variome) to the phenotype (phenome). In this review, we will focus on the clinical presentation, pathogenesis and management of primary genetic soft tissue mineralization disorders. As examples of dystrophic calcification disorders Pseudoxanthoma elasticum, Generalized arterial calcification of infancy, Keutel syndrome, Idiopathic basal ganglia calcification and Arterial calcification due to CD73 (NT5E) deficiency will be discussed. Hyperphosphatemic familial tumoral calcinosis will be reviewed as an example of mineralization disorders caused by metastatic calcification.

Key words: Ectopic mineralization; Pseudoxanthoma elasticum; Pseudoxanthoma elasticum-like syndrome; Generalized arterial calcification of infancy; Keutel syndrome; Idiopathic basal ganglia calcification; Arterial calcification due to CD73 deficiency; Hyperphosphatemic familial tumoral calcinosis; Etiology; Phenotype

Core tip: Ectopic mineralization disorders represent a broad range of phenotypically heterogenous diseases, often leading to significant morbidity and mortality. Involving a complex interplay between different pro-osteogenic mediators and inhibitors of calcification, the mechanisms of ectopic mineralization are progressively being unveiled. Though current knowledge is beyond any doubt the tip of the proverbial iceberg, insights already have significant implications in the diagnosis and daily management of these patients. As such, ectopic mineralization diseases are a fine example of translating variome data to the clinic. Here, we will discuss prototype hereditary ectopic calcification diseases with respect to their presentation, diagnosis and management.

Table 1 Causes of metastatic/dystrophic calcification and ectopic ossification

	Metastatic calcification	Dystrophic calcification	Ectopic ossification
Primary	Primary hyperparathyroidism Pseudo(pseudo)hypoparathyroidism HFTC	PXE PXE-like syndrome GACI Keutel syndrome IBGC ACDC AI	Fibrodysplasia ossificans progressiva
Secondary	Sarcoidosis Vitamin D intoxication Milk-Alkali syndrome Secondary hyperparathyroidism Renal failure Hemodialysis Tumor lysis Therapy with vitamin D and phosphate	Scleroderma Dermatomyositis SLE	Nonhereditary myositis ossificans

ACDC: Arterial calcification due to CD73 deficiency; AI: Amelogenesis imperfecta; GACI: Generalized arterial calcification of infancy; HFTC: Hyperphosphatemic familial tumoral calcinosis; IBGC: Idiopathic basal ganglia calcification; PXE: Pseudoxanthoma elasticum; SLE: Systemic lupus erythematosus.

INTRODUCTION

Physiological biomineralization is a complex multifactorial metabolic process, which in normal conditions is restricted to the extracellular matrix (ECM) of specific body structures, namely the bones, teeth, hypertrophic growth plate cartilage and calcified articular cartilage[1,2]. The intracellular and extracellular mechanisms, underlying physiological biomineralization, rely on a balanced interplay between mineralization inhibitors and propagators (Figure 1)[2,3]. Although in physiological circumstances calcium and inorganic phosphate (Pi) concentrations exceed their solubility in most human tissues, this does not result in mineralization of soft tissues, suggesting that these tissues possess regulatory mechanisms preventing mineral deposition. Mineralizing tissues must be able to modulate these mechanisms to enable calcification[2], but should also contain anti-mineralizing factors to prevent escalation of the calcification process leading to excessive and uncontrolled mineral deposits[1,2]. When these regulatory mechanisms are inadequate, ectopic mineralization, *i.e.,* inappropriate biomineralization in soft tissues, occurs and causes a spectrum of ectopic calcification disorders (Table 1)[2,4].

Uncontrolled mineralization occurs frequently in response to tissue injury or a systemic mineral imbalance. This leads to the development of a calcified lesion, which can occur throughout the body, though tissues as articular cartilage, the cardiovascular (CV) tissues and kidneys seem particularly prone[3,5,6]. Unlike physiological mineralization deposits, which only contain calcium phosphate crystals such as hydroxyapatite, ectopic mineralization depositions may also contain other calcium salts, including calcium oxalates or octacalcium[4].

Regarding the initiation of and pathogenetic mechanisms underlying ectopic mineralization several hypotheses have been proposed (Figure 1): (1) increasing evidence is found that soft tissue calcification can be initiated in matrix vesicles (MVs), extracellular membrane particles (approximately 20-200 nm in diameter), which have a key role in the normal physiological mineralization process[3]. MVs contain calcium-binding non-collagenous matrix proteins, such as secreted phosphoprotein 1 (SPP1; OMIM*166490), which can boost mineralization *in vitro*[7]. MVs initiate mineralization in 2 phases: (1) initial formation of hydroxyapatite in the MV itself: after budding from the plasma membrane, tissue-nonspecific alkaline phosphatase (TNAP; OMIM*171760) activity induces an increase of extracellular Pi concentration, which then enters the vesicles *via* sodium-dependent inorganic phosphate transporters (PiTs). This is followed by calcium influx into the MVs, which is enabled by annexin A5 (ANXA5; OMIM*131230) and phosphatidyl serine (PS), located at the MV inner membrane leaflet[1,3]; and (2) propagation of the calcium salts in the ECM: in the MVs hydroxyapatite crystals continue to grow, eventually rupturing the MV membrane. As a result, the crystals are exposed to the ECM, inducing their further expansion[3,8]; pathological calcification can also be influenced by ectopic osteogenic and chondrogenic signaling, leading to the activation of multiple pro-mineralization proteins[9]. This conversion of tissue-specific cells to bone-like cells has been mainly

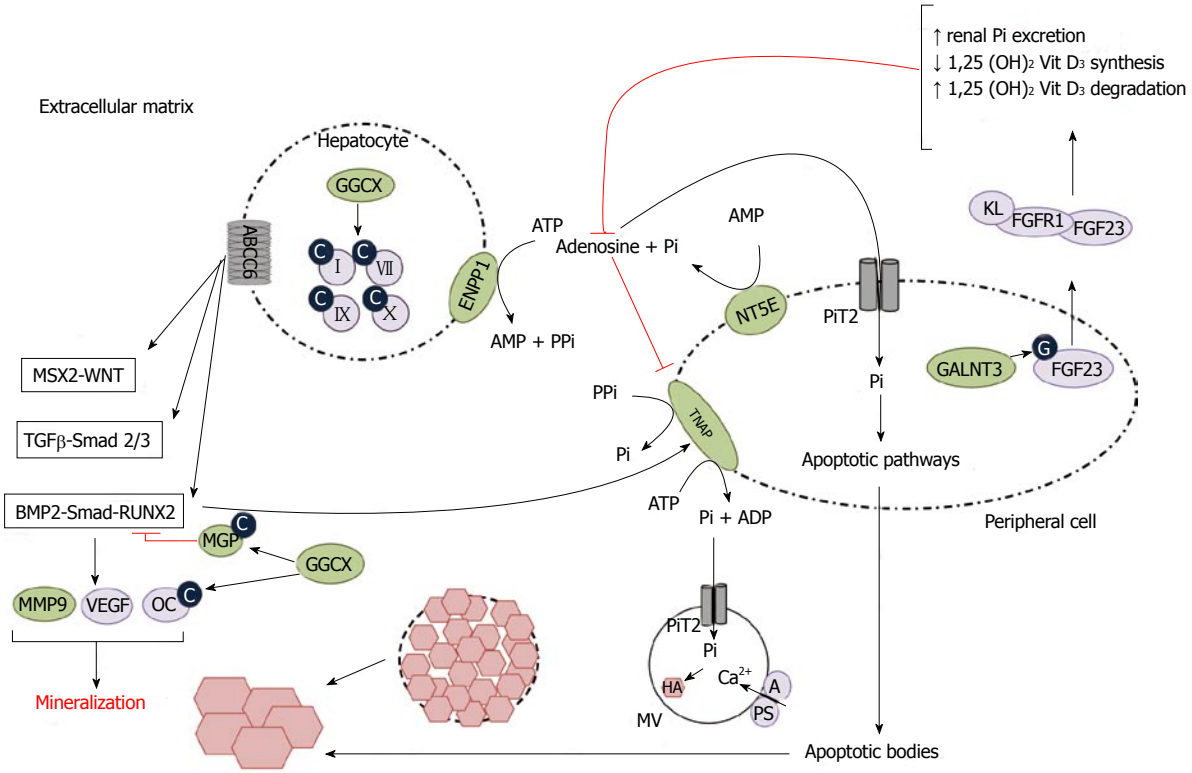

Figure 1 Schematic representation of the pathophysiological mechanisms leading to ectopic mineralization. Hepatocyte: Impairment of ABCC6 function leads to upregulation of pro-osteogenic pathways (MSX2-WNT, TGFβ-Smad 2/3, BMP2-Smad-RUNX2), upregulation of their downstream targets and eventually to ectopic mineralization. GGCX carboxylates and hence activates multiple targets, such as coagulation factors and MGP, the latter being a potent BMP2-inhibitor and hence mineralization inhibitor. When GGCX function is impaired, these targets stay inactive, leading to increased mineralization. ENPP1 converts ATP to AMP and PPi, the latter being a mineralization inhibitor. Impairment of this conversion and hence a decrease in the PPi level leads to increase in ectopic mineralization. Peripheral cell: After glycosylation by GALNT3, FGF23 forms a complex with FGFR1 and KL (coreceptor) which leads to increased renal excretion of Pi, a pro-mineralizing agent and decreased 1,25 dihydroxyvitamin D3, causing a decrease in intestinal Pi absorption. NT5E converts AMP to Pi and adenosine, which inhibits the pro-mineralizing TNAP. Impairment of NT5E function leads to increased TNAP activity and decreased PPi concentration, hence leading to ectopic mineralization. Pi is internalized into the peripheral cell by PiT2 and leaves the cell through apoptotic bodies, which cause ectopic mineralization through apoptotic pathways (not shown). In MVs an influx occurs of Pi *via* PiT2 and of Ca^{2+}, which is facilitated by A and PS. This leads to an accumulation of growing hydroxyapatite crystals, eventually causing the MVs to burst and the crystals to grow in the extracellular matrix. described in vascular calcification, and is probably due to the common mesenchymal origin of vascular smooth muscle cells (VSMCs) and bone cells[1]; (3) apoptosis or programmed cell death is accompanied by the release of apoptotic bodies, which exteriorize PS to the outer membrane of the apoptotic body and therefore face the ECM. There, PS may bind calcium, resulting in an accumulation of calcium and phosphate, as is also seen in MVs, thus contributing to physiological and pathological mineralization[1,10]. Another potential apoptosis pathway includes elevated phosphate levels to induce VSMC apoptosis, a process that is possibly caused by downregulation of growth arrest-specific 6 (Gas6; OMIM*600441) and B-cell CLL/Lymphoma (BCL2; OMIM + 151430), with subsequent caspase 3 activation[11,12]; and (4) reactive oxygen species (ROS), highly reactive oxygen-containing molecules, are formed as byproducts of normal oxygen metabolism and has important roles in cell signaling and metabolism. Nonetheless, if ROS concentration surpasses a critical threshold, oxidative stress, accompanied by important cell damage, can occur[13]. Potential sources of ROS in soft tissues are nicotinamide adenine dinucleotide (phosphate) (NAD(P)H) oxidase, nitric oxide synthase (NOS), xanthine oxidase, cytochrome P450 and cyclo-oxygenase; in addition, mitochondrial dysfunction may also lead to the formation of ROS. ROS possibly causes soft tissue mineralization through either the IκB-NF-κB pathway (inhibitor of κB - nuclear factor kappa-light-chain-enhancer of activated B cells), upregulation of the pro-osteogenic bone morphogenetic protein 2 (BMP2; OMIM*112261) pathway and/or osteogenic conversion

of soft tissue cells[1].

These pathophysiological mechanisms are however not mutually exclusive and display significant crosstalk[1].

Ectopic soft tissue mineralization is a common finding in aging and several common disorders, including atherosclerosis, hypertension, diabetes, chronic kidney disease and autoimmune diseases, and can be related to significant morbidity and mortality in each of these. It has been shown that vascular calcification correlates with an increased risk of myocardial infarction and that it is an independent risk factor for death in patients with coronary artery calcification[14,15]. However, in these complex, multifactorial disorders, multiple genes are likely to contribute, with each gene having only a small effect[16]. Contrary, in primary genetic mineralization disorders mutations in a single gene or few genes can cause an often extreme and life-threatening phenotype. Though individually rare, as a group they affect a considerable number of patients with important impact on quality of life and high morbidity and mortality rates.

Ectopic mineralization disorders are conventionally classified based on the mechanism through which the mineralization takes place: *i.e.,* metastatic or dystrophic calcification or ectopic ossification (Table 1)[14]: (1) metastatic calcification, due to hyperphosphatemia and/or hypercalcemia; (2) dystrophic calcification, which occurs in diseased (metabolically impaired or dead) tissue under normal calcium and phosphate homeostasis[1]; and (3) ectopic or heterotopic ossification, leading to true bone formation[1,4,17,18].

For many of these disorders, important advances have been made in defining their clinical presentation (phenome), their (molecular) etiology (variome) and the correlation between both. This has led to novel insights and perspectives for the management and treatment of the patients, but also supports the complexity of the pathophysiology of soft tissue mineralization.

This review will focus on the clinical presentation, pathogenesis and management of primary genetic soft tissue mineralization disorders due to dystrophic (Pseudoxanthoma elasticum, Generalized arterial calcification of infancy, Keutel syndrome, Idiopathic basal ganglia calcification, Arterial calcification due to CD73 deficiency) or metastatic calcification (Hyperphosphatemic familial tumoral calcinosis).

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum (PXE; OMIM#264800) is a rare, autosomal recessive connective tissue disorder, resulting from ectopic mineralization and fragmentation of elastic fibers. The prevalence of PXE is estimated between 1/25000 and 1/100000 with a carrier frequency of 1/80, although this may be an underestimation due to the variability of the phenotype, which in some cases may hinder the diagnosis[19-21].

Clinical characteristics

PXE primarily affects 3 organ systems, *i.e.,* the skin, the eyes and the CV system, albeit with important inter- and intrafamilial variability in severity[19,21,22]. Usually the skin symptoms are the first to arise, though they are not present in all patients, presenting as soft yellowish papules in flexural body areas (*i.e.,* neck, axilla, elbow, groin and knees) (Figure 2A-E)[19]. These solitary papular lesions can coalesce into larger plaques. Loss of resilience may give the skin a wrinkled aspect and can cause an esthetic burden[1,19]. Less frequently, mucosal lesions (usually at the inner lower lip) are present (Figure 2F)[19]. The emergence of additional inelastic skin folds[1], especially in neck (and thigh) area(s) can also cause functional problems, *e.g.,* when sleeping or riding a bicycle[1,19].

The most common ocular features in PXE patients are peau d'orange and angioid streaks (AS), which themselves cause no functional impairment (Figure 2G). In later stages choroidal (subretinal) neovascularization (CNV) occurs and these neovessels may rupture, causing retinal hemorrhage (Figure 2I). Symptoms will include metamorphopsia and vision loss, which can be permanent if left untreated. More recently, chorioretinal atrophy, subretinal fluid independent from CNV, pattern dystrophy-like changes, debris accumulation under the retinal pigment epithelium, reticular drusen and a decreased fluorescence on late phase indocyanine green angiography were described[23].

CV symptoms, usually arising when patients are 30-40 years old, include accelerated coronary and peripheral artery disease (hypertension, myocardial infarction, intermittent claudication), diastolic cardiac dysfunction and gastrointestinal hemorrhage[24]. In 15% of PXE patients ischemic stroke may occur, at an average age of 49[1,24]. Heterozygous carriers usually develop neither skin nor eye symptoms but can suffer from accelerated atherosclerosis and (mild) diastolic dysfunction of the heart[24].

To date, no correlation has been established between the PXE phenotype and mutations in the main causal gene adenosine triphosphate (ATP)-binding cassette, subfamily C, member 6 (*ABCC6*; OMIM*603234), which complicates the prediction of the evolution and severity of the symptoms in an individual patient[19,25]. The absence of a reliable genotype-phenotype correlation suggests that other genes, so-called modifier genes, may play an important role in influencing the disease course, apart from other factors such as lifestyle, environmental factors and - although less probable - dietary habits[19]. Thus far, only one promising modifier gene, vascular endothelial growth factor A (*VEGFA*; OMIM + 192240) has been identified for the PXE retinopathy[26].

Pathogenesis

PXE is caused by mutations in the *ABCC6* gene, enco-

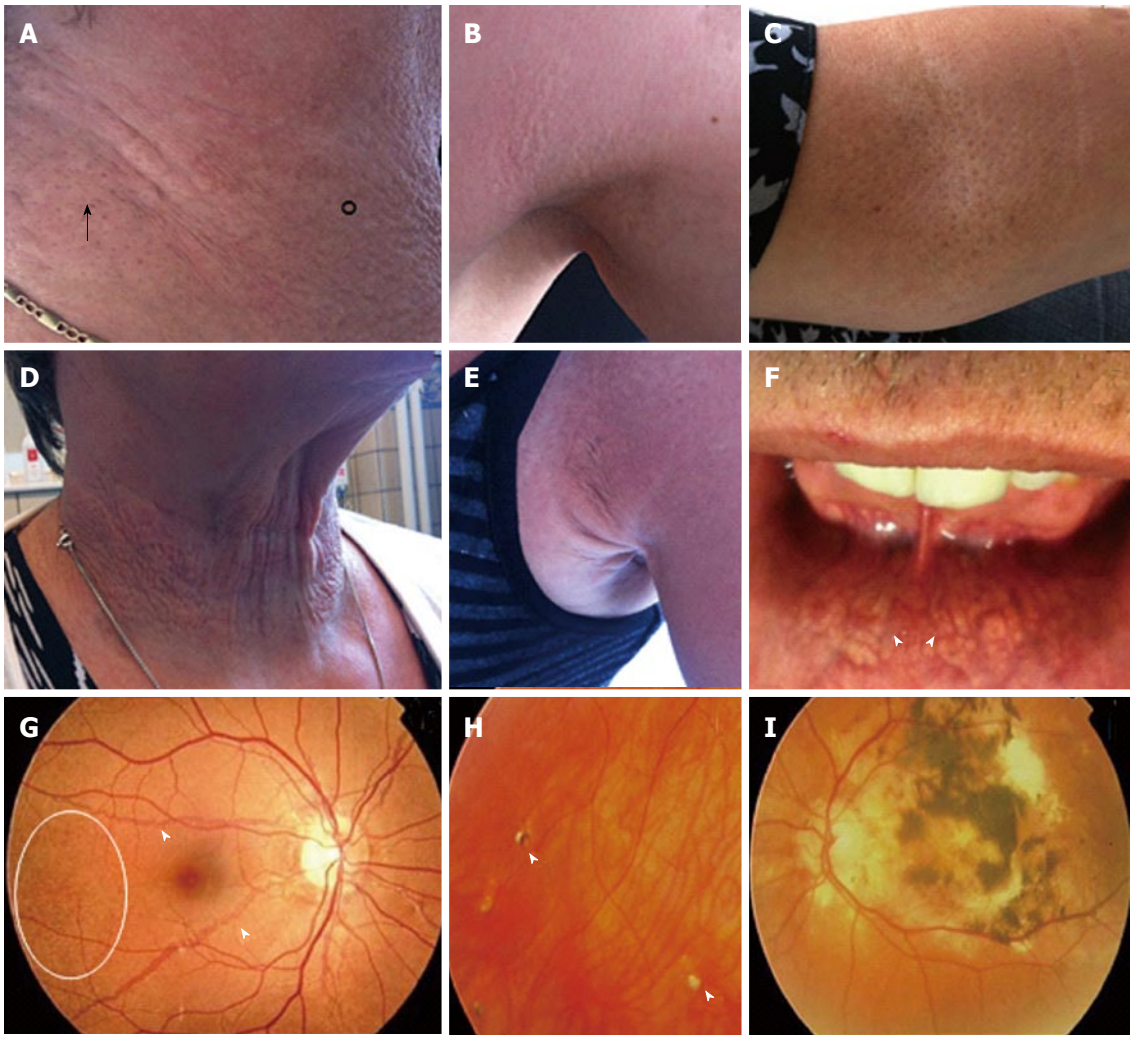

Figure 2 Dermatological (A-F) and ophthalmological (G-I) manifestations of pseudoxanthoma elasticum. A, B: Flexural areas can show papular lesions (°) and coalesced plaques of papules (arrow); C: Cutaneous peau d'orange; D, E: Additional skin folds; F: Yellowish, reticular pattern on the mucosae of the lip (arrowed); G: Ocular fundi show peau d'orange (circle) and angioid streaks (arrowed); H: Comets and comet tails (arrowhead); I: Choroidal and subretinal hemorrhage.

ding an ATP-binding efflux transporter, the substrate and (patho)physiological role of which are yet to be elucidated[27]. The ABCC6 transporter is mainly expressed in the liver and kidneys while only minimally present in the organs affected by PXE[28,29]. This led to the hypothesis that PXE is a metabolic disorder in which a defective transporter causes inefficient transport of one or multiple substrates into the bloodstream[28,29]. As a result, a deficiency of vitamin K (VK) -dependent and -independent mineralization inhibitors occurs, favoring ectopic soft tissue mineralization[23,30,31]. The metabolic hypothesis was reinforced several times, until very recently Ziegler *et al*[32] reported that a conditional, liver-specific *Abcc6*$^{-/-}$ mouse model does not develop ectopic mineralization and concluded that mineralization in PXE occurs through a liver-independent mechanism. This would correspond with a second, so-called cellular, hypothesis which states that the local environment in the affected organ systems is altered; in this respect it was shown that PXE fibroblasts suffer mild chronic oxidative stress because of overexpression of oxidative stress-favoring mediators[31,33].

More recently, 3 pro-osteogenic pathways, *i.e.*, BMP2-Smad (mothers against decapentaplegic, drosophila, homolog of; OMIM*601366)- runt-related transcription factor 2 (RUNX2; OMIM*60021) and transforming growth factor β2 (TGFβ2; OMIM*190220)-Smad2/3 pathways and the MSX2 (muscle segment homeobox, drosophila, homolog of, 2; OMIM*123101)-canonical WNT (wingless-type MMTV integration site family; OMIM*164820) pathway which are associated with vascular mineralization, were found to be upregulated in the skin and eyes of PXE knock-out mice and in PXE patients (Figure 1)[34]. The relevance of BMP2-Smad-RUNX2 signaling was alluded on by previous observations in PXE, including the low levels of carboxylated (active) matrix gla protein (MGP; OMIM*154870)/gamma-carboxyglutamic acid, a potent inhibitor of BMP2, the upregulation of several target genes of RUNX2 such as SPP1, osteocalcin, matrix metalloproteinase (MMP9; OMIM*120361), TNAP and VEGFA, the influence of oxidative stress on BMP2

Table 2 Differential diagnosis of pseudoxanthoma elasticum manifestations[1,19,47,49,53-59]

Disease	Distinct differences with PXE
Beta-thalassemia (PXE phenocopy)	Severe anemia Reduced production of hemoglobin
PXE-like syndrome (*AR*; *GGCX* gene)	More severe cutaneous phenotype not restricted to flexural areas Vitamin K-dependent coagulation factor deficiency
GACI (*AR*; *ENPP1* gene)	Onset in infancy or early childhood Arterial stenosis Early-onset severe myocardial ischemia High mortality rate in early childhood
Fibroelastolytic papulosis, Treatment with D-penicillamine	No ophthalmological or CV phenotype
Buschke-Ollendorf syndrome (*AD*; *LEMD3* gene)	Skeletal manifestations (osteopoikilosis, stiff joints, osteosclerosis) No ophthalmological or CV phenotype No mineralization
Solar elastosis	Dermatological features (lentigines, mottled pigmentation, actinic keratoses, telangiectasias, xerotic texture) No ophthalmological or CV phenotype No mineralization
Late-onset focal dermal elastosis	Onset in 7th to 9th life decade No ophthalmological or CV phenotype
Cutis laxa	No ophthalmological or CV phenotype Histopathology: scarce and mottled elastic fibers, no mineralization
A(R)MD (age-related macular degeneration)	No AS No CV or dermatological phenotype Less unique lesions (outer retinal tabulation or Bruch's membrane undulation)
Presumed ocular histoplasmosis	No AS No CV or dermatological phenotype

AD: Autosomal dominant; AR: Autosomal recessive; A(R)MD: Age-related macular degeneration; AS: Angioid streaks; CV: Cardiovascular; ENPP1: Ectonucleotide pyrophosphatase/phosphodiesterase 1; GACI: Generalized arterial calcification of infancy; GGCX: Gamma-glutamyl carboxylase; LEMD3: Lem domain-containing protein 3; PXE: Pseudoxanthoma elasticum.

expression and the overexpression of RUNX2 in calcified cardiac tissue of the *Abcc6*-related dystrophic cardiac calcification mouse[34-36]. Furthermore, apoptosis was identified as an important process in PXE contributing to mineralization, by activation of BCL2 and multiple caspases[34].

Some insights in the dysfunction of pro- and anti-mineralizing factors in the PXE pathogenesis, have been described in the PXE murine model and/or PXE patients. Several local pro-mineralizing factors seem to be upregulated *in vitro* and/or *in vivo* (TNAP, BMP2) while mineralization inhibitors, such as ecto-5-prime-nucleotidase or CD73 (NT5E; OMIM*129190), SPP1, ankyrin (mouse, homolog of) (ANKH; OMIM*605145) and VK-dependent calcification inhibitors, were found to be less expressed[37-39].

Besides local factors, systemic inhibitors of mineralization such as Fetuin A and more recently inorganic pyrophosphate (PPi), were shown to be less abundant in PXE. PPi is a potent endogenous inhibitor of vascular calcification, both *in vitro* and *in vivo*, which was already shown to be downregulated in PXE fibroblasts, thus promoting pro-calcifying stimuli leading to tissue mineralization[40,41]. Jansen *et al*[42] found low PPi serum levels in both *Abcc6*$^{-/-}$ mice and PXE patients, and concluded that an impaired ABCC6 transporter negatively influences PPi efflux from hepatocytes to the hepatic circulation, though the exact mechanism is poorly understood.

Diagnosis

The diagnosis of PXE is a clinical one to begin with, based on the presence of typical skin and/ or fundus changes. While the skin lesions of PXE can be mimicked macroscopically by other disorders (Table 2), the presence of peau d'orange and/or AS in the ocular fundus can be considered pathognomonic. Diagnostic confirmation can be obtained by skin biopsy, showing shortened, fragmented elastic fibers as well as mineral deposits in the mid-dermis using H&E (hematoxylin and eosin) and von Kossa staining. Molecular analysis of the *ABCC6* gene detects both causal mutations in approximately 95% of patients[1,33,43,44]. Sanger sequencing is still the gold standard, but should be complemented with multiplex ligation-dependent probe amplification, to detect larger deletions and insertions[45]. If no or only one *ABCC6* mutation can be identified, it is worthwhile to screen for gamma-glutamyl carboxylase (*GGCX*; OMIM*137167) mutations as digenic inheritance has been described[46]. Furthermore, the initial presentation of the *GGCX*-related PXE-like disorder with coagulation factor deficiency (see below) can be identical to PXE[47,48]. Sequencing of the ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*; OMIM*173335) gene is useful when no *ABCC6* mutations can be detected in a patient with a histologically confirmed diagnosis of PXE; digenic inheritance of an *ABCC6* and *ENPP1* mutation has so far not been reported[49]. This increasing number of genes which may cause PXE as well as the potential importance of modifier genes, brought about a gradual shift from Sanger sequencing towards the more recently introduced next generation sequencing[26,47,50-52].

Differential diagnosis

The differential diagnosis of PXE manifestations is summarized in Table 2.

Management

To date, PXE management is mainly symptomatic, focusing on prevention and treatment of complications[19]. For ophthalmological complications, preventive measures include wearing glasses and avoiding sports and activities with a (relative) high risk of (head) trauma or increased pressure[19,21,60]. Once fundus changes have appeared, an annual control by an ophthalmologist is important, as well as weekly self-examination using the Amsler Grid. If distortion or metamorphopsia occurs,

Figure 3 Cutaneous features of a pseudoxanthoma elasticum-like patient with increased amount of generalized thick leathery skin folds.

the patient should contact his/her ophthalmologist immediately[20,23]. Timely treatment with anti-VEGF antibodies, such as bevacizumab or ranibizumab, were shown to be successful in forcing back neovessels and preserving visual acuity[1,20,30]. Prophylactic anti-VEGF therapy has however not been proven to be advantageous[19].

The prevention of CV complications consists of controlling traditional CV risk factors (*e.g.,* smoking, obesity, hypercholesterolemia and diabetes)[1]. Upon diagnosis, a baseline screening should be performed with measurement of blood pressure, assessment of biochemical CV risk factors, echocardiography, determination of the ankle-brachial index and duplex ultrasound of the arteries of the neck and lower extremities. If hypertension is found, further assessment with 24-h blood pressure monitoring and an exercise test should be done. Further CV management is tailored based on the results of this screening, usually comprising an annual checkup by a cardiologist and if necessary initiation of secondary prevention[24]. Since heterozygous carriers suffer CV complications more frequently compared to the general population, they should also undergo a baseline CV screening and regular checkups by a cardiologist[24]. Furthermore, the use of anticoagulants, aspirin and nonsteroidal anti-inflammatory drugs should be avoided as they may elevate the risk of gastrointestinal bleeding[1]. When complications do occur, standard interventional or surgical procedures can usually be applied[24,61].

For the skin problems no prevention is possible and therapeutic options are scarce. When functional problems arise, mainly due to excessive skin folds, plastic surgery can be attempted[61]. Possible post-surgery complications include slower wound healing and apparition of skin lesions in the scars[61-63]. Recently, Salles *et al*[64] described a PXE patient in which skin lesions in the neck were successfully treated with fractional carbon dioxide laser therapy. The post-laser reaction - redness, pain, swelling and crusting - was the same as seen in normal skin. After a follow-up of 2 years, the treatment showed an overall satisfactory esthetic result, showing improvement of the skin texture, irregularity, volume and distensibility. Moreover, lipofilling to reduce esthetically disturbing skin folds, especially in the neck region, is being evaluated in an experimental setting[65].

PXE-LIKE SYNDROME WITH MULTIPLE COAGULATION FACTOR DEFICIENCY

In 2007, Vanakker *et al*[1,47] described a new autosomal recessive disorder which was closely related to PXE and coined it the PXE-like syndrome with multiple coagulation factor deficiency (OMIM#610842). To date, the disorder has been described in 12 patients, 8 of which had molecular confirmation of the clinical suspicion[47,48,66-68].

Clinical characteristics

The initial presentation of the PXE-like syndrome is nearly identical to that of PXE, making it often difficult to distinguish the two diseases in young adults. The natural evolution of the PXE-like disorder is however completely different and characterized by severe cutaneous symptoms with the development of thick and redundant skin folds, not restricted to flexural areas but variably expanding toward limbs and abdomen (Figure 3), a mild retinopathy and a deficiency of the VK-dependent coagulation factors (coagulation factors Ⅱ, Ⅶ, Ⅸ, Ⅹ)[1,47,48]. Furthermore, subclinical atherosclerosis and cerebral aneurysms have been described[47].

Pathogenesis

Biallelic mutations have been described in the *GGCX* gene, encoding a gamma-carboxylase enzyme which performs an essential post-translational modification step of a number of so-called VK-dependent proteins, including clotting factors and mineralization inhibitors (Figure 1). It was shown that the PXE-like mutations result in a reduced activity of the enzyme, thus leading to inadequate carboxylation (or activation) of these VK-dependent proteins. This causes a deficiency of coagulation factors and creates an environment which favors ectopic mineralization[1].

Diagnosis

The diagnosis of PXE-like syndrome is relatively straightforward when typical skin lesions are seen in combination with a deficiency in the VK-dependent clotting factors. Biochemically, a prolonged prothrombin time can be found, though the coagulation factor deficiency can be very mild[47]. In young individuals, the diagnosis should be considered in every patient suspected of having PXE in whom no *ABCC6* mutations are found. Histopathology shows fragmentation and calcification of the mid-dermal elastic fibers, being located in the periphery of the fiber[69]. Light microscopy will not allow differentiating with PXE, but on electron microscopy the elastic fibers are more ragged and the calcification is located in the periphery of the fibers

Table 3 Differential diagnosis of the pseudoxanthoma elasticum-like syndrome[19,47]

Disease	Distinct differences with PXE-like syndrome
PXE (*AR*; *ABCC6* gene)	More severe CV and ophthalmological manifestations Skin lesions are less severe and restricted to flexural areas No coagulation factor deficiency associated EM: mineralization in the core of the EF
Cutis laxa	No retinopathy No deficiency of coagulation factors Atherosclerosis and cerebral aneurysm are infrequent Histopathology: scarce and mottled elastic fibers, no mineralization

ABCC6: Adenosine triphosphate-binding cassette, subfamily C, member 6; AR: Autosomal recessive; CV: Cardiovascular; EF: Elastic fiber; EM: Electron microscopy; PXE: Pseudoxanthoma elasticum.

(compared to fiber core mineralization in PXE). The diagnosis can be confirmed by *GGCX* sequencing[47].

Differential diagnosis

The differential diagnosis of PXE-syndrome is summarized in Table 3.

Management

The management of PXE-like patients is similar to that of patients with classic PXE. In most, treatment of the coagulation deficiency is not necessary, though the use of anticoagulants is not advised. In rare cases, supplementation with VK may be useful[47].

GENERALIZED ARTERIAL CALCIFICATION OF INFANCY

Generalized arterial calcification of infancy (GACI; OMIM#20800) is an early-onset, autosomal recessive disorder, which has only been described in approximately 100 mostly Caucasian patients[1,70]. The disease typically affects infants of less than 6 mo of age[71,72].

Clinical characteristics

GACI is characterized by arterial stenosis, resulting from myointimal proliferation of muscular arteries, and early-onset severe myocardial ischemia due to extensive deposition of hydroxyapatite in the inner elastic lamina of medium- and large-sized arteries[1,70,73]. Complications include myocardial infarction, hypertension and congestive heart failure, leading to early demise[1]. Other possible manifestations include dermatological and ophthalmological findings typical of PXE, extravascular (mostly periarticular) calcifications, hearing loss and development of hypophosphatemic rickets after infancy[49,70,71,74-77]. The majority of patients die before the age of 1, with the highest fatality rate in the first six months of life, most commonly due to myocardial infarction, congestive heart failure, multiple organ failure or persistent arterial hypertension[71,72]. Recently, Rutsch *et al*[71] reported a mortality rate of 55%, with a marked decrease in the mortality of patients, which survived the first 6 mo. In some of these, spontaneous resolution of the mineralization was seen[78,79].

Pathogenesis

GACI is caused by inactivating mutations in the *ENPP1* gene, which encodes ectonucleotide pyrophosphatase/phosphodiesterase 1. Under normal conditions, ENPP1 is associated with the outer plasma membrane of VSMCs in arteries and generates extracellular PPi through hydrolysis of ATP to adenosine monophosphate (AMP)[2]. PPi is a potent calcification inhibitor, which was already shown to hinder mineral crystal growth by binding to the crystal surface in osteoblast cultures[1,2,17].

Diagnosis

Neonates with GACI can present with rather aspecific symptoms, such as poor feeding and respiratory distress. Consequently the diagnosis is often only established by detecting arterial calcification using plain radiography, ultrasound or computed tomography. Typically, diffuse vascular and periarticular ectopic mineralization is found. GACI should be considered antenatally when ultrasonographic anomalies include arterial calcifications, hydrops, abnormal cardiac contractility and/or hyperechoic kidneys[80]. Confirmation of the diagnosis is possible through molecular analysis of the *ENPP1* gene which detects mutations in approximately 70% of cases[49,71,81,82]. When no mutations can be found in *ENPP1*, *ABCC6* sequencing should be performed, due to an overlap in the phenotypes of both diseases[70,73]. An arterial biopsy shows fragmentation in the integral elastic lamina with calcium deposition and fibrointimal hyperplasia causing luminal narrowing, which can occur in places devoid of mineralization[72,83]. Conversely, mineralization can occur without luminal narrowing[84]. Apart from calcium, the depositions also contain iron and mucopolysaccharides[84,85]. The lesions are surrounded by a giant cell reaction[86].

Differential diagnosis

The differential diagnosis of GACI is summarized in Table 4.

Management

The treatment options in GACI are limited and rely mostly on the use of bisphosphonates, such as etidronate and pamidronate, which are analogs of PPi. These bisphosphonates possibly act through decreasing bone turnover, inhibiting further growth of mineralized crystals and/or providing an alternative form of PPi that may influence the regulation of mineralization[91]. Vascular calcifications have been reported to disappear under bisphosphonate therapy within a variable time period (2, 5 wk to 2 years). Calcifications do not tend to reappear after cessation of the therapy, although arterial stenosis persists[92,93]. Since prolonged etidronate use in GACI

Table 4 Differential diagnosis of generalized arterial calcification of infancy[73,78,87-90]

Disease	Distinct differences with GACI
PXE (AR; *ABCC6*)	GACI-like phenotype possible, however infrequent CV phenotype usually less severe No onset in infancy Dermatological and ophthalmological phenotypes more prominent
Singleton-Merten Calcification (AD; unknown causal gene)	Dental anomalies (delayed eruption and early loss of permanent teeth, alveolar bone erosion) Osteopenia Acroosteolysis
Metastatic calcification due to hypervitaminosis D, hyperparathyroidism or end-stage renal disease	Different distribution of extravascular calcification (renal tubules, bronchial walls and basal mucosa and muscularis mucosae of the stomach) Microscopic vascular changes in media instead of intima
Congenital syphilis	Only calcification of the (ascending) aorta Diagnosed mainly in adults Hutchinson teeth, interstitial keratitis, saber tibiae, saddle-shaped nose Histopathology: endarteritis obliterans of vasa vasorum with perivascular plasma cells, lymphocytic cuffing and adventitial fibrosis
Iliac artery calcification in healthy infants	Only calcification in the common and internal iliac arteries

ABCC6: Adenosine triphosphate-binding cassette, subfamily C, member 6; AD: Autosomal dominant; AR: Autosomal recessive; CV: Cardiovascular; GACI: Generalized arterial calcification of infancy; PXE: Pseudoxanthoma elasticum.

patients has been linked to severe skeletal toxicity, bisphosphonate therapy should be closely monitored and according to some, should be stopped as soon as the calcifications have disappeared[94]. Nevertheless, the prognosis of patients remains poor with only few long-term survivors, the oldest GACI patient being 25[1,71,79,95]. Recently, Towler *et al*[96] suggested that restoring PPi levels by inhibition of alkaline phosphatase (ALP) and/or upregulation of vascular ENPP1 or ANKH-mediated secretion of intracellular PPi may serve as possibilities to limit vascular calcification.

KEUTEL SYNDROME

Since its first identification by Keutel *et al*[97] in 1971, approximately 30 cases have been described of Keutel syndrome (OMIM#245150), which is an autosomal recessive multisystem disease with an age of onset in childhood (5-15 years)[97,98].

Clinical characteristics

Keutel syndrome is mainly characterized by peripheral pulmonary stenosis, abnormal cartilage ossification or calcification of typically (para)tracheal, bronchial and rib cartilages as well as auricular and nose cartilage[99]. Less frequently soft tissue calcification, *i.e.*, of blood vessels, brain and kidneys, occurs[1]. Other clinical features include CV (ventricular septal defect, pulmonary artery hypoplasia, hypertension) respiratory (recurrent respiratory infections), skeletal (brachytelephalangism, typically sparing the 5th distal phalanx, height below the 25th percentile), neurological symptoms (subnormal intelligence quotient (IQ) in multiple cases) and recurrent otitis media causing inner ear or mixed deafness. Patients have a typical facial gestalt with mild midface hypoplasia, a depressed nasal bridge, small alae nasi and a deep philtrum[100-104]. A long-term follow-up of 4 sisters with Keutel syndrome showed that all clinical manifestations were progressive. Further, these patients developed skin lesions, *i.e.*, multiple erythematous, irregularly bordered macular lesions without induration, typically after the age of 30. Skin biopsy of these lesions failed to show calcification or ossification and loss of elastic fibers was only seen in the papillary dermis[99]. Nevertheless, the prognosis of Keutel syndrome is good in the majority of patients, with life expectancy mainly depending on the severity of the pulmonary complications[99].

Pathogenesis

Keutel syndrome is caused by loss-of-function mutations in the *MGP* gene, encoding matrix gla protein[1]. MGP is an inhibitor of the pro-osteogenic BMP2-Smad-RUNX2 pathway, by inhibiting BMP2 to bind to its receptor. Consequently, MGP, expressed in chondrocytes, functions as a local mineralization inhibitor under physiological conditions (Figure 1)[105,106]. Impairment of its inhibitory function favors pro-mineralizing signaling, leading to ectopic mineralization[98]. Moreover, Cranenburg *et al*[107] reported a patient in whom the levels of carboxylated/uncarboxlated MGP were very low, unresponsive to VK supplementation, but in whom high levels of phosphorylated MGP were found. Phosphorylation is a VK-independent posttranslational modification of MGP which may allow binding of calcium crystals in the absence of optimal carboxylation. It was hypothesized that this phosphorylation-dependent residual MGP activity might be sufficient to prevent development of arterial calcification[108].

Diagnosis

The majority of Keutel syndrome patients are diagnosed during childhood based on clinical presentation and radiographic examinations, with abnormal cartilage calcification and brachytelephalangism as major signs. The clinical diagnosis can be confirmed by sequencing of the *MGP* gene, in which to date 7 loss-of-function mutations have been reported[98,104,109].

Differential diagnosis

The differential diagnosis of Keutel syndrome is summarized in Table 5.

Management

No etiologic treatment exists for Keutel syndrome, hence management is merely symptomatic, including

Figure 4 Transverse computed tomography of the brain displaying symmetrical bilateral ganglia calcification in an idiopathic basal ganglia calcification patient.

(angiographic) dilatation of peripheral artery stenosis and bronchodilating agents for respiratory symptoms (dyspnea and wheezing); the latter however can be inefficient in certain patients[99,108]. Most patients develop hypertension before the age of 20, which can be treated with antihypertensive medication such as perindopril, amlodipine or nifedipine[99].

IDIOPATHIC BASAL GANGLIA CALCIFICATION

Idiopathic basal ganglia calcification (IBGC) is a rare neurodegenerative disorder with unknown prevalence. The disease is sometimes referred to as Fahr's disease, although the the patient Fahr described primarily had mineralization in blood vessels of the white matter of the brain[113]. IBGC affects young to middle aged adults, with an average onset in the 3rd or 4th life decade; however the disease has also been described in childhood[114-116].

Clinical characteristics

IBGC is characterized by bilateral and (almost) symmetrical basal ganglia calcifications (Figure 4)[116]. Ectopic mineralization may also occur in other brain regions, including the nucleus dentatus, thalamus, cerebral cortex and centrum semiovale[116,117]. Neurological symptoms include neuropsychiatric (cognitive impairment, depression, hallucinations, delusions, manic symptoms, anxiety, schizophrenia-like psychosis, personality changes) and movement disorders (*a.o.* parkinsonism, ataxia due to cerebellar involvement, tremor and paresis), as well as headache, vertigo, stroke-like events, orthostatic hypotension, dysarthria, seizures and papilledema due to raised intracranial pressure[116,118]. Both sporadic and familial IBGC cases have been reported, the latter predominantly with autosomal dominant inheritance[116].

Pathogenesis

To date, mutations in 3 genes have been associated with IBGC, *i.e.,* solute carrier family 20 (phosphate transporter), member 2 (*SLC20A2*; OMIM*158378), the beta polypeptide of platelet-derived growth factor (*PDGFB*; OMIM*190040) and platelet-derived growth factor receptor, beta (*PDGFRB*; OMIM*173410). So far, no genotype-phenotype correlation has been found[119]. The *SLC20A2* gene, encoding a Pi transporter (also known as PiT2 which belongs to the type III sodium-dependent phosphate transporter family), is expressed abundantly in a variety of tissues and likely plays a housekeeping role in cellular phosphate uptake (Figure 1)[119,120]. Mutations in the gene have been described in more than 40 IBGC families worldwide and *in vitro* resulted in impaired Pi transport, leading to accumulation of this pro-mineralizing factor[119,121,122].

More recently, a few IBGC patients were reported harboring mutations in *PDGFB* or *PDGFRB*[123-128]. In animal models, *Pdgfrb* has been identified as an essential mediator in the development of pericytes in brain vessels, which have a key role in the maintenance of the blood-brain barrier (BBB). The BBB is hypothesized to be defective in IBGC[123]. Moreover, Villa-Bellosta *et al*[129] found that the PDGFB-PDGFRB pathway seems to be involved in phosphate-induced calcifications in VSMCs by downregulating SLC20A2. All these data suggest that cerebral phosphate homeostasis plays a role in the development of vascular mineralization[129]. The mineralization generally develops within the vessel wall and in the perivascular space, ultimately extending to the neuron. Upon progression, the calcifications start to compress the vessel lumen, which causes impaired blood flow, starting off a vicious circle with further neural tissue damage and mineral deposition. The mineral depositions tend to vary in composition according to

Table 5 Differential diagnosis of Keutel syndrome[98,110-112]

Disease	Distinct differences with Keutel Syndrome
X-linked chondrodysplasia punctata (XL; *ARSE* gene)	Ichtyosis Cataracts Microcephaly, intellectual disability ASD, VSD, PDA Failure to thrive in infancy Age at diagnosis: usually infancy
Warfarin embryopathy	Pectus carinatum Congenital heart defects different from those seen in Keutel syndrome (ASD, PDA, ventriculomegaly)
Combined Vitamin K-dependent coagulation factor deficiency	Easy bruising, mucocutaneous bleeding Osteoporosis with normal serum markers
Relapsing polychondritis	Age at diagnosis: 40-60 yr Cartilage inflammation, possibly progressing to destruction Aortic or mitral valvular disease Facies: saddle nose deformity, multifocal, tender chondritis, including variably floppy or calcified auricles Cranial neuropathies, hemiplegia

ARSE: Arylsulfatase E; ASD: Atrial septal defect; PDA: Patent ductus arteriosus; VSD: Ventricular septal defect; XL: X-linked.

Table 6 Differential diagnosis of idiopathic basal ganglia calcification[116,140-143]

Disease	Distinct differences with IBGC
Basal ganglia calcification as incidental finding on CT scans/ aging	In 1% of CT scans Usually benign No clear etiology, especially when in older patients Asymptomatic
Hypoparathyroidism	Early onset: childhood/adolescence Hypoparathyroidism, hypocalcemia, hyperphosphatemia Alopecia, dry hair Dental dysplasia, caries Moniliasis Albright osteodystrophy symptoms (short stature, round facies, obesity, short metacarpals/metatarsals)
Pseudohypoparathyroidism (AD/maternal imprinting; *GNAS*, *GNASAS1* and *STX1A* gene)	Early onset: childhood/adolescence Hyperparathyroidism, hypocalcemia, hyperphosphatemia Baseline cAMP in urine low; after Ellsworth Howard test subnormal Intellectual disability Albright osteodystrophy symptoms
Pseudo-pseudohypoparathyroidism (AD/paternal imprinting; *GNAS* gene)	Similar phenotype as pseudohypoparathyroidism Normal serum PTH, calcium and phosphorus Intellectual disability (more obvious than in PHP)
Kenny-Caffey syndrome, type 1 (AR; *TBCE* gene)	Growth delay Cortical thickening of long bones Hypocalcemia, hypoparathyroidism
PKAN (AR; *PANK2* gene)	Early onset (10% > 10 yr) Pigmentary retinopathy
DRPLA (AD; CAG expansion in *DRPLA* gene)	Phenotype similar to IBGC
Neuroferritinopathy (AD; *FTL* gene)	Dysphagia
PLOSL (AR; *TYROBP* and TREM2 gene)	Radiography: polycystic osseous lesions Frontal lobe syndrome
Cockayne syndrome; Aicardi-Goutières syndrome	Onset in infancy/early childhood

AD: Autosomal dominant; AR: Autosomal recessive; CAG: Cytosine, adenine, guanine; cAMP: 3'-5'-cyclic adenosine monophosphate; CT: Computed tomography; DRPLA: Dentatorubropallidoluysian atrophy; *FTL*: Ferritin light chain; *GNAS*: GNAS complex locus; *GNASAS1*: GNAS complex locus, antisense transcript 1; IBGC: Idiopathic basal ganglia calcification; PANK2: Panthothenate kinase 2; PHP: Pseudohypoparathyroidism; *PKAN*: Panthothenate kinase-associated neurodegeneration; PLOSL: Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy); PTH: Parathyroid hormone; STX1A: syntaxin 1A; *TBCE*: Tubulin-specific chaperone E; TREM2: Triggering receptor expressed on myeloid cells 2; *TYROBP*: Tyro protein tyrosine kinase-binding protein.

their anatomical site and the proximity to vasculature calcifications, containing components such as calcium phosphate and carbonate; other compounds including glyconate, mucopolysaccharide and metals (iron, copper, magnesium, zinc, aluminum, silver and cobalt) may also be found[116]. Abnormal iron metabolism in IBGC has been described in a single case, showing elevated serum ferritin, reduced levels of serum iron and iron-binding capacity. At autopsy iron depositions were found in the liver, the spleen, the bone marrow and the brain[130]. More recent reports confirm abnormalities in metal metabolism (iron, copper, zinc), although there is no consensus whether the metal levels are elevated (cerebrospinal fluid) or reduced (hair) in IBGC patients[131,132].

Diagnosis

IBGC diagnosis is supported by the following criteria: (1) bilateral calcification of basal ganglia; (2) progressive neurologic dysfunction; (3) absence of biochemical abnormalities; (4) absence of infectious, traumatic or toxic cause; and (5) a significant family history (although sporadic IBGC cases have also been described)[116].

However, the diagnosis can only be established by obtaining a computed tomography (CT) or magnetic resonance imaging (MRI) scan of the brain, showing bilateral, almost symmetric calcifications of one or more of the affected brain regions, and ruling out other abnormalities (showing bilateral basal ganglia calcifications, and developmental defects)[116,133-136]. Other possible investigations, which are typically normal in IBGC patients, include blood and urine testing for hematologic and biochemical (ALP, serum creatinine, osteocalcin, serum lactic acid at rest and after exercise, 1,25-dihydroxyvitamin D_3, serum calcium, phosphorus, magnesium, calcitonin, heavy metals and parathyroid hormone (PTH)) parameters and an Ellsworth Howard test (showing a 10-20 fold increase of urinary 3'-5'-cyclic AMP (cAMP) after stimulation with 200 U of PTH)[116,137-139]. Neurological tests are usually normal (electroencephalography, nerve conduction studies, pattern shift visual-evoked potential studies) or show mild abnormalities (brainstem auditory-evoked potentials)[116].

Genetic testing can confirm the IBGC diagnosis. Sequencing of *SLC20A2* is the first choice, as well as deletion/duplication analysis if no mutation is found, with a mutation detection rate of 40%. If no mutations are found, *PDGFRB* and *PDGFB* sequencing can be performed; the precise mutation detection rate is currently unknown. If no molecular confirmation can be obtained, other (genetic) causes of brain calcification should be considered (Table 6), before establishing a clinical diagnosis of IBGC[116].

Differential diagnosis

Symmetrical calcifications of the basal ganglia are not specific to IBGC and a variety of familial and non-familial conditions should be considered. It should be noted that these calcifications can also be incidental findings on CT scan, especially in older individuals (Table 6)[116,140].

Treatment

Since no etiologic treatment is available, management and treatment options focus on symptomatic relief[116,117,120]. Pharmacologic treatment (*e.g.*, anxiolytics

and antidepressants) for the psychiatric and movement symptoms can be attempted[117,120]. Possibly, an early causative treatment may reverse the calcification process, causing complete recovery of mental functions, which was already described in hypoparathyroidism, another basal ganglia causing disorder, provided that an intervention target can be identified[116].

ARTERIAL CALCIFICATION DUE TO CD73 DEFICIENCY

Arterial calcification due to CD73 deficiency (ACDC), also referred to as calcifications of joints and arteries, is an autosomal recessive disease, which usually takes an onset in young adulthood[16,144].

Clinical presentation

ACDC is mainly characterized by prominent and often symptomatic calcification of the large arteries of the lower extremities (iliac, femoropopliteal and tibial arteries), typically sparing the coronary circulation[16,144]. Furthermore, periarticular calcifications of (large and smaller) joints of the lower extremities have been described[144]. Typical symptoms include claudication, hemodynamically significant peripheral obstructive artery disease of the lower limbs, joint swelling and pain[144]. The disease seems relatively rare, being only reported in 3 Caucasian families[144,145].

Pathogenesis

To elucidate the molecular etiology of ACDC, genome-wide homozygosity mapping was performed in three families, revealing homozygous and compound heterozygous loss-of-function mutations in the *NT5E* gene[144,145]. *NT5E* encodes the glycosyl phosphatidylinositol (GPI)-linked plasma membrane CD73 ecto-enzyme, which has 5' ectonucleotidase activity and thus converts AMP to extracellular adenosine and Pi[146]. The enzyme is located on the plasma membrane of vascular cells, supplying adenosine to cell surface receptors[145]. Adenosine is produced immediately downstream of ENPP1 in the extracellular ATP-degradation pathway on the surface of vascular cells, and a lower adenosine level leads to impaired inhibition of TNAP[16,144]. St Hilaire *et al*[144] hypothesized that increased TNAP activity reduces PPi levels, allowing calcification to occur (Figure 1). Since the vascular calcification in ACDC seems to be limited to the lower extremities, it is likely that members of other ectonucleotidase families, such as ectonucleoside triphosphate diphosphohydrolase 1 or CD39 (*ENTPD1*; OMIM*601752) and its isoforms or cardiac ectonucleoside triphosphate diphosphohydrolase 6 or CD39L2 (*ENTPD6*; OMIM*603160) (members of the ectonucleoside triphosphate diphosphohydrolase (E-NTPDase) family), may compensate NT5E activity in other vascular beds[16,147]. An alternative explanation for this predilection may be the particular distribution of adenosine receptors in these vascular beds[148].

Diagnosis

An ACDC diagnosis can be established based on clinical presentation and a full radiographic workup of the patients, as well as determination of the ankle-brachial index, which should be reduced. Plain radiography can visualize the vessel calcifications; magnetic resonance angiography and especially CT angiography can show diffuse and gross calcification of obstructing lesions. Biochemical indices, including serum electrolytes, cholesterol and vitamin D-levels, PTH, C-reactive protein, rheumatoid factor and erythrocyte sedimentation rate should all be normal. The clinical suspicion can be confirmed by *NT5E* sequencing[144].

Differential diagnosis

Other - often not - hereditary causes of vascular calcification have to be excluded, *e.g.,* diabetes mellitus type 2 and impaired renal function[144]. Since joint swelling and pain was present in all three described families, rheumatologic diseases should also be excluded[144].

Management

Because of the rarity of the disease, no treatment guidelines are available. Bisphosphonates, which were proven to be successful in GACI, possibly by restoring PPi levels, may also be a good treatment option in ACDC[91,144]. Adenosine deficiency could be addressed using dipyridamole, which inhibits its cellular reuptake *in vitro* and *in vivo*. Other possible therapeutic options include adenosine receptor agonists or direct TNAP inhibitors (*e.g.,* lansoprazole), all of which need to be further investigated[144].

HYPERPHOSPHATEMIC FAMILIAL TUMORAL CALCINOSIS

Contrary to the disorders described above, autosomal recessive hyperphosphatemic familial tumoral calcinosis (HFTC; OMIM#211900), is characterized by metastatic mineralization[1,149]. Patients usually show first signs in the first or second decade of life[150].

Clinical characteristics

The most prominent clinical manifestation of HFTC is periarticular mineralization of the skin and subcutaneous tissue, mainly affecting the upper limbs and hip regions, although involvement of other localizations (spine, temporomandibular joints, metacarpals/metatarsals and popliteal space) have also been reported[151]. The calcium salt depositions usually present as firm painful tumorlike masses, which may gradually enlarge over a period of years, causing functional problems including restricted joint mobility[149,151]. Complications of the overlying skin, including pain, infection and ulceration, can cause scarring and deformity[1,149,151]. Other possible manifestations of the disorder are dental abnormalities and retinal AS[152].

Pathogenesis

HFTC can be caused by mutations in UDP-N-acetyl-alpha-D-galactosamine: polypeptide N-acetylgalactosaminyltransferase 3 (*GALNT3*; OMIM*601756), fibroblast growth factor 23 (*FGF23*; OMIM*605380) or klotho (*KL*; OMIM + 604824), all of which are key regulators of the phosphate metabolism[1]. GALNT3 protects intact FGF23, a phosphaturia-causing protein, from proteolytic processing by O-glycosylation of Threonine residue 178 in a subtilisin-like proprotein convertase (SPC) recognition sequence motif. In this way, FGF23 is activated and enabled to secrete from the cell, while this glycosilation also competitively inhibits proteolytic FGF23 cleavage by proteases. Hence, this glycosylation step is proposed to be a post-translational regulatory model. In the presence of (nonsense/missense/splice-site) *GALNT3* mutations, intact FGF23 is cleaved prior to secretion which leads to an accumulation of fragmented FGF23 and a reduced amount of active FGF23, causing hyperphosphatemia[153,154]. In physiological conditions FGF23 binds to the FGF receptor 1, of which KL, a β-glucuronidase, is an important co-receptor, inducing high affinity interaction between FGF23 and its receptor. This activates the further downstream effects of this pathway, including the maintenance of serum phosphate levels within the normal range by increasing renal phosphate excretion and both a reduction of synthesis rate and acceleration of the degradation of 1,25-dihydroxyvitamin D_3 to reduce intestinal phosphate absorption (Figure 1)[155,156]. Moreover, KL works independently from FGF23 as an enzymatic inhibitor of renal NaPi-2a (sodium/phosphate cotransporter) transporter activity - which requires glucuronidase activity, subsequent proteolytic degradation and possibly internalization of the transporter - eventually leading to reduced renal expression of the transporter[157]. FGF23 fulfills its biological functions in a tissue-specific way, which is likely to be regulated by the limited local distribution of KL[155]. Inactivating mutations in FGF23 as well as missense mutations in KL cause FGF23 deficiency. Consequently renal phosphate reabsorption and 1,25-dihydroxyvitamin D_3 synthesis is increased, leading to elevated serum concentrations of phosphate, 1,25-dihydroxyvitamin D_3 and calcium and ectopic mineralization[155].

Diagnosis

Next to clinical examination and family history, the diagnosis of HFTC is mainly based on a full radiographic workup: (1) Plain radiographs show the typical appearance of periarticular amorphous, multilobulated and cystic calcifications[158]; (2) CT, showing cystic loculi with fluid-fluid levels caused by calcium layering; (3) MRI imaging, showing lesions of inhomogeneous intensity, help to document the extent and interconnectivity of individual lesions and can help to determine possible surgical approaches; (4) scintigraphy, using a phosphate compound radiolabel (technetium-99m methylene diphosphonate) is helpful in determining the activity level of the disease; and (5) ultrasonography can help to localize fluid collections[149]. A typical feature of HFTC is the absence of erosion/bone destruction by adjacent soft-tissue masses[149]. Biochemically, hyperphosphatemia with normocalcemia, normal or slightly elevated 1,25-dihydroxyvitamin D_3, hypoparathyroidism and low intact FGF23 proteins levels can be found[152]. A biopsy should be avoided, because of the risk of an infection and should only be done as a last resort. Histopathology shows that mineralization depositions fill up the cystic loculi (active stage), which causes them to become encapsulated by fibrous tissue, eventually ending the mineralization process (relative latent stage)[150].

Differential diagnosis

The differential diagnosis of HFTC is summarized in Table 7.

Management

HFTC should be treated according to the location, size of the lesion and its relations to its environment. A first treatment option is medically reducing hyperphosphatemia through phosphate depletion, by dietary phosphorus restriction and/or the administration of phosphate binding chelating agents such as aluminum hydroxide. This method has a variable success rate, both in normo- and hyperphosphatemic cases. When combined with acetazolamide, which induces phosphaturia, a synergistic effect occurs, especially in the hyperphosphatemic form of familial tumoral calcinosis[149].

A second treatment option is early surgical resection of the lesions; however a considerable recurrence rate of the lesions, which have the tendency of growing faster, poses a major problem. Therefore it is very important that resections contain the lesion, and preferably should contain a wider perilesional area/band, including the hypervascular region beyond the periphery of the lesion. Broad resections can cause problems in case of voluminous lesions, which may require extensive reconstructive surgery[149]. Surgery is indicated when lesions are painful, recurrently infected, ulcerated or when functional impairment occurs[149]. Surgical complications include: (1) prolonged drainage of the wound, possibly leading to delayed wound healing and sinus tract formation; (2) secondary infections due to chronic wound problems, especially when the disease is extensive or when resection is incomplete; and (3) recurrence, which is more frequently seen after incomplete resection[167].

During the active stage of the disease, primary medical treatment of HFTC is justified and may even be recommended, because the postresection recurrence rate of lesions is even higher in this stage. In the relative latent stage, encapsulation occurs which hinders ion exchange, thus making surgery more advantageous[149]. Alternative treatment options, including steroids,

Table 7 Differential diagnosis of hyperphosphatemic familial tumoral calcinosis[149,151,158-166]

Disease	Distinct differences with HFTC
Calcinosis universalis	Calcium depositions in tendons and muscle tissues Normophosphatemia High hemosedimentation Microcytic and hypochromic anemia
Calcinosis circumscripta	Adult onset Local calcinosis Fingers symmetrically affected
Calcific tendinitis	Adult onset Calcification limited to tendons
Synovial chondromatosis	Lesions arising from synovial tissue Widespread throughout the body Not all lesions are calcified
Osteosarcoma	Long bone malignant tumor 2nd life decade or late adulthood No subcutaneous/skin lesions
Fibrodysplasia ossificans progressiva (AD; *ACVR1* gene)	Hallux valgus, monophalangism and/or malformed first metatarsal Sporadic episodes of painful soft tissue swellings (flare-ups) in 1st life decade
Tophaceous gout	Severe form of gout Severe joint deformity, chronic pain and functional decline More prominent in Asian population (slow metabolizers) and in young men with strong genetic predisposition
Calcific myonecrosis	Post-traumatic (time interval of several years possible) Lower limbs only
NFTC (AR; *SAMD9* gene)	Reddish-to-hyperpigmented skin lesions during the first year of life (preceding calcified nodules) Severe conjunctivitis and gingivitis Normophosphatemia
Secondary tumoral calcinosis	Renal insufficiency, hyperparathyroidism, or hypervitaminosis D
Rheumatological diseases	Usually normophosphatemia and - calcemia Possibly positive results in antinuclear, anti-Smith, anti-centromere and anti-scleroderma antibodies, which should all be negative

ACVR1: Activin A receptor, type 1; AD: Autosomal dominant; AR: autosomal recessive; HFTC: Hyperphosphatemic familial tumoral calcinosis; NFTC: Normophosphatemic familial tumoral calcinosis; SAMD9: Sterile alpha motif domain-containing protein 9.

bisphosphonates, calcitonin and radiotherapy, have not been proven to be effective[149].

CONCLUSION

Ectopic mineralization disorders comprise a wide range of heterogeneous diseases, which can affect a variety of tissues, causing important health problems. Insights in the mechanisms that cause these diseases have led to the observation that many - if not all - are closely related to one another from a mechanistic point of view. The considerable differences in clinical presentation and natural course however suggest that our current knowledge is merely the proverbial tip of the iceberg and that the subtle mechanisms which render each disease to be unique are still largely to be uncovered. Nevertheless, the pathophysiological knowledge to date has already led to several successful treatment options and a number of promising targets for the future. As such, ectopic mineralization diseases are a fine example for the interaction between the variome and the phenome.

Abstract

Quorum sensing (QS) is cell communication that is widely used by bacterial pathogens to coordinate the expression of several collective traits, including the production of multiple virulence factors, biofilm formation, and swarming motility once a population threshold is reached. Several lines of evidence indicate that QS enhances virulence of bacterial pathogens in animal models as well as in human infections; however, its relative importance for bacterial pathogenesis is still incomplete. In this review, we discuss the present evidence from *in vitro* and *in vivo* experiments in animal models, as well as from clinical studies, that link QS

systems with human infections. We focus on two major QS bacterial models, the opportunistic Gram negative bacteria *Pseudomonas aeruginosa* and the Gram positive *Staphylococcus aureus*, which are also two of the main agents responsible of nosocomial and wound infections. In addition, QS communication systems in other bacterial, eukaryotic pathogens, and even immune and cancer cells are also reviewed, and finally, the new approaches proposed to combat bacterial infections by the attenuation of their QS communication systems and virulence are also discussed.

Key words: Quorum sensing; Virulence; Infections; *Pseudomonas aeruginosa*; *Staphylococcus aureus*; Animal models

Core tip: In this manuscript we discuss the basics aspects of quorum sensing (QS) and its relationship with human infections, focusing in two major QS bacterial models, the opportunistic Gram negative bacteria *Pseudomonas aeruginosa* and *Staphylococcus aureus*.

INTRODUCTION

Several important bacterial pathogens, like *Pseudomonas aeruginosa* (*P. aeruginosa*), *Staphylococcus aureus* (*S. aureus*), and *Vibrio cholerae,* utilize quorum sensing (QS) cell communication to coordinate the expression of multiple virulence factors and associated behaviors such as swarming and biofilm formation, once a population size threshold is reached. QS systems consist of an enzyme that catalyzes the synthesis of the signal (such as acyl-homoserine lactones or cyclic peptides) and a receptor that binds the signal and reprograms the expression of several genes, including those encoding the enzyme that produces the signal, creating a positive feedback loop. In bacterial pathogens, most of the QS controlled genes codify several different virulence factors, such as proteases, toxins, and adhesins[1]. The expression of QS controlled phenotypes is energetically costly to the cells and only provides an advantage if it is expressed when cells reach high densities[2,3]; hence, in the context of bacterial infections, the expression of QS regulated virulence factors is delayed until a sufficient bacterial load is achieved and once this threshold is reached, bacteria coordinate their attack against the host, which maximizes the probability of establishing the infections and disseminating them, hence increasing the pathogen fitness. In fact, QS along with subversion of the immune system are the main factors that determine the bacterial infectious doses. Hence those bacterial pathogens that need small doses to infect, generally lack QS systems but are very effective at inactivating the immune response by killing professional phagocytes. In contrast, those bacterial pathogens that need high infectious doses rely in QS for the coordination of the expression of virulence[4]. In this review, the current knowledge about QS control of virulence factors in two main model bacterial pathogens, *P. aeruginosa* and *S. aureus* (which are also responsible for nosocomial and wound infections), will be discussed along with the relationship of their QS systems, its virulence in animal infection models, and the data available from human infections. Furthermore, the role of QS in other important infections and the role of QS in immune and cancer cells are discussed. Finally, proposed novel approaches of blocking QS/virulence as an alternative in fighting recalcitrant bacterial infections are also reviewed.

QS-CONTROLS OF THE EXPRESSION OF VIRULENCE FACTORS *IN VITRO*

P. aeruginosa

P. aeruginosa possesses at least three functional QS circuits; two of them are mediated by N-acyl homoserine lactones (HSL) signals and the other mediated by quinolones (Figure 1). The HSL-QS systems were first described and they were named after the virulence factors that were first identified under their control; hence, the Las system was discovered as a positive regulator for elastase production through the expression of the structural elastase gene lasB[5]. This system (by LasI HSL-acyl-synthase) produces the 3-oxo-C12-homoserine lactone (3-oxo-C12-HSL), that binds its receptor LasR which then dimerizes and binds promoters that contain *las* boxes, turning on the expression of several genes, including lasI, which then in a positive feedback loop increases the production of *3*-oxo-*C*12-HSL, the other HSL mediated QS system was named Rhl since it controls the expression of the biosurfactant rhamnolipids[6]. This system (RhlI) produces N-butyryl-L-homoserine lactone that is sensed by RhlR and also shows positive autoregulation[7]. The third QS system is mediated by different kinds of signals, alkyl quinolones, specifically 2-heptyl-3-hydroxy-4-quinolone(Pseudomonas quinolone signal or PQS) which is synthesized from anthranilate by the products of *pqsABCDEH* genes and sensed by PqsR (MvfR)[8,9]. The three systems are interconnected and function in a hierarchical way[10]; the Las system is the first to become activated, and it in turn it stimulates the Rhl and PQS systems[11,12], while PQS activates Rhl[13] and RhL inhibits PQS[11,14]. Moreover, 3-oxo-*C*12-HSL, the Las signal, is able to bind functional

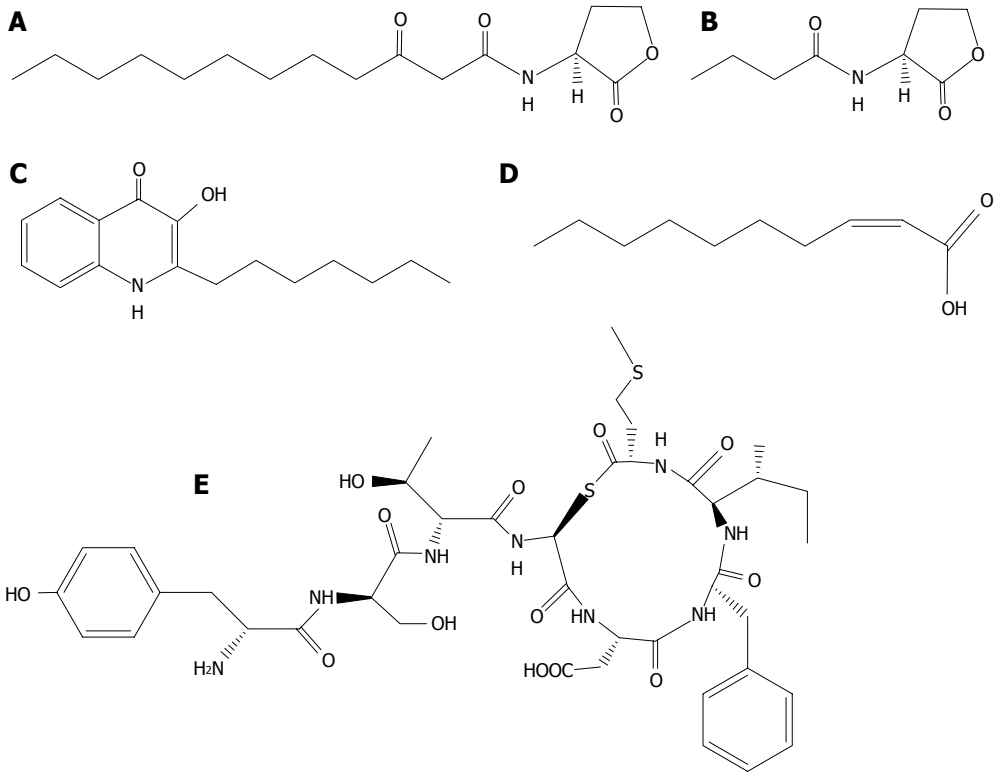

Figure 1 Structures of representative quorum sensing signal molecules of *Pseudomonas aeruginosa*. A: 3-oxo-C12-homoserine lactone; B: N-butyryl-L-homoserine lactone; C: 2-heptyl-3-hydroxy-4-quinolone; D: DSF-like fatty acids, cis-2-decenoic acid) and *S. aureus* (E: AIP group I).

RhlR dimmers, promoting their dissociation and inactivation[15]. In addition to control *lasB* elastase, the Las system also controls the expression of *lasA* elastase, exotoxin A (PA1148), and alkaline protease (PA1246)[16], and the Rhl also controls the expression of the phenazine pyocyanin a pigment able to cause oxidative damage to the eucaryotic host, promoting the production of reactive oxygen species and depleting the host antioxidant defense mechanisms[17], while the PQS system increases the expression of *lasB* elastase and pyocyanin[9]. In fact, the regulation of virulence factors by these 3 QS systems is complex and often overlaps[18]; for example, RhlR is apparently enough to compensate the absence of LasR at least in stationary phase cells in which it promotes the production of exoproteases, pyocyanin, PQS, and the 3-oxo-*C*12-HSL[18,19]. To add even more complexity, recently the role of environmental signals, such as the availability of iron and phosphate in influencing QS systems has been beginning to be explored[20]. In addition, other ions such as calcium strongly influence the production of QS modulated virulence factors such as pyocyanin, and proteases[21] and in fact there is solid evidence that indicates that the chemical composition of the sputum in cystic fibrosis patients promotes the use of the PQS system for communication, preferentially over the HSL systems[22]. Moreover the presence of metabolites like 2,3-butanediol (end product of bacterial fermentation from species that coexist with *P. aeruginosa* in the lung of cystic fibrosis patients) enhance the production of QS controlled virulence factors (phenazines and exotoxin) and improve biofilm formation *via* the Las QS system[23]; hence, the expression of QS-virulence factors *in vivo* is likely influenced by several variables, related with the state of the host as well as the presence or absence of other bacterial species. Indeed, the simultaneous utilization of several QS systems in bacteria, may serve different purposes like identifying community composition[24] or distinguish phases in population development[25], and a recent study shows that the concomitant utilization of Las and Rhl systems allows *P. aeruginosa* to simultaneously assess their population density and the presence of nutrients by combinatorial communication. Therefore, the secretion of QS controlled factors is subjected to "AND-gate" like responses to multiple signal inputs, allowing effective expression of secreted factors in high-density and low mass-transfer environments[26]. Another important role of QS systems in regulating bacterial physiology is that they are implicated in the tolerance against stress[27-29] that allow them to maximize their chances to effectively contend and survive the immune system attack[30], which may be a major determinant for the establishment and progression of *P. aeruginosa* and other pathogens infections.

S. aureus

S. aureus produces several virulence factors and many

of them are regulated by QS. In Gram positive bacteria, regulation by QS is generally mediated by autoinducing cyclic peptides. Specifically for *S. aureus,* QS controls the expression of virulence factors such as hemolysins, leukocidins, cell surface adhesins, exoenzymes, and biofilm formation *via* the Agr system, which relies on the autoinducing peptide (AIP) (Figure 1E). AIPis encoded by *agrD* and consists of 7-9 amino acids, and has a 5-membered thiolactone ring[31-33]; this peptide is secreted by the membrane protein AgrB and activated by the AgrC sensor kinase[1]. The Agr system regulates the expression of several genes by the production of two regulatory RNAs, RNAII and RNAIII[34], which are produced from promoters P2 and P3 respectively[34,35]. Transcription from the *agr* operon (*agrA*, *agrB*, *agrC* and *agrD*) is regulated by a phosphorylated AgrA homodimer from P2[36], while RNAIII is produced by AgrA from P3. RNAIII, which is the effector of the system, upregulates *α*-haemolysin, and increases the production of proteases, toxins, and the synthesis of capsule, while it repress protein A (which allows *S. aureus* to evade opzonization), and the expression of surface adhesions[1,31,34,35,37,38]. Such modulation of the expression of several virulence factors by the Agr system allows *S. aureus* to express a different repertoire of those determinants according to the kind of disease and the environmental conditions including the host status. Noteworthy is that *in vitro* the appearance of clones with diminished QS had been observed; these clones are apparently social cheaters which exploit cooperative individuals without contributing with the production of virulence factors. The presence of cheaters during infections may be very relevant for disease progression, since in controlled experiments, the ratio between cheaters and cooperating individuals strongly affects the mortality rate and extent of infection; *i.e.*, the severity of the infections are inversely proportional to the percentage of cheaters in the population[39]. Among the QS-controlled virulence factors in *S. aureus*, RNAIII is very important since it regulates biofilm formation, and resistance to antibiotics as well as the establishment of chronic infections is intimately related to the biofilm formation abilities of pathogens[40]. However, the *in vivo* biofilms in which *S. aureus* exists can be very complex environments, due the presence of several other bacterial species and their multiple interactions with each other and with the host, hence *in vitro* models for studying *S. aureus* virulence may have the disadvantage of not revealing the real expression of virulence factors. This hypothesis is supported by significant differences in the expression of several virulence factors in *S. aureus* grown in calf serum compared with those grown in defined CDM medium, since in serum the expression of hemolysins, enterotoxins, proteases, iron acquisition factors, and of RNAIII is significantly higher than in standard growth medium, and such differences are partially due the low iron concentration in serum[41,42].

QS-CONTROLS OF THE EXPRESSION OF VIRULENCE FACTORS *IN VIVO P. AERUGINOSA* QS AND VIRULENCE IN ANIMAL MODELS

A number of animal models including the nematode (*Caenorhabditis elegans*), fruit fly (*Drosophila melanogaster*), zebrafish (*Danio rerio*) and mouse (*Mus musculus*), have been used to identify and define the role of virulence determinants in the pathogenesis of *P. aeruginosa*[43,44]. The attenuation of its QS is achieved by two basic strategies: (1) the utilization of mutant strains with QS genes disrupted; and (2) the quenching of QS by treatments that interfere with it; these methods have shown that QS systems as well as QS-independent virulence determinants are required for *P. aeruginosa* infections in animals.

The main animal model that was used to discover the relationship between QS and virulence of *P. aeruginosa* is the nematode *C. elegans*. In 1999 Tan and coworkers, first described conditions to test the role of QS in virulence using this model, showing that the reference strain PA14 kills the nematode either after days (slow killing) or quickly after a few hours (fast killing)[45]. Their evidence indicate that fast and slow killing occur by distinct mechanisms; the slow killing involves an infection-like process and correlates with accumulation of PA14 within worm intestines, while the fast killing is mediated by the production of phenazines(regulated by QS); that increase active oxygen species[45,46]. A third mode by which *P. aeruginosa* can kill *C. elegans is lethal paralysis; this mechanism is mediated by QS since* Darby and coworkers, using QS-less mutant strains of *P. aeruginosa*, found that the lethal effect is associated with a rapid neuromuscular paralysis, caused by the action of diffusible unidentified factors whose production requires the *las* and *rhl* genes, since the infection with a *lasR* mutant and with a *rhlR* reduces the paralysis (by 28%-100% and 100% respectively)[47]. A potential target of these diffusible factors is the EGL-9 worm protein, which is expressed in the neuronal muscle tissues[47]. In a recent study, a reduction of 83% in the death of the nematodes by the double mutant (PA14*rhlRlasR*) was reported; however, the analysis of individual mutants, revealed that only the *rhlR* mutant reduced death 69%, implying that the RhlR system is crucial for infection under their experimental conditions[48]. In addition to lethal paralysis and slow and fast killing, a fourth kind of *C. elegans* death induced by *P. aeruginosa* is the "red death", characterized by the formation of red precipitate (PQS + Fe^{3+} complex) within the intestine of the nematodes. This mode of death is mediated by the quinolone dependant QS system Mvfr-PQS in coordination with the PhoB phosphate sensor and the pyoverdine iron acquisition system[49]. The role of QS in *P. aeruginosa* infectivity and virulence in *C.*

elegans is also evidenced by the effect of QS inhibitors, since a synthetic analog of HSL, meta-bromo-thiolactone (Figure 2A) that partially inhibits *in vitro* the LasR and RhrlR systems also reduces the death of worms infected with PA14, to 60% at 24 h. Interestingly, the *in vivo* action of the quencher in the worm model occurs mainly through the RhrlR system[48]. Moreover, phenylacetic acid (Figure 2B), which is a byproduct of the degradation of antibiotics such as penicillin G and cephalosporin Gby G acylase[50], increases the survival of PAO1 infected nematodes by 53%, while untreated worms die within 72 h. This protective activity is perhaps a consequence of interfering with the LasR and RhrlR systems, due to the structural similarity of phenylacetic acid with salicylic acid, a quorum quencher[51]. Another compound,2,5-piperazinedione (Figure 2C), increases the survival of worms by 66%, compared to untreated ones, and it was shown by molecular docking that it interacts with an amino acid residue (E145) in LasR, which is required for correct binding of the natural HSL ligand[52]. Similarly cucurmin (Figure 2D), a secondary metabolite from *Curcuma longa,* increases the survival of worms by 28%; this compound decreases the expression of genes involved in biofilm formation and attenuates HSL production in PAO1. Thus, it was suggested that it may act as a quorum quencher, delaying the synthesis of HSL molecules or by impairing autoinducers perception[53]. Moreover, various enzymes that degrade natural autoinducers are able to decrease the pathogenicity of *P. aeruginosa*; for example, adding the purified acylase PvdQ to *C. elegans* infected with *P. aeruginosa* PAO1, strongly reduces their pathogenicity and increases the nematodes life span[54]. Although the utilization of *C. elegans* as a model for studying *P. aeruginosa* infections has been very fruitful, recently it was proposed to use the fruit fly (*D. melanogaster*) as an animal model for the study of the *P. aeruginosa* pathogenesis, since the fly has a higher similarity to human[55-57]. The importance of both *P. aeruginosa* HSL QS pathways for infection was also demonstrated in *D. melanogaster* using the feeding assay, in which the bacteria are ingested and a local infection type is established in the intestine. In this assay the PA103 (*las*R), PDO100 (*rhl*I), PDO111 (*rhl*R), PAOR1 (*las*R) and PAOJP2 (*las*I/*rhl*I) mutant strains were avirulent with respect to wild-type PAO1 whose infected flies were killed at 14 d post-infection. Similarly, using the nicking assay (needle pricking), in which an injury is produced in the dorsum of the flies and *P. aeruginosa* is added to the wound, all mutant strains showed a lower death rate than wild-type, including the PDO100 mutant (*rhlI*) with 50% survival of the flies compared to 90% death for the PAO1 wild-type 35 d post-infection[57]. However, in contrast to the work with *C. elegans,* to date the effect of quorum quenching in *P. aeruginosa* virulence in the fly was not yet evaluated. With regard of these two infection models, Clatworthy and colleagues pointed out that a drawback to study *P. aeruginosa* infections using invertebrate hosts are the differences between their immune response and the one of vertebrates. For example, *C. elegans* and *D. melanogaster* do not have an adaptive immunity, or complex multilineage immune cells, such as those present in vertebrates[58]. Thus it is important to analyze the participation of QS in the pathogenesis of *P. aeruginosa* in vertebrate animal models, like zebrafish and mice. Specifically for zebrafish, the microinjection of PA14 QS$^-$ mutant strains (*lasR* and *mvfR*) during two different stages of fish development [28 and 50 h post-fertilization (hpf)], revealed that the participation of these two transcriptional activators during the infections is different and is influenced by the maturity of the immune system at different stages of the embryo development, since for the *lasR* mutant, only a 40% decrease in the death of the embryos at 50 hpf (a developmental stage when both macrophages and neutrophils are present) was recorded, whereas the *mvfR* mutant showed a moderate effect by decreasing death by 20% to 28 hpf (an stage in which only macrophages are present), but a higher effect of 60% decrease at 50 hpf[58].

For murine models, different protocols have been used to determine the participation of QS in *P. aeruginosa* pathogenicity[43,44]. The thermal induced injury model is frequently used and consists of producing a burn of second or third degree on the dorsal side of the mouse using water at 90 ℃ and subsequent inoculation of *P. aeruginosa.* Several experiments using this model have linked QS and virulence; for example, a PAO1-R1 (Δ*las*R) mutant has a diminished ability to spread systemically, as well as lower dispersion through the lesion at early stages[59,60]. Also, mice infected with PA14 *pqsA* show a 75% survival rate in contrast to 10% survival with wild-type PA14[61]. Similarly, virulence is reduced in PAO1 *lasR, lasI*, and *rhlI* mutants, with the greatest effect seen for the double mutant *lasI-rhlI* that decreased the mortality of animals by approximately 88%, significantly reduced the number of c.f.u in the lesion, liver and spleen, and delayed the spread of the bacteria from the lesion[59]. In agreement, similar results were found using the pneumonia model in neonatal mice, in which *lasR* mutants showed reduced virulence and are unable to replicate efficiently in the lung tissue; as a consequence, less damage occurs and the bacterial infection does not spread[62]. A third kind of experimental infection, the foreign-body infection model, consists in introducing a fragment of *P. aeruginosa* infected silicone into the peritoneal cavity of mice. This model was successfully used to determine the participation of QS in biofilm formation[43]. In this system, the mutant strain *lasR-rhlR* disappears from the silicone fragments during the first 7 d of infection, in contrast with wild-type PAO1 cells which remain in the silicon implant for at least 14 and up to 21 d. Critically, the establishment of the PAO1 infection in the implants depends in the mouse strain that is used, since for Balb/c, bacterial counts in the implants decayed constantly from day one and several of the implants were completely cleared after 21 d, while for the NMRI strain, bacterial counts initially decreased

(day 1 to 4), then remained constant and finally increased at levels similar to the initials at day 15[63].

Regarding studies testing the quorum quenching effect on virulence, by using the foreign body model, it was found that the intraperitoneal addition of furanone C-30 greatly increased the bacterial clearance rate (Figure 2E)[63]. In agreement a similar effect was observed with the lung infection model in mice in which a related compound, C-furanone 56 (Figure 2F) accelerated the bacterial clearance from the lungs, reducing the severity of the damage and significantly increasing mice survival[64]. Another quorum quencher, the synthetic molecule ajoene (ajoene 4,5,9,-trithiadodeca-1,6,11-triene-9-oxide) (Figure 2G), is able to attenuate the production of various *P. aeruginosa* QS-controlled virulence factors *in vitro*, while in the pulmonary infection model in mice infected with PAO1, its prophylactic administration from two days before the infection and during its course, reduced the bacterial c.f.u. in the lungs 500-fold relative to the non-treated mice[65]. Moreover, in the burn mice model, the intravenous administration of three related quorum quenchers, the anthranilic acid analogues: 2-amino-6-chlorobenzoic acid, 2-amino-6-fluorobenzoic acid, and 2-amino-4-chlorobenzoic acid (Figure 2H-J), that inhibit the biosynthesis of quinolone signals and disrupt the MvfR-dependant gene expression, restrict the systemic spread of the PA14 strain and decreases the animals death by 30% to 50%[61].

QS IN *P. AERUGINOSA* HUMAN INFECTIONS

The importance of the QS systems of *P. aeruginosa* in human infections is highlighted by their presence in most clinical strains that were isolated during the moment of the infection. This was demonstrated in 2004 by Schaber *et al*[66], by screening 200 isolates from patients with urinary tract, lower respiratory tract, and wound infections. Of those isolates, 97.5% (195 isolates) had robust functional HSL-QS communication systems and hence were able to produce elastase (codified by the genes *lasB* and *lasA,* which expression is QS dependent through LasR) and high levels of both HSL autoinducers while only 5 isolates failed to satisfy those criteria; however, 2 isolates were identified as being the same bacteria, but isolated at two different times from the same patient, and for one isolate there was no clinical data available to support that it was implicated in an infective process[66]. Hence only approximately 1% of the isolates that were implicated in infections appeared to be QS deficient. Critically, one of these isolates had no *lasR* and *rhlR* functional genes. In addition the authors demonstrated that those isolates deficient in HSL-QS systems produced high levels of non-QS controlled virulence factors, such as the ExoS and ExoT proteins that are components of the type three secretion system. Hence, perhaps this was an adaptive response that potentially could compensate for the decrease in virulence caused by QS deficiency., Nevertheless, the production of those proteins in the QS proficient isolates was not evaluated, and the virulence of the isolates was not tested using infection models. Other studies have reported similar results;, for example, the characterization of 442 *P. aeruginosa* isolates colonizing the respiratory tract of 13 intubated patients identified 9 genotypically different strains and of these, 6 strains produced both HSL-autoinducers and the virulence factors: elastase, exoproteases, rhamnolipid, hydrogen cyanide, and pyocyanin *in vitro*, and two of them had mutations in both *lasR* and *rhlR* genes, while the third had a mutant *lasR* gene[67]. Another study performed with 100 isolates from patients with respiratory infections that were collected from sputum, tracheal aspirate, and bronchoalveolar lavage identified 11 HSL-QS deficient isolates, six of them with absent *QS* genes (one isolate negative for *rhlR*, two isolates negative for *rhlI* and *rhlR,* and three isolates were negative for *rhlI*, *rhlR*, *lasI* and *lasR*). Interestingly, this study found a negative correlation between the expression of QS controlled virulence factors and antibiotic resistance[68]. Furthermore, the analysis of 82 *P. aeruginosa* clinical strains isolated from urinary tract infections identified 6 isolates deficient in the production of both HSL autoinducers, biofilm, rhamnolipids, and elastase, correlating with the absence of the *lasR* gene in one isolate and the absence of *lasI, lasR, rhlR* in another isolate, while the other 4 isolates harbored point mutations that probably inactivated their *lasI, lasR, rhlR*, and *rhlI* genes[69].

Taken together, these independent studies indicate that about 90% of *P. aeruginosa* isolates that cause infection generally preserve active HSL-QS systems, although clearly a small percentage of the isolates have those systems impaired by mutations or loss of the important QS regulatory genes, nevertheless, in all these studies, the third QS system of *P. aeruginosa*, the quinolone dependent system, was not evaluated; hence, it is not reliable to conclude that these isolates were indeed 100% QS deficient. In addition, the existence of cell communication systems not yet described in this organism cannot be ruled out, and indeed in the reference strain PAO1, cell communication by fatty acids was recently discovered (DSF-like fatty acids, cis-2-decenoic acid) (Figure 1D)[70]. Another possibility that may explain the isolation of QS deficient strains from infections is the presence of multiple *P. aeruginosa* strains in the infection site and that the QS deficient isolates coexist with QS proficient strains; this was demonstrated recently in 8 patients with cystic fibrosis (CF), in which a complex mixture of QS-proficient and deficient isolates were found. Interestingly, among all the patients, the deficiency of the isolates in individual QS regulated phenotypes (LasA and LasB elastase, rhamnolipids, growth in adenosine, and HSL signals) ranged from 0 to approximately 90% and no single

patient with 100% QS deficient isolates was found.

Such high diversity in isolates from the same patient likely is the result of a complex and multifactorial selective process, perhaps including social components like the advantages accrued by QS-deficient clones that use the resources made by the QS positive strains (siderophores, proteases, *etc.*), without contributing to the generation of the public goods; these bacteria are termed social cheaters[71]. Regarding the importance of QS for infections, these results indicate that at the population level, QS may be essential for CF infections; however, more studies increasing the number of CF patients and including other kinds of infections are necessary to better understand the importance of *P. aeruginosa* QS in the infective process. In addition, the elucidation of factors that shape the mosaic-like composition of isolates in patients or in animal models need to be determined in order to design better anti-QS therapies since the current ones are focused on laboratory strains with QS-proficient systems rather than clinical strains recently isolated from infections[72,73]. Although such factors are still unknown, some variables like: the severity and progression of the infection, the nutritional, health, and immunological status of the patients, the exposure of the susceptible individuals to only one, a few, or several strains and the bacterial loads during the infections could be involved. In this sense, animal models would be useful to evaluate the role of these and other valuables in the colonization diversity in the patients, for example experiments comparing the colonization of well feed animals and animals with a deficient nutrition, immune competent animals and immunosuppressed ones, or healthy animals compared to animals harboring important disorders such as the alpha-1-antitrypsin deficiency that promotes major pulmonary inflammation, degradation of lung tissue, and eventually manifestations of pulmonary emphysema, *etc*. using several bacterial strains (QS proficient and QS deficient) alone or in combination could be very valuable to determine the factors involved in the *in vivo* bacterial ecology in infections.

In addition, although *P. aeruginosa* virulence is multifactorial[74], the individual importance of QS controlled virulence factors in different kinds of infections is a current research area, and the role of molecules from the HSL autoinducers themselves, to extracellular factors like rhamnolipids, elastase, pyocyanin, *etc*. have been established. For example several independent studies have shown that the main *P. aeruginosa* autoinducer N-(3-oxododecanoyl)-HSL is readily detected in sputum samples collected from patients with cystic fibrosis[75-77], which correlates with a QS dependent gene expression during the infections[78-80]. However, besides its role as a signal, the autoinducer is also able to inhibit lymphocyte proliferation as well as secretion of tumor necrosis alpha by macrophages and interferon gamma by T-cells[27]. Moreover QS controlled secreted factors such as alkaline protease can interfere with the classical and the lectin pathway-mediated complement activation *via* cleavage of C2, blocking phagocytosis and killing of *P. aeruginosa* by neutrophils[81]. Also elastase, by cleaving the pulmonary surfactant protein-A, can contribute to phagocytosis evasion[82]. Furthermore, rhamnolipids are able to disrupt calcium-regulated pathways and protein kinase C activation, preventing the induction of human beta-defensin-2 in keratinocytes[83]. Remarkably, the production of rhamnolipids in mechanically ventilated patients is associated with the development of life-threatening ventilator-associated pneumonia (VAP), while elastase production and QS independent production of the cytotoxins ExoU and ExoS are not[84]. Another QS controlled virulence factor, the polysaccharide alginate, protects *P. aeruginosa* biofilm cells from IFN-gamma-mediated macrophage killing[85]. Surprisingly, the importance of pyocyanin, a blue redox-active compound which is one of the main *P. aeruginosa* virulence factors studied *in vitro* and one of the more notorious in infections (present in large quantities in sputum from patients with cystic fibrosis infected by *P. aeruginosa)* during clinical infection is still underexplored[86].

S. AUREUS QS AND VIRULENCE IN ANIMAL MODELS

The participation of SarA and Agr *S.aureus* QS systems in pathogenicity has been evaluated using numerous animal models, in which the bacteria induce diseases such as osteomyelitis, septic arthritis, endocarditis, endophthalmitis and soft tissue abscesses. By using the mutant strains *agr* and *sarA,* as well as QS inhibition, the participation of these systems in the infectivity of the bacterium and the damage of tissues has been proved. Intravenous inoculation of the bacteria in mice induces the development of septic arthritis. In this model, *agr* mutants showed a reduced ability to induce the pathology since it is produced in only approximately 10% of the animals while the wild-type strain produces it in approximately 60% of the inoculated mice. Furthermore, in mice infected with the mutant strain, the arthritis severity is less, and only a few developed erosive arthropathy in contrast to those infected with wild-type[87]. Similarly in the endophthalmitis-rabbit model, which is established by the intraocular injection of the bacteria, *agr* mutants produced a smaller loss of neuroretinal function during the first 3 d of the infection, with respect to the wild-type strain. In addition, those infected with the mutant strain had normal eye histology, whereas those infected with the wild-type strain showed focal retinal destruction and mild vitritis[88]. In a subsequent study employing the same animal model, no significant differences in the rabbits eyes infected with the mutant strain (*sarA*) and with the wild-type were found; however, the simultaneous deletion of genes *agr* and *sarA* resulted in a near to complete attenuation of virulence[89]. Moreover, employing the model of endocarditis in rabbits, which consists in introducing a

catheter into the ventricle and subsequently colonizing it by intravenous administration of the bacteria, it was observed that single mutations (*sarA* and *agr*) diminish the bacterial ability to induce the pathology, while a *agr*/*sarA* double mutant was incapable of inducing endocarditis in 100% of the animals inoculated with 10^3 or 10^4 c.f.u.[90]. Another infection model in mammals is the murine brain abscess model in which lesions are produced by embedding bacteria in agarose beads that are later inoculated in the cranial cavity. In this model, the *agr*/*sarA* double mutant, but not the single mutants, had reduced virulence, lower proliferation in the brain and poorly developed abscesses that were drastically smaller than those produced by the wild-type strain. Furthermore, the double mutation attenuates the expression of pro-inflammatory cytokines and chemokines[91]. Similarly invertebrate models such as the nematode *C. elegans*, which is killed by feeding on *S. aureus,* showed similar outcomes, since mutating *sarA* or *agr* increased the survival of the worms with respect to the wild-type strain[92].

Regarding the effect of quorum quenching in *S. aureus* animal infections, several inhibitory peptides have been evaluated; for example, in the murine subcutaneous abscess model, the administration of the synthetic autoinducer analog of AIP-Ⅱ peptide (Figure 2K) in a single dose was able to decrease the formation of abscesses, and although AIP-Ⅱ prevents expression of the *S. aureus agr* QS regulon for only a short time period, this transient inhibition is sufficient to achieve significant effects[93]. Other QS inhibitory peptides such as the RNAⅢ-inhibiting peptide (RIP) and its analogues (Figure 2K and L), that inhibit the phosphorylation of a target protein called "target of RNAⅢ-activating protein" (TRAP), leading to the suppression of virulence factor production *in vitro*[94,95], are also effective *in vivo.* For example, in the vascular-graft rat model, the administration of RIP (Figure 2L), both locally and systemically, is able to completely inhibit the formation of biofilms in graft and in polymethylmethacrylate beads infected with methicillin-susceptible and resistant *S. aureus*. Similarly, in the mouse sepsis model, administering RIP significantly reduced the bacterial load and mice mortality; this effect is potentiated by co-administration of antibiotics like cefazolin, imipenem, or vancomycin[96]. In addition, using the graft rat model, a RIP treatment increases its effectiveness in combination with antibiotics rifampin and temporin, and the complete elimination of infection is achieved by combining it with temporin A[97]. The same phenomenon has been documented with a derivative of RIP, termed FS3, which contains a substitution of alanine in the second position, since FS3 in combination with daptomycin has higher efficiency than single compounds, in the rat model of vascular graft staphylococcal infection[98]. Also in this model, a similar effect was obtained, by combining tigecycline and the RIP analogue called FS8 which contains a terminal alanine (Figure 2M)[99]. Taken together these extensive studies demonstrate the participation of *S. aureus* QS systems in its pathogenicity and indicate that QS inhibition in combination with antibiotics is a promising new strategy that may be effective to treat the infections produced by this important pathogen.

QS IN *S. AUREUS* HUMAN INFECTIONS

Although it is not always pathogenic to humans, the Gram (+) bacterium *S. aureus,* is frequently found in the human respiratory tract and on the skin and it is considered as a transient member of the human microbial flora[32], it is able to cause several kind of infections with a plethora of clinical manifestations. There are risk factors that complicate the infection caused by *S. aureus*, including the presence of prosthetic material and immunosuppression[100], and it is considered one of the three main causes of nosocomial bacterial infections. Among the many kinds of *S. aureus* infections, skin ones are very common; for instance, in children it is the main cause of impetigo, a superficial skin infection that according to its clinical manifestations is divided into non-bullous and bullous impetigo, the non-bullous is the most common form, the lesions begin as papules that progress to vesicles with erythema on its periphery. These become pustules that later form adherent crusts with a golden appearance and can be accompanied by regional lymphadenitis, although systemic symptoms are usually absent. Bullous impetigo is seen in young children in which the vesicles enlarge to form flaccid blisters with clear yellow liquid, which later becomes darker and turbid, leaving a thin brown crust[3,4]. Other common infections produced by *S. aureus* are hair follicle infection or folliculitis, furunculosis, and cellulitis. In addition to skin infections, *S. aureus* also causes respiratory tract infections such as nosocomial and septic pneumonia, septic pulmonary emboli and post viral empyema. It also infects the apocrine glands, causes musculoskeletal infections, produces bacteremia and its complications like sepsis, septic shock, and infective endocarditis and is able to produce toxic shock syndrome and food poisoning. Therefore, *S. aureus* is a major health concern worldwide.

Although the role of QS in regulating the expression of several virulence determinants including toxin production, and biofilm formation have been extensively studied *in vitro* and in animal models, its importance in actual human infections is yet under studied; nevertheless, it is known that as in the case of *P. aeruginosa* the great majority of *S. aureus* clinical isolates implicated in human infections possess active QS systems (agr^+). Although some agr^- strains are also commonly found in *S. aureus* infections[101-103], the presence of both kind of strains during infection indicates that agr^+ and agr^- variants may have a cooperative interaction[103] and also raises the possibility that social interactions like QS cheating may exist during the

infections[39]. In addition, the link of QS and biofilm formation in *S. aureus* strongly suggests that this QS is important for the development and establishment of its chronic infections[32]; however, further work in this area is needed to define the importance and the specifics of QS in regulating *S. aureus* virulence in human infections.

QS ANTIVIRULENCE DRUGS

P. aeruginosa

To date, there are a large number of quorum quenching (QQ) compounds reported. In general, the three types of QQ compounds are degraders of AHL autoinducers, synthase inhibitors, and receptor inhibitors. Here the QQ compounds used against *P. aeruginosa* are sorted into seven categories.

Halogenated compounds

One of the best characterized QQ compounds is the synthetic brominated furanone 4-bromo-5-(bromomethylene)-2(5*H*)-furanone known as C-30 (Figure 2E)[104]. This compound was synthetically modified from the natural brominated furanone (5*Z*)-4-bromo-5-(bromomethylene)-3-butyl-2(5*H*)-furanone of the algae *Delisea pulchra*. Another furanone compound is 5-(bromomethylene)-2(5*H*)-furanone, also called furanone C-56 (Figure 2F) which is a derivative of the secondary metabolites produced by the algae[105]. Interestingly, although C-30 is effective for the attenuation of several QS-dependent virulence factors *in vitro* and in animal models, resistance against this compound has been found both in laboratory PA14 derived mutants and in clinical isolates; to date, the only resistance described mechanism is the active efflux of this compound by the MexAB-OmpR pump but the existence of other mechanisms cannot be ruled out[72,106,107]. Furanone C-56 affects the processes of biofilm formation and dispersal although it does not influence initial attachment to abiotic substrata. In addition, indole (Figure 3A) produced from L-tryptophan by a variety of bacteria and 7-hydroxy indole (7HI) (Figure 3B), an oxidized compound of indole created by bacterial oxygenases, are extracellular signals that attenuate the production of biofilm and virulence factors in *P. aeruginosa*[108]. In addition, among 31 natural and synthetic indole analogs, 7-fluoroindole (7FI) (Figure 3C) was identified to be a QQ compound capable of reducing the production of virulence factors such as 2-heptyl-3-hydroxy-4(1*H*)-quinolone, pyocyanin, rhamnolipid, pyoverdin, and pyochelin[109]. 7FI shows higher inhibition toward biofilm formation than indole or 7HI.As another fluorine compound which shows the QQ ability, 5-fluorouracil (5-FU) (Figure 3D), an anticancer uracil analog, also is a potent inhibitor of *P. aeruginosa* virulence[110]. Since 5-FU is basically used for clinical purposes as a chemotherapeutic approach in patients with cancer, it holds promise as a QQ compound for clinical use. However, clinical strains resistant against this compound have been identified[72,107].

Based on the previous report that chlorolactone (CL) is an inhibitor to the QQ receptor[111], three other synthetic CL analogs were tested for QQ effects. As a result, meta-bromo-thiolactone (mBTL) (Figure 2A) was the most effective QQ compound since pyocyanin production and biofilm formation were inhibited in the presence of mBTL, in addition, mBTL moderately protected *C. elegans* and human lung epithelical cells from killing by *P. aeruginosa*[48]. Other halogenated QQ compounds include the derivatives of anthranilic acid which is the primary precursor of 4-hydroxy-2-alkylquinolines (Figure 2H-J)[61]. The halogenated anthranilic acid analogs inhibit quinoline biosynthesis and the expression of QS-related genes. Beyond that, halogenated maleimide analogs also are QQ compounds; in particular, bromo- and iodo-substituted maleimides decrease bacterial attachment and biofilm formation whereas chloro-N-methyl-maleimide has bacteriocidal action rather a QQ effect[112]. In addition to this, 5-chloro-1,3-benzoxazol-2(3H)-one[113] also called chlorzoxazone[114] are QQ compounds that contain a halogen group (Figure 3G).

Lactonases and acylases

Degrading enzymes such as lactonases and acylases are another class of QQ compounds. Their effect on QQ is due to the degradation of AHL-based autoinducers. To date, some unique lactonases have been characterized; for example, the halotolerant lactonases derived from *Bacillus* spp[115] and a thermally-stable lactonase from *Bacillus weihenstephanensis* P65[116], which may be useful for future applications. Lactonase itself or in combination with ciprofloxacin prevented systemic spread of the bacteria in murine burn wounds infected with *P. aeruginosa*, while for the combination mice mortality was completely abolished and skin regeneration was promoted[117]. In addition, immobilized esterases and acylases embeded on medical plastic materials inhibit biofilm formation[118]. Another unique approach using a lactonase is to utilize an engineered *Lactobacillus plantarum* strain expressing the lactonase AiiA from *Bacillus thuringiensis* 4A3[119]. Extracellular virulence factors such as pyocyanin, protease, elastase, and rhamnolipids of multi-drug resistant clinical isolates of *P. aeruginosa* were inhibited and the attachment to uroepithelial cells was reduced by co-culturing *P. aeruginosa* with the engineered strain. The original trial was performed using a *P. aeruginosa* strain capable of expressing a lactonase derived from *Microbacterium testaceum*, which led to reduced production of virulence factors and attenuated cytotoxicity against human lung epithelial cells[120]. A new trial using genetic engineering has been recently reported; this is by an engineered T7 bacteriophage expressing a lactonase with activity for a broad-range of bacterial hosts[121]. The engineered T7 bacteriophage was able to inhibit the biofilm formation of a consortium of *P. aeruginosa* and *Escherichia coli*.

QQ compounds found by several screening approaches

For searching for novel QQ compounds, structure-based computational screens and high-throughput screens have been conducted. An ultra-high-throughput, cell-based assay to screen a library of approximately 200000 compounds was used to find an inhibitor which can decrease the gene expression regulated by the Las system[122]. As a result, PD12 (Figure 3J), a tetrazole with a 12-carbon alkyl tail and V-06-018, a phenyl ring with a 12-carbon alkyl tail (Figure 3K), which have both similarity with the structure of 3OC12-HSL, were identified as QQ compounds.In addition, a compound having QQ ability was also found among a series of 1,3-benzoxazol-2(3H)-one derivatives[113]; thereby, 1,3-benzoxazol-2(3H)-one (Figure 3F), 5-chloro-1,3-benzoxazol-2(3H)-one (Figure 3G), 6-methyl-1,3-benzoxazol-2(3H)-one (Figure 3I), and 5-methyl-1,3-benzoxazol-2(3H)-one (Figure 3H) have QQ ability. As another approach for clinical application of QQ compounds, the thousands of drugs clinically used in the treatment of different diseases were screened to find drugs with QQ properties which can be applicable to humans. By the screening, it was found that an anthelmintic drug, niclosamide (Figure 3L) strongly inhibits the QS response by *P. aeruginosa*[123], although the active compound was demonstrated to be 5-FU

which was already described as a QQ agent[107,110]. Moreover, since antibiotics are also robust compounds for clinical use, inhibition of QS by antibiotics was surveyed. As a result, it was found that low concentrations of azithromycin, ceftazidime, and ciprofloxacin inhibit QS in *P. aeruginosa*[124]. In addition, QS in a *P. aeruginosa* environmental isolate was inhibited at sub-inhibitory concentrations of tobramycin[125] although other studies demonstrated that a low concentration of tobramycin induces biofilm formation[126].

Screening using a computational approach and molecular docking analysis has also been useful for evaluating the binding capacity of QQ compounds to receptor proteins; thereby, new potential QQ compounds were identified. Pharmacophore modeling and *in silico* screening to find an antagonist for QS in *P. aeruginosa* indicated that a compound with tetravalent lead has QQ ability[127]. Another two compounds thimerosal (Figure 3M) and phenyl mercuric nitrate (Figure 3N) were selected as QQ compounds based on their similarity to the Pb-QQ compound. Also, the automated docking program by which the docking capability of a ligand to a receptor can be analyzed identified 5 potential new QQ compounds; among the candidates, baicalein (Figure 3O) has the strongest QQ ability as it inhibits biofilm formation of *P. aeruginosa* and the QQ effect by baicalein increases synergistically in the presence of ampicillin[128]. Also, another 5 compounds were identified to be QQ by using a structure-based virtual screening approach targeting the QS receptor LasR; of the 5 compounds, the most promising was 5-imino-4,6-dihydro-3H-1,2,3-triazolo[5,4-d]pyrimidin-7-one also called G1 (Figure 3P)[129].

Other AHL antagonists

Some of QQ compounds described above are antagonists of AHL molecules; hence their QS inhibition effect is triggered by interrupting the binding (interaction) between AHL molecules and receptors. To date, there are a large number of AHL antagonists; for example, patulin (Figure 3Q)[130], salicylic acid (Figure 3R)[114], 3-oxo-C12-(2-aminophenol) (Figure 3S)[131], and nifuroxazide (Figure 3T)[114] as well as C-30 (Figure 2E)[104]. In addition, 4-nitropyridine-N-oxide (Figure 3U) is a QQ compound[132], which also reduces bacterial adhesion to silica-coated surfaces[133]. Other QQ compounds are pyrimidine (Figure 3V)[134], N-decanoyl-L-homoserine benzyl ester (C2) (Figure 3W)[135], 2,5-piperazinedione (Figure 2C)[52], and phenylacetic acid (Figure 2B)[51]. The bacterial sensitivities to several antibiotics (tobramycin, gentamycin, cefepime, and meropenem) in the presence of C2 were higher than those without C2[135]. This may be due to the synergistic interactions between C2 and the antibiotics. In addition, QQ by the cyclic dipeptide 2,5-piperazinedione (Figure 2C) might be due to interference with the binding of the natural ligand 3-oxo-C12-HSL to its receptor protein based on the molecular docking analysis[52]. Phenylacetic acid (Figure 2B), which is similar to salicylic acid, has been reported to be a QQ compound[51].

Inhibitors with different QS targets

There are some reports on inhibitors with QS targets different than AHLs and receptors.A new class of antivirulence compounds was reported by Shouldice *et al*[136]; the QQ compounds interact with the bacterial periplasmic protein DsbA, which is essential for the folding and function of exported virulence factors. Another target of QQ compounds is mono-ADP-ribosyltransferase which functions as a bacterial toxin[137]. Some newly-identified QQ compounds were found by using a virtual screen of commercially available compounds combined with a directed poly(ADP-ribose) polymerase; thereby, V23 (Figure 3X), V30 (Figure 3Y), and P1 (Figure 3Z) compounds as well as NAP (Figure 3A1)[137] and PJ97A (Figure 3B1)[138] were identified as inhibitors of toxin production[137]. Other antagonists are a series of compounds targeting PqsR, the receptor of the *pqs* system[139]. Among the analogs of 2-heptyl-4-hydroxyquinoline (HHQ) synthesized, three HHQ analog with 6-CN (Figure 3C1), 6-CF_3 (Figure 3D1), or 6-NO_2 (Figure 3E1) along with n-C_7H_{15} are the best competitors[139], which are promising starting compounds for further drug design.

Cell extracts and secretion products from isolated microorganisms

Based on the concept that microbial interaction (inhibition, repression, acceleration, and dependence) is a complex phenomenon due the large numbers of microbes, a new approach to isolate unique microorganisms with QQ ability and to utilize cell extracts and secretion products has been recently reported. Among the 46 marine bacterial isolates, 11 extracts from *Bacillus*, *Marinobacter*, *Halobacillus*, *Staphylococcus*, or *Ferrimonas* species showed antibiofilm activity against *P. aeruginosa*[140]. The partially-purified antibiofilm compound from S6-15 (similarity with *Bacillus pumilus*) is stable up to 60 ℃ and under neutral and alkaline conditions. In addition, its QQ ability was inactivated by the treatment by enzymes such as proteinase K, trypsin and lysozyme[140]. Also, bacteria able to utilize AHL molecules as a sole source of carbon and nitrogen have been isolated and characterized as AHL-degrading bacteria[141]. Among 41 isolates which retained QQ activity after heat treatment, some of the isolates showed impaired QS inhibition after the treatment by proteinase K whereas the other isolates remained active. In addition, actinomycetes with QQ activity were also isolated from marine sponge. In this study, methanol extracts of 12 actinomycetes had an inhibitory effect on the production of QS-mediated virulence factors[142]; in particular, of the three strains which showed very good anti-QS activity, the most promising strain is NIO 10068 (*Streptomyces* sp.) that secretes cinnamic acid and/or linear Pro-Gly dipeptide which may be QQ compounds. Further bacteria capable of having QQ ability were also isolated from healthy coral species[143]; of 120 bacterial

isolates, up to 24% of the isolates showed anti-QS activity. In particular, a *Favia* sp. coral isolate inhibits the biofilm formation of *P. aeruginosa* by secreting a low-molecular mass compound which is not inactivated by heat and proteinase K[143]. Also, a cell-free lysate of endophytic bacteria isolated from *Pterocarpus santalinus* Linn. also showed QQ activity[144]. *Bacillus firmus* PT18 and *Enterobacter asburiae* PT39 isolated as the endophytic bacteria exhibit potent AHL degrading ability by inhibiting about 80% violacein production in a biosensor strain. QQ activity by the cell lysate was effective against biofilm formation rather than to planktonic cells, and the QQ activity was due to the presence of AHL lactonase in cell-free lysate[144].

Moreover, a small cyclopropane-containing fatty acid, lyngbyoic acid (Figure 3F1), a major metabolite produced by the marine cyanobacterium, *Lyngbya* cf. *majuscule* has been identified to be a QQ compound capable of strongly inhibiting Las-QS system[145]. In addition, the biosurfactant, lunasan produced by *Candida sphaerica* UCP 0995 is also a QQ compound[146]. Recently, it was discovered that a conditioned high density lipoprotein is also a QQ compound capable of reducing the virulence of *P. aeruginosa* by influencing *las*-and *rhl*-QS systems as well as biofilm formation[147]. Furthermore, ultra-small solid lipid nanoparticles for the pulmonary delivery, which are prepared by using various pharmaceutical lipids, are fabricated to deliver QQ compounds to a target site without any penetrable cellular barrier[148]. In this study, plain small solid lipid nanoparticles exhibited anti-virulence properties themselves.

QS inhibitors from food and plant sources

Since biocompatibility of QQ compounds to higher organisms is one of the important requirements for clinical use, there are a lot of trials to find QS inhibitors from food and plants. The anti-QS activity of aqueous extracts from edible plants and fruits, like pineapple, plantain, and sapodilla, was evaluated; most of these extracts showed QQ activity without inhibiting bacterial growth in *P. aeruginosa*[149]. Also, analogs from a natural bicyclic diterpeniod lactone, andrographolide which is the main phytoconstituent from *Andrographis paniculata* Nees (herb), were screened to evaluate QQ activity[150]. An andrographolide-based compound, 14-(5-cyclopentylvaleryl) andrographolide (compound 11b) (Figure 3G1) had the best QQ activity among all the new compounds. In addition, some QQ compounds were found from traditional Chinese medicine by using a molecular docking analysis and QS assays[151]. As a result, emodin (Figure 3H1) had a certain antibiofilm activity as well as the ability to increase the activity of ampicillin against *P. aeruginosa*.

Furthermore, five sesquiterpene lactones of the goyazensolide (Figure 3I1)and isogoyazensolide-type (Figure 3J1)isolated from the Argentine herb *Centratherum punctatum*[152], iberin (Figure 3K1)from horseradish[153], allicin (Figure 3L1)from garlic[154], and phenolic components {([6]-gingerol (Figure 3M1),[6]-shogaol (Figure 3N1), zingerone (Figure 3O1)} from ginger[155] and anacardic acids[156] are QQ compounds, which might be suitable for further development of antivirulence and antibacterial agents.

S. aureus

Since QS regulates the expression of multiple *S. aureus* virulence determinants, and since the frequency of drug resistant clinical strains causing infections is rising (like methicillin-resistant *S.aureus* "MRSA"), several compounds aiming to disrupt these regulatory interactions have been identified; among them, perhaps the best characterized is the QS inhibitor RIP (Figure 2L), an endogenous *S. aureus* peptide that is able to decrease the damage of *S. aureus* in several animal models as discussed before[94,157]. At the molecular level, the production of several toxins is activated in a cell density manner by the RNAIII-activating protein (RAP) and by the autoinducing peptide (AIP), and is inhibited by RIP and by inhibitory AIPs; RAP participation in the pathogenesis consists in inducing the phosphorylation of a 21-kDa protein (known as target of RAP or TRAP). While RIP inhibits its phosphorylation, the phosphorylation of TRAP is essential to create the autoinducing loop since it leads to the activation of RNAIII synthesis[94]. In addition to decreasing the damage of *S. aureus* during infection, RIP treatment also is able to prevent its adhesion to human kidney cells and its biofilm formation on dialysis catheters[158]. Other effective peptides analogues to RIP are FS3 and FS8 (Figure 2M) discussed previously[98,99]. Moreover, recently four AIP non-functional peptide analogues were identified; these peptides have an ample spectrum since they can repress many AgrC receptors (type I-IV) and have a very high affinity. For example, treatment with the peptides block hemolysis (at picomolar concentrations)and attenuate the production of toxic shock syndrome toxin-1 by 80% at nanomolar concentrations; hence, these compounds are the most potent synthetic inhibitors of QS in *S. aureus* to date[159].

Beyond the QS inhibitory peptides, several other interesting molecules able to block the expression of *S. aureus* virulence factors have been discovered, among them, the small molecule biaryl compounds in which the aromatic rings either are either fused or separated by a short linker. This result is particularly interesting, since they are able to inhibit the production of the alpha-hemolysin and the modulin-α toxin in a dose-dependent manner without inhibiting bacterial growth, since they are effective against methicillin-resistant *S. aureus*, and since one of the effective compounds is diflunisal (Figure 3P1), an Federal Drug Administration-approved nonsteroidal anti-inflammatory drug[160]. Diflunisal has the clear advantage that it could be easily repurposed for treating *S. aureus* infections or could be used to coat catheters and other medical devices just as was recently done for 5-FU (Figure 3D)[161], which has QS inhibitory activity against *P. aeruginosa*[110], *Escherichia coli* (*E. coli*)[162] and perhaps several other

pathogens. In addition, some natural products with QS inhibition activity against *S. aureus* like 2,5-di-*O*-galloyl-dhamamelose (hamamelitannin) (Figure 3Q1), a non-peptide analog of RIP found in the bark of the plant *Hamamelis virginiana* had been identified. This compound is effective *in vitro* to inhibit virulence without affecting growth, and *in vivo* in a rat graft model, preventing device-associated infections[163]. Moreover, recently the screening of 83 essential oils led to the identification that black pepper, cananga, and myrrh oils and their common constituent cis-nerolidol (Figure 3R1) strongly attenuate *S. aureus* biofilm formation, its hemolytic activity, and protect *C. elegans* against its infection. Although their mechanism is not fully understood yet, transcriptional analyses showed that at least black pepper oil treatment inhibited the expression of the α-toxin gene (*hla*), nuclease genes, and QS regulatory genes[164]; similar effects can be observed with treatments with trans-stilbene (Figure 3S1)and resveratrol (Figure 3T1)[165].

QS SYSTEMS ARE PRESENT IN SEVERAL OTHER IMPORTANT BACTERIAL PATHOGENS

In addition to *P. aeruginosa* and *S. aureus,* several other bacterial pathogens utilize QS systems to control the expression of multiple virulence factors during infection. Among the more relevant for human health are *Vibrio* spp, *Acinetobacter* spp**,** *Burkholderia cepacea,* and enteric bacteria like *Escherichia* spp. and *Salmonella typhimurium*. The following section is an overview of their known QS systems and their relationship with virulence.

Vibrio spp.

Vibrio is a genus of facultative anaerobic Gram-negative bacteria possessing a curved rod shape (comma shape) typically found in saltwater. Several species are pathogenic to animals including humans and are responsible for food borne infections that are usually associated with eating contaminated food or water. In addition, they also cause wound infections and septicemia. The first QS system was described in the bioluminescent marine bacterium *Vibrio fischeri*, considered the paradigm for QS found in most Gram-negative bacteria. *Vibrio fischeri* colonizes the light-emitting organs of the squid *Euprymna scalopes*, in which it multiplies and reaches a high population density and induces the expression of luminescence genes. This gene expression occurs in a coordinated fashion[166]. The squid uses the light conferred by the bacteria to hide its own shadow in shallow waters and thus avoid predators[167]. To date several QS systems have been described in *Vibrio* spp.

In Vibrio harveyi, the following three QS systems are known: (1) LuxM (synthase), LuxN (receptor) and 3OHC4HSL (signal); (2) LuxS (synthase), LuxP (receptor) and AI-2 (signal); and (3) CqsA (synthase), CqsS (receptor) and CAI-1 (signal).

These systems are associated with bioluminescence, siderophores, protease and extracellular polysaccharide (EPS) production, and other virulence factors[168-170].

In Vibrio cholerae, two QS systems have been described: (1) LuxS (synthase), LuxP (receptor) and AI-2 (signal); (2) CqsA (synthase), CqsS (receptor) and CAI-1 (signal).

These systems have been associated with biofilm formation, EPS production, and other virulence factors[169].

Finally, in *Vibrio fischeri* three QS systems are known: (1) LuxI (synthase), LuxR (receptor) and 3OC6HSL (signal); (2) AinS (synthase), AinR (receptor) and C8HSL (signal); and (3) LuxS (synthase), LuxP (receptor) and AI-2 (signal).

These systems are associated with bioluminescence, host colonization, and motility[168,170]. Other QS systems found in various *Vibrio* spp. and in *Legionella pneumophila* utilize hydroxyketones (AHKs) as signalling molecules[170].

Acinetobacter spp.

Acinetobacter is a genus of aerobic, non-motile Gram-negative bacteria that are widely distributed in nature, commonly occurring in soil. Among them, some species like *Acinetobacter baumannii* (*A. baumannii*) are frequently isolated in nosocomial infections, especially in intensive care units, since they attack debilitated and immunocompromised patients; in addition they have a high tolerance against antibiotics and an inherent ability to acquire antibiotic resistance genes, being therefore a serious emergent health problem. Their QS systems consist of homologues of the LuxR and LuxI proteins of *Vibrio fischeri* known as AbaR (receptor) and AbaI (synthase) and play a role in biofilm formation and motility in *Acinetobacter* spp[171] and in *Acinetobacter baumannii*[172]. This QS system is an important virulence factor responsible for the outstanding antibiotic resistance and survival properties in the latter species[173]. However, the role of QS systems in the regulation of other virulence factors implicated in the development of infection has not yet been established[174].

Synthesis of N-(3-hydroxydodecanoyl)-L-HSL (3-hydroxy-C12-HSL) is catalyzed by AbaI from *Acinetobacter* strain M2 (initially characterized as *Acinetobacter baumannii*, although genomic sequencing studies have distinguished this strain as *Acinetobacter nosocomiales*[174,175]). The completed genome sequence of *A. baumannii* strain ATCC 17978 indicates that autoinducer synthase AbaI (gene *A1S_110*) and acyltransferases may be the sole participants in the synthesis of AHL signals of variable chain length by the organism[176]. Many strains of *Acinetobacter* (63%) produce more than one AHL. However, none of the AHL signals can be specifically assigned to a particular species of the genus[177]. *Acinetobacter* quorum signals are not homogenously distributed, and therefore

distinction between virulent and non-virulent strains on the basis of QS signals is difficult. Communication between bacteria with respect to cell density is integral to the maturation of *Acinetobacter* spp. Biofilm[176,178]. Mutation of *abaI*, which produces the acyl-homoserine lactone molecule, resulted in a 30%-40% reduction in biofilm production relative to that of the isogenic parental strain[173]. Exogenous addition of purified *Acinetobacter* acyl homoserine lactone restored biofilm maturation in the *abaI* mutant[176].

Burkhordelia cepacea

The *Burkholderia cepacia* complex is a group of Gram-negative bacteria composed of at least 18 different species; they are important human pathogens which produce pneumonia in immunocompromised individuals that are affected by lung diseases such as cystic fibrosis. All *Burkhordelia cepacea* complex members encode at least one QS system that consists of homologues of the LuxR and LuxI proteins of *Vibrio fischeri* [CepI(synthase), CepR (receptor), and AHLs C8-HSL and C6-HSL (signal)]. AHL production in the *Burkhordelia cepacea* complex is strain-dependent with respect to both the quantity and type of AHL molecules[179,180]. Another QS system in the *Burkhordelia cepacea* complex is the CciIR system [CciI (synthase), CciR (receptor), and/AHLs C8-HSL and C6-HSL (signal)][181]. Phenotypic assays and global transcript and protein analysis with *cepIR* and *cciIR* mutant strains have shown that AHL-mediated QS controls various functions, including swarming motility, biofilm formation and the production of virulence factors, such as proteases (*e.g.,* the metal proteases ZmpA and ZmpB), siderophores, toxins and antifungal agents[179].

In 2008, Boon *et al*[182] reported the identification of a novel fatty acid signal molecule that is produced by several *B. cenocepacia* strains. The structure of the molecule synthesized by *B. cenocepacia* J2315 was identified as *cis*-2-dodecenoic acid, referred to as BDSF (*Burkholderia* diffusible signal factor). BDSF is structurally related to DSF (diffusible signal factor, *cis*-11-methyl-2-dodecenoic acid), which was first isolated from supernatants of *Xanthomonas campestris* pv *campestris.* The BDSF-regulated QS system is involved in the control of several functions. Mutation of *rpfFBc* resulted in decreased motility, reduced adherence to porcine mucin, diminished exopolysaccharide (EPS) production and lowered protease activity. In addition, the BDSF mutant strains were found to be more susceptible to antimicrobial agents, and their ability to form biofilms was shown to be strongly reduced[179].

Escherichia spp./Salmonella typhimurium

E. coli and *S. typhimurium* are related enteric Gram-negative, facultative anaerobic bacteria. Although most *E. coli* strains are commensal for warm-blooded organisms, such as mammals, some serotypes cause serious food poisoning and other kinds of infections like urinary tract infections and neonatal meningitis, while *S. typhimurium* and other *Salmonella* pathogenic serovars are responsible for Salmonellosis, an infection that causes diarrhea, fever, vomiting, and abdominal cramps. Although usually the illness resolves after four to seven days without medical treatment, several million people are infected by this bacterium each year. In *E. coli* and *S. typhimurium*, three QS systems have been described: (1) Unknown (synthase), SdiA (receptor) and 3OC8HSL (signal). This system has been associated with motility and acid resistance[183]; (2) LuxS (synthase), LsrB (receptor) and AI-2 (signal). Lsr operon expression (AI-2 uptake)[184]; and (3) Unknown (synthase), QseC (receptor) and AI-3 (signal). This system has been implicated in virulence, motility and biofilm formation[185].

QS SYSTEMS BEYOND BACTERIA

QS systems have been extensively studied in bacteria and are of great interest for understanding the development of clinically-significant infections, but whether eukaryotes have cell signaling systems similar to bacterial QS mechanisms is a question that has recently drawn the attention of research worldwide. In this section, we will discuss some examples of eukaryotic microorganisms and human cells that use QS for the development of certain biological functions. The first report of a QS system in eukaryotes was carried out more than 40 years ago, when it was observed that dense cultures of the fungi *Candida albicans* show a reduced tendency towards the morphological transition from yeast to hypha, which is considered a key virulence factor for this opportunistic fungal pathogen[186]. To date, several compounds have been identified as responsible for this phenomenon, such as 2-phenylethanol, tryptophol, farnesol, farnesoic acid, and tyrosol[187]; these QS molecules are secreted by *C. albicans* and when they accumulate over a threshold level, they trigger changes in: (1) fungal dimorphisms[186]; (2) biofilm formation[188]; and (3) expression of virulence genes[189]. In addition, in other dimorphic fungi (*Mucor rouxii, Histoplasma capsulatum, Ceratocystis ulmi*), the "inoculum size effect" is usually observed; however, QS autoinducers in these organisms have not been identified[187]. In 1997, it was discovered that in the protozoan parasite of humans *Trypanosoma cruzi,* the differentiation of replicating and slender forms to non-dividing and stumpy ones is also a density-dependent (quorum) response that limits the population size[190]. This phenomenon is mediated by the soluble factor SIF (stumpy induction factor) that is released by trypanosomes, and a recent study revealed that the QS signaling in *T. cruzi* shares components with the quiescence pathways of mammalian stem cells, providing novel therapeutic targets *via* QS interference[191]. Like those parasitic species described thus far, in 2006 it was demonstrated that the budding yeast *Saccharomyces cerevisiae* endure morphological transition from the yeast form to

Table 1 Quorum sensing systems and quorum sensing-virulence associated phenotypes in the reviewed organisms

Organism	QS systems	Regulated phenotypes
Gram (-) bacteria		
Pseudomonas aeruginosa	(1) LasI (S)-LasR (R)-HSL (s) (2) HSL RhlI-RhlR (3) Alkyl quinolones (PQS)	Expression of several virulence factors including: Pyocyanin, pyoverdine, elastase, alkaline protease, HCN, rhamnolipids and biofilm formation
Vibrio harveyi	(1) LuxM (S)-LuxN (R)- 3OHC4HSL (s) (2) LuxS (S)-LuxP (R)-AI-2 (s) (3) CqsA (S)-CqsS (R)-CAI-1 (s)	Expression of bioluminescence genes and several virulence factors including: Siderophores, protease, EPS production
Vibrio cholerae	(1) LuxS (S)-LuxP (R)-AI-2 (s) (2) CqsA (S)-CqsS (R)-CAI-1 (s)	Expression of several virulence factors including: Biofilm formation and EPS production.
Vibrio fischeri	(1) LuxI (S)-LuxR (R)-3OC6HSL (s) (2) AinS (S)-AinR (R)-C8HSL (s) (3) LuxS (S)-LuxP (R)-AI-2 (s)	Expression of bioluminescence, host colonization and motility genes
Acinetobacter spp	(1) Abal (S)-AbaR (R)-3OHC12HSL (s)	Expression of virulence factors including biofilm formation.
Burkhordelia cepacea	(1) Cep1 (S)-CepR (R)-C8HSL,C6HSL (s) (2) Ccil (S)-CciR (R)-C8HSL,C6HSL (s)	Expression of swarm motility genes and several virulence factors including: proteases, siderophores, toxins, antifungal agents and biofilm formation
Escherichia coli *Salmonella typhimurium*	(1) Unknown (S)-SdiA (R)-3OC8HSL (s) (2) LuxS (S)-LsrB (R)-AI-2 (s) (3) Unknown (S)-QseC (R)-AI-3 (s)	Expression of motility genes, acid resistance and virulence factors including biofilm formation
Gram (+) bacteria		
Staphylococcus aureus	(1)AgrB (S)-AgrC (R)-AIP(s)	Expression of several virulence factors including: hemolysins, leukocidins, cell surface adhesins, exoenzymes, and biofilm formation
Fungi		
Candida albicans	2-phenylethanol, tryptophol, farnesol, farnesoic acid, and tyrosol as (s)	Fungal dimorphism, biofilm formation and expression of virulence genes
Mucor rouxii, Histoplasma capsulatum, Ceratocystis ulmi	QS (s) unknown	Fungal dimorphism
Saccharomyces cerevisiae	Phenylethanol and tryptophol as (s)	Transition from yeast to filamentous form
Protozoa		
Trypanosoma cruzi	SIF soluble factor as (s)	Differentiation of replicating to non-dividing forms
Mammal cells		
$CD4^+$T cells	IL-2 (s) and IL-2Rα (R)	Regulation of the $CD4^+$T cells population
Cancer cells	Multiple (S) and (R) and paracrine factors as (s)	Regulation of the metastatic process

IL-2: Interleukin 2; SIF: Soluble inhibitory factor; QS: Quorum sensing; PQS: Pseudomonas quinolone signal; EPS: Exopolysaccharide.

a filamentous form in response to both cell density and the nutritional state of the environment. This induction is mediated by the phenylethanol and tryptophol auto signaling molecules, that regulate the transcription of a set of approximately 150 genes and which include *FLO11*, an essential gene for filamentous growth as well as several others genes that may play a role in the transition from the exponential to the stationary growth phase[192,193]. However, not only parasitic infections or traits present in unicellular eukaryotes are controlled by QS, since surprisingly in our body the number of cells of the immune system is maintained throughout a similar mechanism, where IL-2 is produced and secreted by activated $CD4^+$ T cells and sensed with high affinity (IL-2Rα) by a population of $CD4^+$ Treg, which in turn can regulate the number of total $CD4^+$ T population[194] by competition for the IL-2 factor[195]. Failure of QS due to the absence of IL-2 or by defects on the sensor IL-2Rα leads to lymphoid hyperplasia and autoimmune diseases[196]. Furthermore, in 2009 Hickson *et al*[197] proposed that cancer cells may use QS mechanisms to operate as communities and regulate different multicellular functions as the metastatic process resembles bacterial biofilm formation and dispersion. This idea emerged based on several lines of evidence that suggested a close relationship between high cancer cell densities and high metastatic ability[197]. This relationship can be possibly explained by the fact that the cells secrete paracrine factors or autoinducers that increase their metastatic efficiency; these observations have been made since the 90's[198] and recently by combining mathematical modeling with experimental evidence, the presence of QS systems in cancer was confirmed[199]. Such interesting findings are now opening new areas of study, including the development of future clinical applications (a summary of all the QS reviewed is provided in Table 1).

Abstract

The knowledge of gallstone disease (GSD) is crucial to manage this condition when organizing screening and preventive strategies and identifying the appropriated clinical therapies. Although cholecystectomy still be the gold standard treatment for patients with symptomatic GSD, expectant management could be viewed as a valid therapeutic method for this disorder. If early treatment of GSD decreases the morbidity or avoids further cholecystectomy, it may save clinical care costs in later disease periods sufficiently to offset the screening and early treatment costs. In addition, whether routine screening for GSD is worthwhile depends on whether patients are willing to pay the ultrasonography screening cost that would reduce the risk of cholecystectomy. In this review we discuss the epidemiology, management, and economic evaluation of screening of GSD among type 2 diabetics.

Key words: Gallstone disease; Epidemiology; Management; Economic evaluation; Type 2 diabetes

Core tip: According to the willingness-to-pay viewpoint, this review indicated that from the societal perspective but not from consumer viewpoint, it is worthwhile to organize a routine ultrasonography screening for gallstone disease in diabetic population for further cholecystectomy prevention.

INTRODUCTION

Gallstone disease (GSD) is a common gastrointestinal condition with crystalline deposits in the gallbladder and impaired excretion of bile into the intestine throughout the world[1]. GSD yields a relative lower mortality rate, however, a relative higher risk of mortality in GSD patients is not totally explained by the high mortality rate of related cancer. This high morbidity of GSD substantially affects the economy and public health[2]. The increasing incidence of GSD over the past several decades is due to parallel modifications in personal dietary habits and physical activity associated with the Western lifestyle[3]. In the absence of an organized screening program for symptomatic GSD, treating GSD and related complications yields substantial medical burden[1].

Based on the Wilson criteria, GSD is needed to screen due to it is one of essential health issues; the disease natural course should be known; there should be a recognizable latent or early symptomatic state; a screening process is easy to do and interpret, accurate, acceptable, reliable, and has good sensitivity and specificity; there should be an acceptable treatment recognized for this disorder; treatment is much better if began early; there should be a clinical policy on who should be treated; both diagnosis and treatment have good efficacy; and this condition should be a continuous disease process[4]. Both obesity and the metabolic syndrome have been viewed as risk factors related to GSD formation[3,5,6]. Epidemiologic evidence suggested that people with diabetes mellitus were at higher risk of stone formation[3,7]. Academic studies indicated an increased morbidity of GSD in diabetic patients[7-9]. In addition, hypertriglyceridemia, hyperinsulinemia, and autonomic neuropathy (leading to gallbladder hypomotility and biliary stasis) were also revealed as associated factors to the incident GSD diabetic population[7,8]. This implies that GSD formation and diabetes development may share pathophysiologic pathways[3]. However, how diabetes predisposes to GSD is still not well known[8].

The choice of ultrasound scanning in GSD evaluation is ideal as it is cheap, non-invasive, safe, and repeatable without known adverse effect on the patients in clinical scenarios[10]. For symptomatic GSD subjects, expectant management may also indicate a valid clinical therapy although cholecystectomy still represents the gold standard[11]. From the viewpoint of preventive medicine, early detection of GSD by routine ultrasonography screening followed by appropriate therapy could avoid the further cholecystectomy. This review aims to explore the epidemiology, management, and economic evaluation of screening of GSD among type 2 diabetics.

THE CLINICAL DIAGNOSIS OF GSD

It is often a diagnostic challenge to determine which abdominal symptoms are related to GSD. Typically, GSD pain occurs in the right upper quadrant of the abdomen, but pain is not specific in this area[12]. Fewer than 50% of those with GSD actually have clinical symptoms, and fewer than 10% further develop potentially life-threatening complications[13]. The physicians must depend on the patient's description of the pain and results of laboratory examinations and diagnostic imaging to decide a appropriate diagnosis[12]. The physical examination also may show mild epigastric or right upper quadrant tenderness, but most patients do not have significant physical characteristics[13]. The majority of asymptomatic GSD will remain asymptomatic for a long time period.

Mechanisms underlying GSD formation include supersaturation of bile with cholesterol, consequent sedimentation, crystallization, and stone formation and abnormal gallbladder motor function with resultant delayed emptying and stasis of bile[10]. The availability of ultrasonography as viewed a valid tool for GSD diagnosis has allowed the evaluation of GSD morbidity[2]. It is safe, fast, and not expensive and involves no radiation exposure[13]. Positive findings include single or multiple stones, a positive Murphy sign on contact with the ultrasonographic probe, thickening of the gallbladder wall, and pericholecystic fluid[14]. Patients are usually left feeling unwell for as much as one or two days. If obstruction persists, it worsens movement and palpation, is associated with fever, and is localized to the right upper guardant part of abdomen, with the pain becoming sharp, which will result in acute cholecystitis[12,15]. Clinical studies showed higher positive (0.99-1.00) and negative (0.90-0.96) predictive values regarding the diagnostic efficacy, indicating that ultrasonography is a reliable technology for GSD screening[1,16]. However, a drawback is that its accuracy is dependent on the people who perform and interpret it[13].

Biliary pain occurs when the neck of the gallbladder is hindered by a gallbladder or stone pressure rises, producing a visceral foregut pain[15]. Factors that relate to choledocholithiasis include tests of abnormal liver function, common bile duct dilation of eight mm or more, and common bile duct stones identified by ultrasonography[17]. In addition, the abdominal plain radiography or computer tomography (CT) scan should also exclude the presence of calcified stones[18-20].

THE MORBIDITY OF GSD

Epidemiological studies in both Eastern and Western countries showed that ultrasonography is an reliable diagnostic tool for GSD morbidity[2,21-23]. The mechanisms of GSD have been implicated in type 2 diabetes. Some controversy exists regarding the association between diabetes and GSD, although population-based epidemiologic studies have demonstrated a positive relationship between type 2 diabetes and increased morbidity of GSD[1,24-26]. The possible pathogenic mechanism for this is that type 2 diabetic population

BMI: Body mass index; CHD: Coronary heart disease.

with GSD may cause acute cholecystitis more obvious and make higher likelihood of progression to septicemia compared with non-diabetic subjects, who exhibit functioning gallbladders normally. Type 2 diabetic patients may show a higher lithogenic bile index compared with non-diabetics after adjustment for sex and age[9]. The association between type 2 diabetes and GSD is stronger among patients who have a history of treated diabetes mellitus than it is among those with a single disease history of diabetes, that is, hyperglycemia may affect gallbladder motility[21]. The linkage between obesity, diabetes, and GSD most likely originate from metabolic syndrome[16,27]. In addition, diabetic patients represent cases of hyperglycemia that reflect relevant effects on gallbladder motility[9].

Tables 1 and 2 indicate that many evidence-based studies of the prevalence, incidence, and risk factors for GSD have been conducted. However, it is difficult to appropriately compare the results of some studies because the heterogeneous nature of these studies (for example, patient selection), which varied significantly. The prevalence of overall GSD was higher than the general Chinese population in Taiwan when using the same methodology of GSD assessment[8,42]. Previous population based studies had resulted in disparate findings on diabetes mellitus and GSD[24,25]. In Italy, the estimated prevalence of GSD is significantly higher in diabetic patients than in the general population (24.8% *vs* 13.8%)[43]. In New Zealand, the prevalence of GSD in diabetics was estimated to be 32.7% as compared to 20.8% in the control group[44]. An epidemiological study in Nigeria concluded that 17.5% of the diabetic patients had GSD on ultrasound[10]. The study about the prevalence of GSD in Chinese type 2 diabetics is rare or lack of appropriate statistical methods. The overall prevalence of GSD among type 2 diabetics in Kinmen was 14.4%, including single stone 8.0%, multiple stones 3.2%, and cholecystectomy 3.2%[42]. Further, the overall prevalence among elderly type 2 diabetics was 17.1% (men: 14.5%, women: 19.0%), which included the presence of single stone, 9.1%; multiple stones, 4.4%; and cholecystectomy 3.7%[45]. Upon international comparison, the prevalence of any type of GSD falls within the range of 10%-32% in type 2 diabetics and is higher than that in non-diabetic patients[44,46-49].

Cross-sectional study designs only reveal useful information of disease prevalence, but reveal nothing about the incidence or temporality in the study population. To explore the incidence and causal relationships between predictive factors and disease, the population needs to be re-examined regarding follow-up time. The morbidity of GSD increases as age increases, noticeably elevating in people aged 40 years and older and becoming from 4- to 10-fold more likely[4,16]. The incidence of GSD appears to vary among test diabetic populations and differs among studies conducted in disparate countries[1]. In the general and elderly Chinese type 2 diabetes population, the incidence of GSD was 3.56% per year (95%CI: 1.78%-6.24% per year) and 4.17% per year (95%CI: 2.22%-7.05% per year), respectively[9,26]. Previous epidemiologic studies showed that the annual incidence of overall GSD in type 2 diabetics was higher than that in other general population-based studies[9,22]. In addition, evidence-based studies exploring GSD in the elderly sub-population have focused almost entirely on the consequences of

Table 2 Incidence of gallstone disease in various populations

Ref.	Study year	Screened number	Setting	Incidence of gallstone	Associated factors
Festi *et al*[2]	2008	9611	Italy	0.67% (0.66% in males, 0.81% in females)	Risk factors: In men: increasing age, high BMI, history of diabetes, peptic ulcer and angina, and low cholesterol and high triglyceride levels; In females: increasing age and high BMI Predictors: In men: increasing age and pain in the right hypochondrium In females: increasing age

interventions such as percutaneous cholecystostomy and endoscopic retrograde cholangiopancreatography, or on the management of elderly patients with symptomatic biliary disease at hospitals[50,51]. The annual incidence of GSD in elderly type 2 diabetics was also higher than that in younger diabetic patients or the general population using the same methodology of GSD assessments[2,26]. To explore the incidence and risk factors for GSD is essential to prevent its development and avoid the further cholecystectomy caused by complications, which is often insidious in nature.

Gallstone formation is multifactorial, and involves constitutional and environmental factors. People with GSD have increased mortality, overall mortality, and mortality from cardiovascular disease and cancer. This relationship exists for ultrasound diagnosed GSD and cholecystectomy[33]. GSD with complications, especially cholecystitis and cholangitis, in the elderly is related to higher morbidity and mortality rates[52].

THE NATURAL COURSE OF GSD

The natural course of GSD is usually not malignant, but complications contribute substantially to medical care costs and may even be life threatening[40]. One of the essential advantages of early detection of GSD is that ultrasonography could diagnose asymptomatic stages, which incurs early treatment and the prevention of major complications such as acute pancreatitis or gallbladder cancer[53,54]. The increasing magnitude and epidemiologic shifts in the natural history of GSD worldwide qualify for the need of research in different geographical areas, and also to explore the predictive factors[55,56]. This is particularly because the majority of risk factors associated with GSD are potentially modifiable[41]. In addition, cholecystectomy could be used to treat GSD, that is, the estimated utility value in subjects with GSD will be a 0.09 increase from this therapy. Thus, the number of quality-adjusted life years obtained from cholecystectomy would be 1.8 (0.09 × 20) if subjects had a life expectancy of 20 years[57]. Screening regimes for GSD depend on the incidence and progression rates as well as the risk factors that change these rates. An understanding of the disease progression of GSD would appropriately determine the benefits of prevention strategies.

A chronic disease model according to the epidemiologic information of GSD is necessary to allow the benefits of intervention to be modeled. Since GSD may only persist a short duration before cholecystectomy, a shorter desirable interscreening interval may be warranted. The disease progression of GSD affects the decision of a screening interval for the surveillance of this patient population. In addition, the effectiveness of screening strategy for GSD is determined by the progression of GSD[58]. Since the natural history of GSD may not be homogeneous across study countries, assumptions of disease progression parameters could not be directly compared from previous results[11,59]. Several evidence-based studies on the natural history of GSD also have been conducted[11,58]. A clearer understanding of the risk factors associated with GSD may help us to identify cases and to reduce the risk in some patients[60].

For the disease natural course of GSD, the four-state Markov chains model following the pathway of

proliferative phase is showed as follows:

$$\underset{\text{(State 1)}}{\text{No GSD}} \xrightarrow{\lambda_{12}} \underset{\text{(State 2)}}{\text{single stone}} \xrightarrow{\lambda_{23}} \underset{\text{(State 3)}}{\text{multiple stones}} \xrightarrow{\lambda_{34}} \underset{\text{(State 4)}}{\text{cholecystectomy}}$$

To estimate the progression rates, let λ_{12}, λ_{23}, and λ_{34} indicate the annual progression rate from state 1 to state 2, from state 2 to state 3, and from state 3 to state 4, respectively. The annual progression rates from single stone to multiple stones and from multiple stones to cholecystectomy are estimated as 0.114 (95%CI: 0.015-0.173) and 0.148 (95%CI: 0.101-0.242), respectively. Corresponding average durations in single stone state and multiple stones stage are 8.77 (95%CI: 5.78-66.67) years and 6.76 (95%CI: 4.13-9.90) years, respectively. The application of parameters to the annual transition probabilities from single stone state to multiple stones state and from multiple stones state to cholecystectomy state are 10.00% and 13.76%, respectively. An annual screening program could reduce cholecystectomy by 82.9% (95%CI: 75.7%-90.4%) compared with the non-screening group. Comparatively, biennial screening, 3-year screening, 4-year screening, and 5-year screening could reduce cholecystectomy by 71.6% (95%CI: 57.0%-88.8%), 64.8% (95%CI: 46.1%-81.5%), 49.6% (95%CI: 23.9%-75.3%), and 32.1% (95%CI: -2.8%-66.7%), respectively[58]. However, one problem is in four-state Markov chains model, we should be aware that single stone might not always consequentially develop into multiple stone.

Many factors such as obesity and type 2 diabetes have been indicated to be significant risk factors related to GSD[1,9,11], and the transition state is probably unstable over time. The screening efficacy of preventing cholecystectomy associated with GSD depends on early diagnosis. To choose the frequency of sonographic check-ups as well as sensitivity and specificity, it is helpful to know the disease scenario and progression from the asymptomatic state to the symptomatic state. This characteristic will provide early diagnosis and therapeutic strategies for GSD[57].

THE MANAGEMENT OF GSD

The treatment options for GSD are according to few crucial steps such as typical symptoms, further complications, and gallbladder function, as well as size and composition of GSD[18]. Cholecystectomy remains the reliable operation for patients with symptomatic GSD. It is safe because the lowest risk of recurrence and more than 90% of patients with complete biliary pain relief[12]. Currently, it is also under argumentation if cholecystectomy may be also used for pre-symptomatic GSD. It is generally presumed that surgical procedures are not suggested routinely in symptom-free subjects due to the low rate of complications[18].

Statins used could relieve hepatic cholesterol biosynthesis and may reduce biliary cholesterol secretion, consequently causing decreased cholesterol concentration in bile[61]. A larger observational study showed academic evidence that long-term use of statins is related to a decreased rate of diagnosed GSD requiring advanced cholecystectomy[62]. Another population-based case-control study also indicated that long-term sustained statin use decreases incident GSD in both men and women[63]. The results may be one of clinical relevancies given that GSD represents a major burden for medical care systems[62]. In addition, a previous study showed that ezetimibe could not only prevent cholesterol GSD through obstructing intestinal cholesterol absorption so that biliary cholesterol secretion is decreased, and gallbladder motility function is reserved by desaturating bile in gallstone-susceptible C57L mice disputed to the lithogenic diet, but also promote the dissolution of cholesterol GSD through a greater capacity to develop an abundance of unsaturated micelles[64]. For both prevention and treatment of cholesterol GSD, ezetimibe is viewed as a novel and potential cholelitholytic agent[65].

Oral bile acids have successfully dissolved GSD in an extremely limited patient population for the nonsurgical treatment of GSD[12]. The clinical effectiveness of bile acid therapy was determined in symptomatic GSD smaller than 15 mm within a functioning gallbladder[12]. Oral bile acids could be only selected in symptomatic GSD patients who are unsuitable for cholecystectomy and have small, uncalcified, and cholesterol-enriched stones with a patent cystic duct in a functioning gallbladder[18,66]. Currently, bile acid therapy is revealed only for patients unsuitable or unwilling to receive cholecystectomy[12,67].

A previous study showed that acute cholecystitis grows in up to 10% of symptomatic GSD patients and leads to the entire obstruction of the cystic duct[68]. Once acute cholecystitis is found, patients should be revived with intravenous fluids, accompanying medical conditions should be stabilized, and surgery should be performed at the earliest time[12]. In addition, GSD could migrate from their primary site in the gallbladder through the cystic duct and into the common bile duct[12]. An essential treatment for choledocholithiasis includes gallbladder removal and clearance of retained common bile duct stones. The findings of a prospective, multi-center, randomized controlled trial comparing single-stage laparoscopic cholecystectomy (LC) and laparoscopic stone extraction with preoperative endoscopic retrograde cholangiopancreatography followed by LC indicated that the procedures were equally effective in the clearance of common bile duct stones[69].

THE ECONOMIC EVALUATION OF SCREENING OF GSD

Based on the welfare economic theory, the maximum value of individual's willingness-to-pay (WTP) is defined as the benefit to an individual receiving medical service or intervention[70]. For the WTP perspective, the payment vehicle not only refers to the means of payment by

a patient, but also is assumed as total cost of both copayment for health insurance scheme and out-of-pocket money which is not covered by health insurance benefit[71]. An evidenced-based study indicated that 24.4% of subjects would not like to pay a screening cost for GSD detection, implying that they did not think GSD status would influence their daily quality of life. The WTP values were significantly higher in individuals with more advanced GSD than in those with mild GSD. This also suggests that GSD associates with impaired quality of life and thus such patients would pay more to reduce the sequelae of further cholecystectomy[70].

Economic evaluations are criticized commonly by decision makers for ignoring budget impacts, about which decision makers are desperately concerned. Payers could get into financial difficulty if they adopt too many cost-effectiveness interventions and affordability, which depends on the overall volume of patients, is therefore a prime concern[11,72]. Few well-organized population-based studies have been conducted to explore the cost and effectiveness of GSD screening regimes. The cost-benefit analysis was used in one study to discuss whether a GSD screening regime compared with non-screening group is worthwhile in Taiwan from different viewpoint. The findings revealed that indirect costs play a main role in the routine GSD screening regime. Annual screening program could save the most discounted indirect costs per case (NTD220345) (US$6995.1; 31.0NTD = 1USD) compared with non-screening group. Based on the health care payer's viewpoint, annual screening discounted net cost was NTD24893 (US$790.3) per case. This implied that from health care payer's viewpoint, the clinical efficacy from the routine annual screening regime could not exceed the cost incurred in the GSD screening strategy. To consider the indirect cost, the NTD245238 (US$7785.3) net saving per case indicates that from the societal perspective, the annual screening program is rather constructive ($P < 0.0001$)[72]. In Chile, a screening program for GSD in a high risk sub-population reveals significant cost-effectiveness. The incremental cost-effectiveness ratio of universal screening compared with elective intervention, high risk intervention, and selective screening programs were estimated US$180, US$147, and US$481, respectively[73]. Preventive strategies aimed at GSD screening incur both substantial medical budgetary savings and highly cost-effective clinical care.

METHODOLOGICAL CONSIDERATION

Since GSD has a more complicated clinical aspect, it is not the rule for people with GSD definitely to progress towards more serious complications. In clinic, 60% of the patients with GSD are asymptomatic throughout their life. In these people, early detection may not help them to avoid possible healthy problem. In addition, up to now, there has been no effective early treatment for GSD that could prevent the resulting cholecystectomy. What we could and we should do now for GSD patients is to find the patients more likely to have a serious outcome in the future and perform an early cholecystectomy to avoid the secondary common bile duct stone, gallstone pancreatitis and possible cancerization. That is why some asymptomatic patients are indicated for cholecystectomy. Also, some asymptomatic patients with diabetes and cardio-cerebrovascular complications should be treated by cholecystectomy in a stable condition to avoid unpredictable attack of GSD. That is currently the aim for GSD screening. Furthermore, since the natural history of GSD may be heterogeneous and more complicated, according to current knowledge, there is no relationship between the number of gallstones and cholecystectomy. We still have no clear idea about how the gallstone produces and what is the progression factors for GSD.

CONCLUSION

In conclusion, GSD is an escalating major health problem and involves constitutional and environmental factors. Considering the fact that oral bile acids could be only selected in an extremely limited patient population (symptomatic gallbladder disease patients who are unsuitable for surgery and have small, uncalcified, and cholesterol-enriched stones), the majority of patients with or without complications will need surgery. Without suitable screening programs for symptomatic GSD, treating GSD and related complications yields substantial medical care costs. Whether routine screening for GSD is worthwhile depends on whether subjects are willing to pay the ultrasonography screening costs that would reduce the risk of further cholecystectomy.

Abstract

Magnetic resonance imaging (MRI) is highly sensitive in identifying residual breast cancer following neoadjuvant chemotherapy (NAC), and consequently is a commonly used imaging modality in locally advanced breast cancer patients. In these patients, tumor response is an important prognostic indicator. However, discrepancies between MRI findings and surgical pathology are well documented. Overestimation of residual disease by MRI may result in greater surgery than is actually required while underestimation may result in insufficient surgery. Thus, it is important to understand when MRI findings are reliable and when they are less accurate. MRI most accurately predicts pathology in triple negative, Her2 positive and hormone receptor negative tumors, especially if they are of a solid imaging phenotype. In these cases, post-NAC MRI is highly reliable for surgical planning. Hormone receptor positive cancers and those demonstrating non mass enhancement show lower concordance with surgical pathology, making surgical guidance more nebulous in these cases. Radiologists and surgeons must assess MRI response to NAC in the context of tumor subtype. Indiscriminate interpretations will prevent MRI from achieving its maximum potential in the pre-operative setting.

Key words: Breast; Magnetic resonance imaging; Neoadjuvant chemotherapy; Biomarkers; Phenotypes

Core tip: Following neoadjuvant chemotherapy, breast magnetic resonance imaging (MRI) most accurately predicts surgical pathology in triple negative, Her2 positive and hormone receptor negative tumors, especially if they are of a solid imaging phenotype. In these cases, post-neoadjuvant chemotherapy (NAC) MRI is highly reliable for surgical planning. Hormone receptor positive cancers and those demonstrating non mass enhancement show lower concordance with surgical pathology, making surgical guidance more nebulous in

these cases. Radiologists and surgeons must assess MRI response to NAC in the context of tumor subtype.

How to use magnetic resonance imaging following neoadjuvant chemotherapy in locally advanced breast cancer. *World J Clin Cases* 2015; 3(7): 607-613 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i7/607.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i7.607

INTRODUCTION

Breast cancer is a heterogeneous disease consisting of many different tumor subtypes, each with its own biology, prognosis, and treatment options. These subtypes are characterized by distinct molecular profiles, proliferation rates, and tumor receptors, including estrogen receptor (ER), progesterone receptor (PR) and human epidermal growth factor receptor 2 (HER2). In today's paradigm of personalized medicine, biomarker profiles allow tailoring treatment strategies to the individual tumor. Current treatment of locally advanced breast cancers includes chemotherapy, hormone therapy [if hormone receptor (HR) positive] and surgical resection. Increasingly, chemotherapy is given prior to surgery. Neoadjuvant chemotherapy (NAC) offers advantages in terms of adding prognostic information and improving surgical options. Tumor response to NAC is an important prognostic indicator. Patients who have a pathologic complete response (pCR) following NAC have improved overall survival, disease-free survival and recurrence-free survival[1-6]. NAC can also facilitate breast-conserving surgery in patients whose initial presentation may have warranted mastectomy[7-9]. Even if patients still have residual disease, especially if they need radiation, breast conservation will have fewer complications than mastectomy and radiation. As treatments improve and responses to NAC become more common, a new challenge arises - accurately determining the extent of surgical resection needed to excise residual tumor. Magnetic resonance imaging (MRI) is highly sensitive in identifying residual disease following NAC, with multiple studies demonstrating it to be more accurate than mammography, ultrasound or physical examination[10-16]. Consequently, MRI is a commonly used imaging modality in locally advanced breast cancer patients.

In these patients, pre-operative MRI is an important addition to the decision-making armamentarium. The appearance of breast cancer on MRI can be classified by its morphology into phenotypic categories[17], which are associated with response to NAC and ability to offer breast-conserving surgery[17,18]. Overall, MRI has been shown to be the most sensitive imaging modality by which to follow a patient's response to NAC and to be more sensitive than clinical examination[11-16,19-23]. While an excellent test, MRI is far from perfect. Discrepancies between MRI findings and surgical pathology are well documented. Overestimation of residual disease by MRI may result in greater surgery than is actually required (larger lumpectomies, wider margins, mastectomy)[1,24]. Underestimation may result in insufficient surgery, resulting in positive margins and re-excisions[1]. Thus, it is important to understand when MRI findings [particularly radiologic complete responses (rCR)] are reliable and when they are less accurate.

The general question of the accuracy of an rCR to predict a pCR may be overly broad - accuracy needs to be considered in the context of tumor subtype. Literature has shown that the accuracy of post-NAC MRI is related to tumor subtype, with the strongest evidence arising from multi-institutional trials like I-SPY[18] and Translational Breast Cancer Research Consortium Trial 017[25], as well as additional support from multiple single-institution studies[26-29]. A smaller literature base suggests that MRI phenotype is also related to the accuracy of MRI in the post-NAC, pre-operative setting.

In this manuscript, we review the evidence for accuracy of post-NAC MRI findings and focus on how best to use MRI in this setting, specifically for the evaluation of extent of disease and pCR. In particular, this review will evaluate the association between the diagnostic performance of MRI in the post-NAC setting and the biomarker profile of the tumor, as well as the association between pre-NAC phenotypic tumor appearance on MRI and diagnostic accuracy. A clear understanding of these relationships can be valuable in setting appropriate treatment goals and expectations[18]. In much the same way each breast cancer requires a tailored treatment strategy, a strategy for tailored imaging interpretation should also be employed and would enable more accurate recommendations to be made for individual patients.

ASSOCIATIONS WITH MRI PHENOTYPE

The relationship between phenotypic MRI appearance of breast cancers and response to NAC has been studied[17,29]. Although phenotypic categorizations vary slightly, in general, phenotypes tend to focus on the separation of solid and well-contained unifocal (Figure 1A) and multifocal masses from more diffuse and infiltrative non-mass enhancement (NME) (Figure 1B)[17,18,29]. These phenotypes impact NAC response, with well-defined mass phenotypes more likely to have a response sufficient to allow for breast conserving surgery[17,18]. Well-defined masses also show higher concordance between MRI and surgical pathology, with an rCR in the setting of solid phenotypes (particularly hormone-negative tumors) predictive of a corresponding pCR at surgery[18]. On the other hand, MRI is less accurate in predicting pCR in tumors presenting as non-mass/diffuse enhancement, with larger discrepancies between post-NAC MRI and surgical pathology[18].

Studies have also suggested that these differing phenotypic appearances have particular patterns of

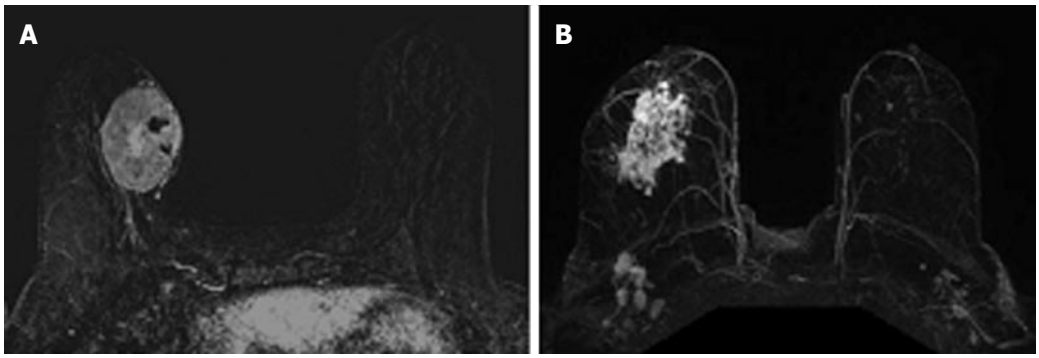

Figure 1 Magnetic resonance imaging phenotypes solid unifocal mass (A) and more diffuse non-mass enhancement (B).

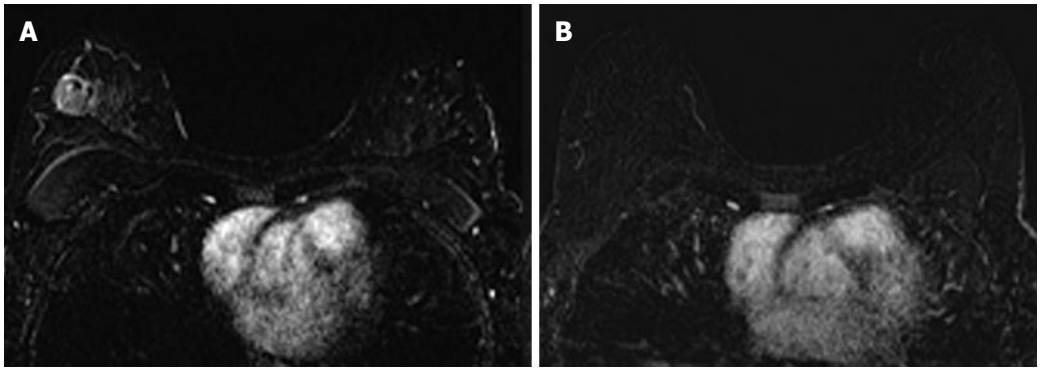

Figure 2 Forty-two years old woman with triple negative right breast cancer. A: Baseline axial T1-weighted post-gadolinium fat-saturated magnetic resonance image demonstrates a 3.6 cm unifocal mass in the upper outer quadrant; B: Post-neoadjuvant chemotherapy magnetic resonance imaging demonstrates complete resolution of the mass seen previously. Surgical pathology demonstrates biopsy site changes and expected changes related to chemotherapy with no evidence of residual cancer.

response to NAC[17,24,29-31]. Locally advanced malignancies presenting as a mass lesion often shrink in a concentric pattern to a smaller mass. Following NAC, NME often diminishes to a scattered pattern of residual disease that can extend throughout the original area of involvement, though as small foci that are difficult to detect on MRI. Residual infiltrating single cells will likely not be visible on MRI.

The associations between MRI accuracy and phenotype are likely confounded by tumor biomarker status. Comparisons of MRI phenotypes relative to tumor biomarker profiles[18,24,28,29,32,33] have shown a number of trends, with an association between unifocal mass presentation and triple negative tumors (TN: ER negative, PR negative, Her2 negative) (Figure 2). Multifocal mass presentation is more common in HER2+ (and questionably in HR positive) tumors. Although they do not have a characteristic phenotypic presentation, HR positive cases, especially ER positive tumors, are more likely to present as non mass/diffuse enhancement compared to other subtypes (Figures 3 and 4). Although these relationships have been demonstrated, all phenotypes are seen in all biomarker profiles[18].

ASSOCIATIONS WITH TUMOR BIOMARKERS

Extent of disease evaluation

The impact of tumor biomarkers on the accuracy of MRI for detecting the extent of disease must be considered when interpreting post-NAC MRI in anticipation of surgical resection. In addition to the individual status of receptors, biomarkers can categorize tumors into different subtypes. Tumor subtypes include luminal (ER/PR positive, Her2 negative), Her2 positive, and basal (ER/PR/Her2 negative; analogous to TN.) Multiple studies have demonstrated that in the post-NAC setting, the MRI assessment of extent of residual disease is most accurate in tumors that are either TN (Figure 2) or Her2 positive.

McGuire *et al*[26] retrospectively reported their institutional experience and found that MRI was most accurate in estimating pathologic size of residual disease in the Her2 positive and TN subtypes. Additionally, they found that MRI was more likely to underestimate the amount of residual disease in the luminal subtype (ER/PR positive, Her2 negative) when compared with TN or Her2 positive tumors. In a study done by Loo *et al*[29], MRI findings correlated well with the pathologic findings in the TN and Her2 positive breast cancers, but not with ER positive or Her2 negative breast cancers. Kuzucan *et al*[24] evaluated only Her2 negative cancers, and report similar findings-higher concordance between post-NAC tumor size on MRI and pathologic size in HR negative tumors compared to HR positive tumors. In Kuzucan's study, MRI accuracy was also increased in tumors expressing high levels of the proliferation marker Ki-67 (defined as > 40% positive). A study by

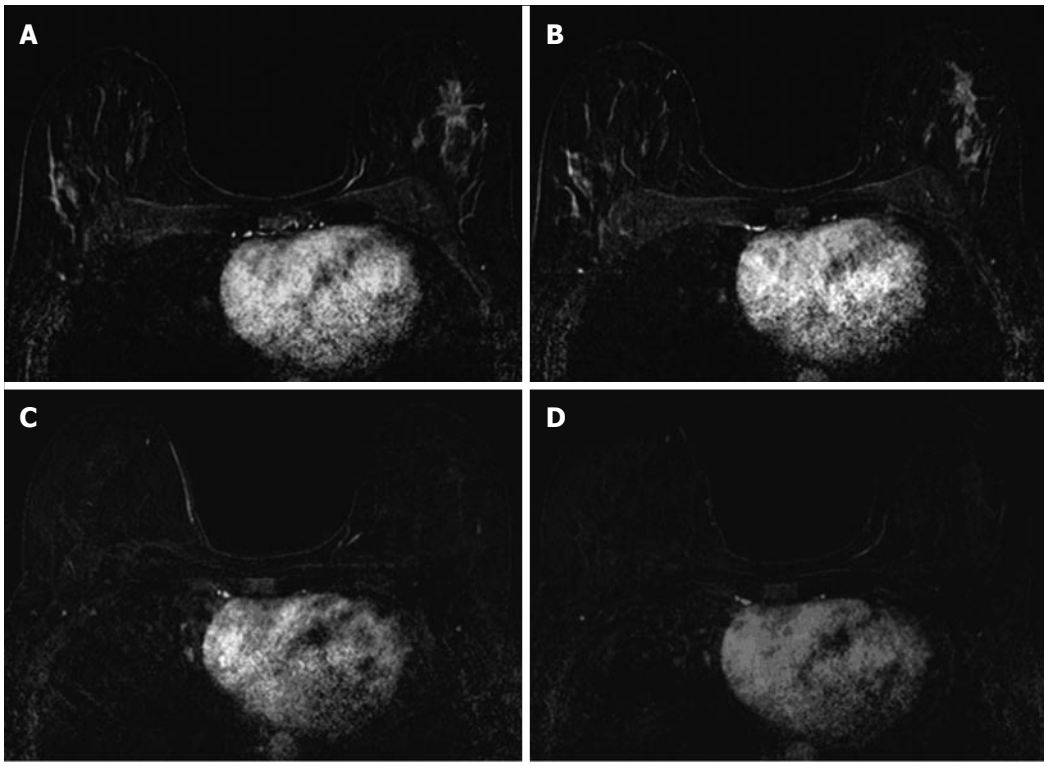

Figure 3 Thirty-seven years old woman with HR+ left breast cancer. A and B: Baseline axial T1-weighted post-gadolinium fat-saturated magnetic resonance image demonstrates a speculated mass and contiguous non-mass enhancement extending posteriorly for a total of 7 cm of disease in the upper outer breast; C and D: Post-neoadjuvant chemotherapy magnetic resonance imaging demonstrates decrease in size and degree of enhancement of prior findings. Surgical pathology demonstrates 6.9 cm of invasive ductal carcinoma.

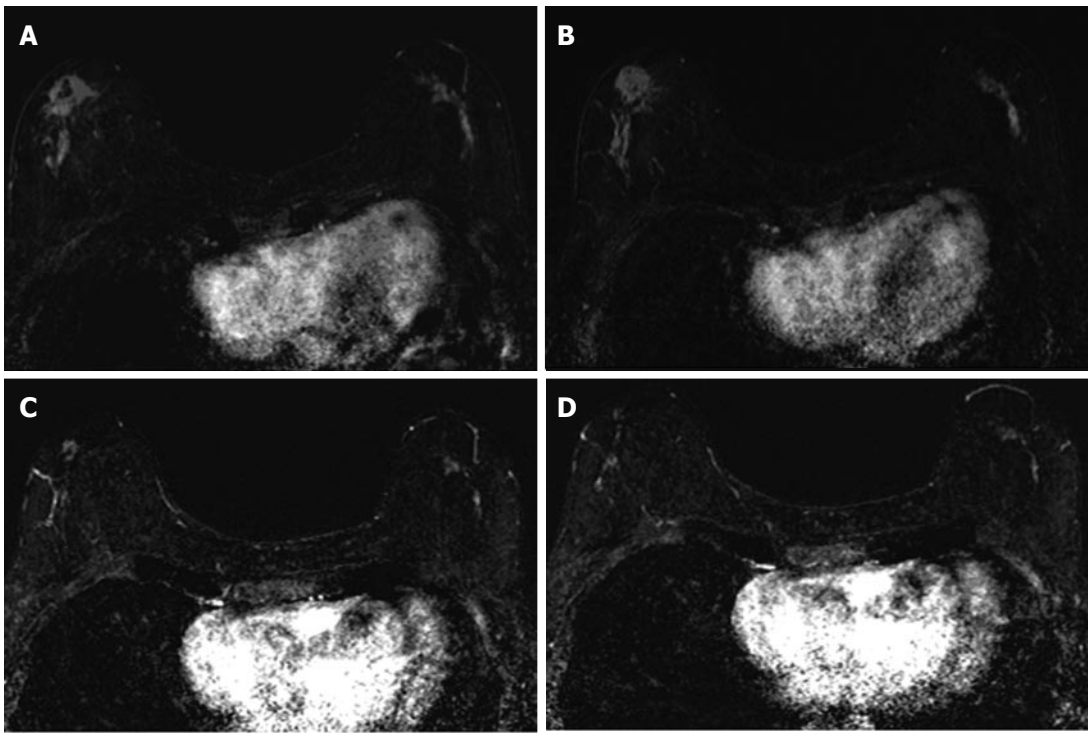

Figure 4 Sixty-four years old woman with bilateral HR+ breast cancer. A and B: Baseline axial T1-weighted post-gadolinium fat-saturated magnetic resonance image demonstrates 3.2 cm irregular mass and contiguous non-mass enhancement (NME), spanning up to 7.2 cm, in the right central outer breast and 3.5 cm of clumped linear NME in the central outer left breast; C and D: Post-neoadjuvant chemotherapy magnetic resonance imaging demonstrates decrease in size of the right breast mass and NME. NME in the left breast demonstrates only mild improvement. Surgical pathology demonstrates 4.3 cm of residual disease on the right and 3.7 cm of disease on the left.

Kim *et al*[34], which investigated TN cancer, also found that Ki-67 affects the diagnostic accuracy of MRI, with higher correlation between MRI and residual tumor size at surgery in Ki-67 positive patients.

In I-SPY, a multicenter neoadjuvant trial with serial MRIs over the course of therapy, there were the fewest discrepancies between the post-NAC MRI tumor size and pathologic size in Her2 positive, HR negative, and TN tumors[18]. Overall, 38% of patients analyzed had a size discrepancy of at least 2 cm between MRI and surgical pathology, with two thirds of these discrepancies being an overestimation of disease on MRI. These size discrepancies were significantly more common in HR+/Her2- tumor subtypes. Additionally, size discrepancies differed by MRI phenotype; among the solid phenotypes, underestimation of disease by 1.5 cm or more was rare. These Her2+, HR-, and TN tumors were also the tumor subtypes most likely to have a substantial response to NAC. The experience at our institution is in accordance with other published reports. In cases of Her2 positive, HR negative, and TN tumors, if there is residual disease on MRI, it is highly likely that there will be residual disease in the surgical specimen. Underestimation of disease in these subtypes is rare, particularly in the triple negative group where no false negative MRI's were seen.

pCR evaluation

Apart from measuring residual disease for the purposes of surgical planning, the ability of MRI to predict a pathologic complete response (pCR), a surrogate for improved outcome, is of particular importance in breast cancer management. Attaining pCR gives prognostic information that can be used for decision making, including the type of surgical procedure and/or reconstruction to recommend, and is also used as an immediate endpoint in evaluating the efficacy of NAC. Data show that pCR is associated with improved outcomes, and is more predictive when assessed by individual tumor subtype than for all subtypes combined[1,35]. A non-invasive method to accurately determine whether or not a pCR had been achieved would potentially change how trials are designed, and could eventually change surgical management of breast cancer.

While MRI accuracy depends on both its positive predictive value (PPV), and its negative predictive value (NPV), the NPV becomes the most important variable if the goal is to spare a patient invasive treatment in the setting of an rCR. That is, one must be able to trust that a negative MRI is a true negative in order to safely omit surgical resection or other treatment. In the reported papers looking at the accuracy of MRI for predicting pCR in the post-NAC setting, one must note that relatively high accuracy is possible with a low NPV. This can occur when MRI has a very high PPV, ultimately leading to high accuracy despite low NPV. In tumor subtypes that are less likely to respond to NAC, such as luminal tumors, the likelihood of residual disease is high, resulting in high PPV. However, the chance of a false negative is also highest in this group, so despite high apparent accuracy (driven by PPV), an rCR should be interpreted with caution (Figures 3 and 4).

Just as the accuracy of MRI in predicting extent of disease differs by tumor subtype, it appears that the ability of MRI to accurately predict pCR also differs by tumor subtype[24]. The NPV of MRI for predicting pCR differs by tumor subtype, highest in HR negative/Her2 positive tumors and triple negative (Figure 2) tumors[18,24-26,36]. In our report of I-SPY patients, when the post-NAC MRI underestimated residual disease (which occurred 4.3% of the time), all the discordant cases were either HR positive (Figures 3 and 4) or had diffuse phenotypes (Figure 4)[18].

Recently, several groups have reported on the accuracy of post-NAC MRI for correctly identifying pCR. Of note, some groups define pCR as the absence of any invasive tumor cells (the preferred definition of the FDA)[37], while others require the absence of both invasive and *in situ* disease - this definition must be noted when interpreting study findings, as residual *in situ* disease may lead to higher local recurrence rates[38].

One retrospective multicenter study of 746 women undergoing NAC found overall NPV for MRI of 47% and accuracy of 74% for predicting pCR[25]. The NPV for MRI varied by tumor subtype, and was highest amongst HR-/Her2+ tumors (62%) and TN tumors (60%). The overall accuracy was highest for HR+/Her2 negative tumors, likely because the PPV in this group was 91%. This likely reflects the fact that because this subtype is the least likely to respond to NAC, the pretest probability for having residual disease is higher.

Single institution studies have shown similar results. Chen *et al*[27] demonstrated the vast difference in MRI accuracy by tumor subtype, with accurate prediction of pCR in 95% of Her2 positive tumors, but only in 50% of Her2 negative tumors. Kim *et al*[34] found MRI accurately predicted pCR in 91% of TN cases. Kuzucan *et al*[24] focused on Her2 negative patients, and also found higher accuracy in HR negative tumors, with a PPV of 88% and NPV of 88%. In HR positive tumors, MRI had a PPV of 100% but an NPV of only 56%. The authors noted that the higher NPV in the HR negative tumors may have been related to a higher prevalence of solid tumor phenotypes, acknowledging that tumor phenotype impacts MRI accuracy and response to NAC[24]. In Ko *et al*[28]'s 2013 report, overall PPV was 89.6% and NPV was 83.8%. Of the five false negative MRI's in their study, 3 were ER positive, 2 were Her2 positive, and 3 initially appeared as non mass enhancement. The most recent report, by Bufi *et al*[36] in 2014, shows the highest NPV rates to date. In the TN tumor subtypes, they report NPV of 100%. In the Her2 positive subtype, they report NPV of 100% using diffusion weighted imaging, suggesting that newer advanced MRI techniques may improve accuracy of MRI in different subtypes[36].

CONCLUSION

MRI most accurately predicts pathology in TN, Her2 positive and HR negative tumors, especially if they are of a solid imaging phenotype. In these cases, post-NAC MRI is highly reliable for surgical planning. Hormone receptor positive cancers and those demonstrating NME demonstrate lower concordance with surgical pathology, making surgical guidance more nebulous in these cases.

While MRI may not yet meet the necessary NPV threshold to safely allow for omission of surgical treatment, this may be feasible for specific tumor subtypes in the future. It is unclear whether or not the differential accuracy of MRI by tumor subtype is mediated by tumor phenotype, tumor response to NAC, or biological differences that affect imaging, or possibly by all of these factors. Regardless, it is clear at this point that radiologists and surgeons must assess MRI response to NAC in the context of tumor subtype. If imaging interpretations are not made in this context, pre-operative MRI will continue to be limited by both overestimation and underestimation of residual disease. The same way each breast cancer requires a tailored treatment strategy, tailored interpretation strategies should also be employed. Future work on redefining thresholds for enhancement interpretation based on tumor biology and on the development of receptor subtype-based imaging protocols may improve accuracy in the future.

With the understanding that pCR predicts recurrence free survival, if an rCR can confidently predict pCR (as in TN and Her2 positive tumors), then an rCR can predict recurrence free survival. As an imaging predictor for such important outcomes, MRI interpreted in the context of tumor subtype would be a tremendous asset in decision-making and patient counseling.

Abstract

With the term "oncological screening", we define the overall performances made to detect early onset of tumors. These tests are conducted on a population that does not have any signs or symptoms related to a neoplasm. The whole population above a certain age, only one sex, only subjects with a high risk of developing cancer due to genetic, professional, discretionary reasons may be involved. Screening campaigns should be associated, when risk factors that can be avoided are known, with campaigns for the prevention of cancer by means of suitable behavior. The goal of cancer screening cannot however be limited to the diagnosis of a greater number of neoplasms. Screening will be useful only if it leads to a reduction in overall mortality or at least in mortality related to the tumor. Screening should then allow the diagnosis of the disease at a stage when there is a possibility of healing, possibility that is instead difficult when the disease is diagnosed at the appearance of signs or symptoms. This is the reason why not all campaigns of cancer screening have the same effectiveness. In Italy, every year there are about 150000 deaths due to cancer. Some of these tumors can be cured with a very high percentage of success if diagnosed in time. Cervical cancer can be diagnosed with non-invasive tests. The screening test used all over the world is Papanicolaou (Pap) test. This test may be carried out over the entire healthy population potentially exposed to the risk of contracting cancer. Public health has begun the screening campaigns in the hope of saving many of the approximately 270000 new cases of cancer reported each year. Screening is done following protocols that guarantee quality at the national level: these protocols are subject to change over time to reflect new realities or to correct any errors in the system. A simplified sketch of a possible route of cancer screening is as follows: (1) after selecting the target population, for example all women between 25 and 64 years (in the case of monitoring of cervical cancer), an invitation letter with the date and time of the appointment, planned according to the acceptance capacity of the hospital, is sent to all individuals; (2) an examination, which depending on the individual and the type of cancer to be monitored, for example, can

be a Pap smear, is performed and the patient can go home; (3) once available the results of examinations, if negative, they shall be communicated to the person concerned that will be notified by mail and will be recalled for a second test at a few years of distance, in the case of non-negativity, instead, the patient is contacted by telephone and informed of the need to carry out further examinations: it is said that the patient is in the "phase two" of the screening pathway; (4) in phase two, reached by only a small portion of the interested parties (usually less than 3%-5%), more in-depth tests are carried out, which, depending on the individual and the type of cancer, can be: cytological and colposcopic examinations, the removal of a fragment of tissue (biopsy) and subsequent histological examination, additional tests such as ultrasound, radiography, or others such as computerized tomography, magnetic resonance imaging, positron emission tomography, *etc.*, in case of negativity, the concerned person will be called for new control tests at a a few years of distance, in case of non-negativity, it will be proposed instead an oncologic therapeutic plan and/or surgery to treat the diagnosed tumor; and (5) once the treatment plan is completed, the individual enters the follow-up protocol, which is monitored over time to see if the tumor has been completely removed or if instead it is still developing. Cervical cancer is undoubtedly the most successful example of a cancer screening campaign. Paradoxically, its effectiveness is one of the strongest reasons to criticize the usefulness of vaccination against human papillomavirus (HPV) in countries where the screening service with Pap test is organized in an efficient manner. Cervical cancer screening protocols are directed to sexually active women aged 25-64 years: they provide the Pap test performed by examining under a microscope or by staining with a specific "thin prep" the material taken from the cervix with a small spatula and a brush. It is recommended to repeat the test every two or three years. It is important to emphasize that women vaccinated against HPV must continue the screening with Pap test. Although some screening programs (*e.g.*, Pap smears) have had remarkable success in reducing mortality from a specific cancer, any kind of screening is free from inherent limitations. The screening methods are in fact applied to large parts of the apparently healthy population. In particular, the limits for certain cancers may be as obvious as to prohibit the introduction of an organized screening program. Potential limitations of organized screenings are basically of two types: organizational and medical. The limits of organizational type relate to the ability of a program to recruit the whole target population. Although well organized, a screening program will hardly be able to exceed a coverage of 70%-80% of the target population, and in fact the results of the current programs are often much smaller. The limits of medical type are represented by the possibility of reducing the overall mortality, or specific mortality, using a specific screening campaign.

Key words: Cervical cancer; Screening; Papanicolaou test; Human papillomavirus test; Vaccination

Core tip: Most cases of cervical cancer are preventable and, if caught early, highly curable. Despite this, cervical cancer is the second most common cause of cancer death and a leading cause of morbidity in women worldwide. Unfortunately, cure is less likely when the disease is diagnosed at an advanced stage. Although the human papillomavirus is considered the major causative agent of cervical cancer, yet the viral infection alone is not sufficient for cancer progression.

INTRODUCTION

Human papillomavirus (HPV) belongs to the diverse group of sexually transmitted viruses that manifest affinity to the squamous epithelia of the skin and mucous membranes. It has been proved that types 16 and 18 in particular could lead to cervical cancer. High-risk strains of HPV (HR-HPV) types have been found in cervical cancer worldwide[1]. The Papanicolaou (Pap) smear was the mainstay of screening in women for over 60 years[2]. All current guidelines recommend colposcopy for women with high-grade squamous intraepithelial lesions (H-SIL), with a view to performing a biopsy or conization. Randomized controlled trials and retrospective comparisons much more strongly suggest that regular well-organized smear testing prevents a number of deaths due to cervical cancer. It should be remembered that many cellular atypia found on cervical smears never progress to cancer. The frequency of overdiagnosis has not been studied. Smear-based screening appears to have very few serious adverse effects. In practice, despite the lack of solid evidence, it seems unreasonable not to recommend screening for cervical cancer. Organized screening is preferable to opportunistic screening performed without quality controls and without research to optimize screening strategy[3,4]. The available technology for prevention and its developments allows real opportunities for cervical cancer elimination in defined populations to be foreseen[5-8].

PHASE ONE: CYTOLOGY AND HPV DNA TESTING

Two quality metrics for gynecologic cytology are

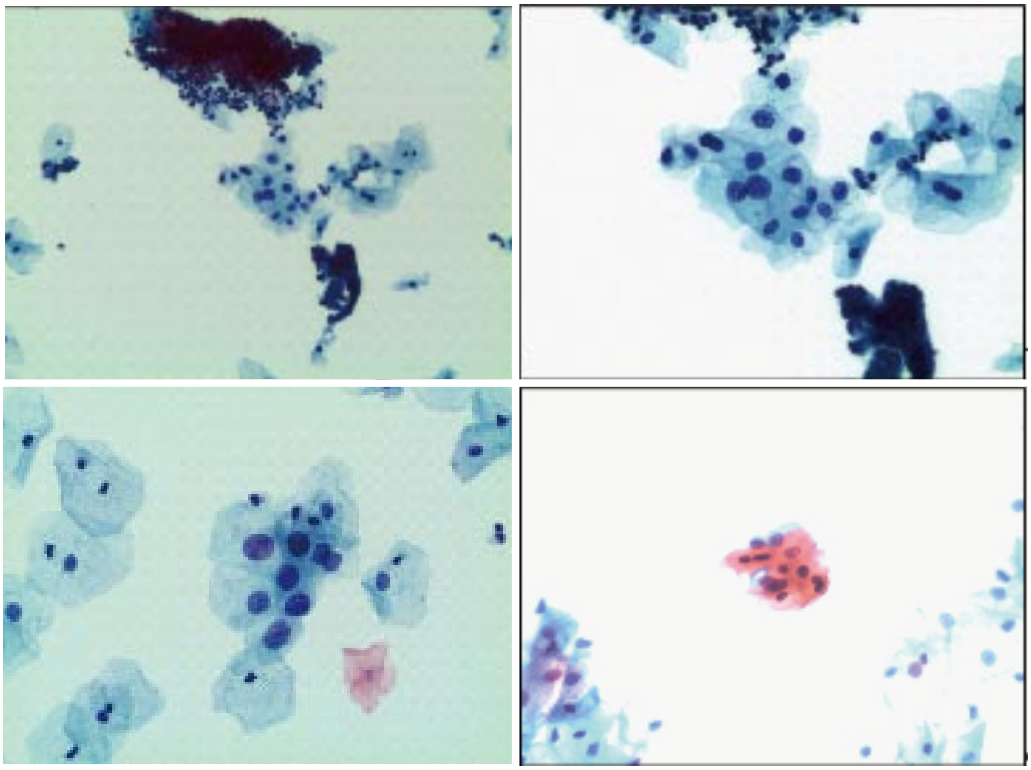

Figure 1 Atypical squamous cells of undetermined significance.

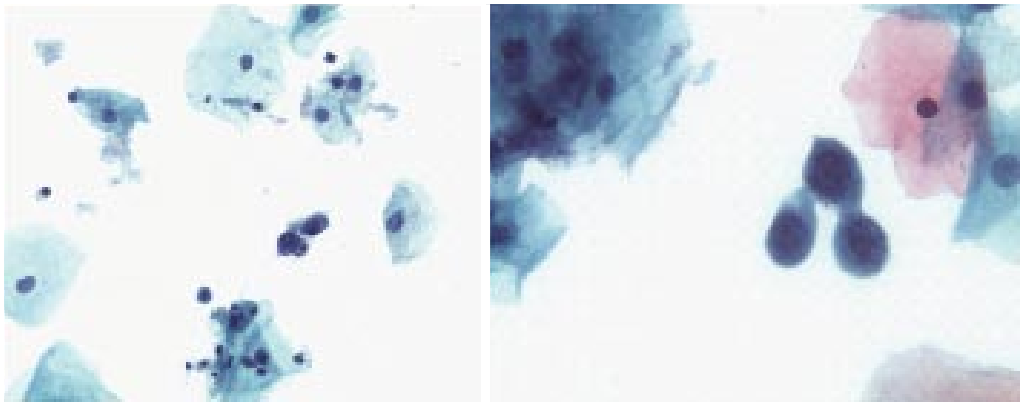

Figure 2 Atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion.

available: "prospective rescreening" and "retrospective rescreening". Most laboratories (> 85%) prospectively rescreen more than 10% of Pap tests interpreted as negative for intraepithelial lesion or malignancy. Most (72%) report inclusion of less than 20% high-risk cases. Most laboratories use multiple measures to define "high risk". Most laboratories (96.2%) retrospectively rescreen Pap tests from the preceding 5 years only. In most laboratories (71.4%), only Pap test results with H-SIL or worse prompt retrospective review. Upgraded diagnoses from negative for intraepithelial lesion or malignancy to atypical squamous cells (ASC), cannot exclude H-SIL (ASC-H), should be monitored (Figures 1-5)[9-18].

PHASE TWO: COLPOSCOPY AND HISTOLOGY

Though in the 1980s colposcopically-directed biopsy excluded over 90% of cervical intraepithelial neoplasia (CIN) 3 or worse (CIN3+), recent reviews found sensitivity of colposcopically-directed biopsy for CIN3+ of 50%-65%. Studies from China showed that the sensitivity of colposcopically-directed biopsy for CIN3+ is higher for large CIN3+ than for small CIN3+ and higher for associated high-grade cervical cytology than for low-grade cervical cytology. Colposcopically-directed biopsy excluded over 90% of CIN3+ in the 1980s because colposcopy clinics in the 1980s evaluated women with

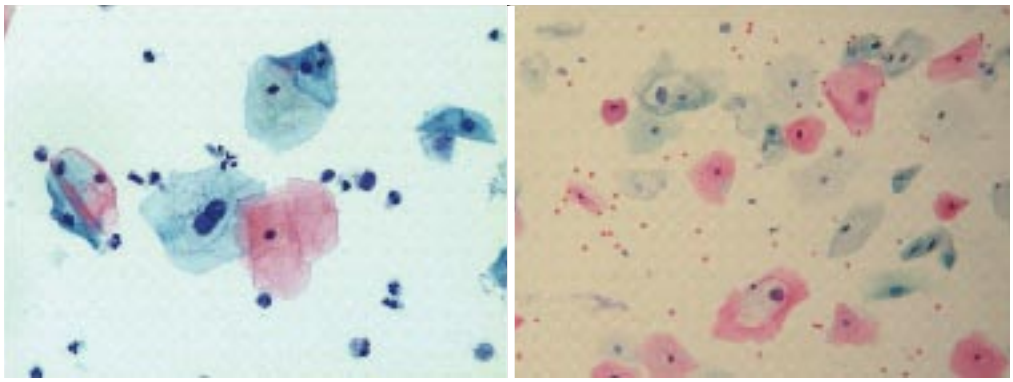

Figure 3 Low-grade squamous intraepithelial lesion.

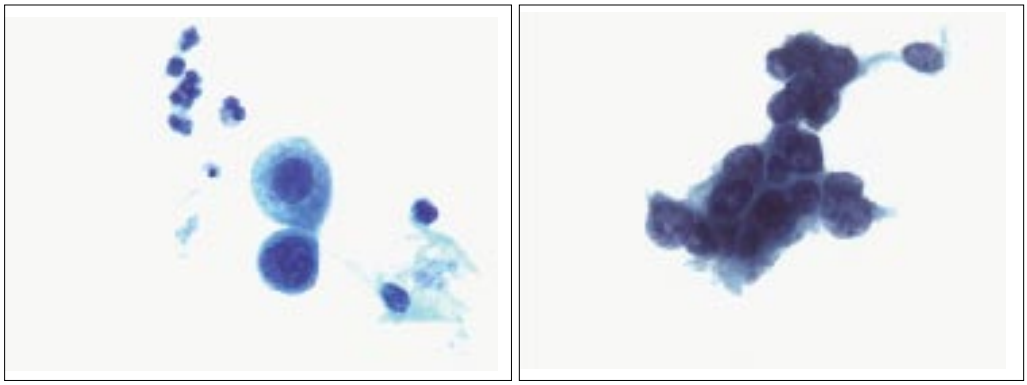

Figure 4 High-grade squamous intraepithelial lesion.

Figure 5 Atypical glandular cells.

high-grade cytology that had large CIN3+. It no longer excludes CIN3+ well because current colposcopy clinics evaluate women with low-grade cytology that have small CIN3+. When colposcopically-directed biopsy is used to exclude CIN3+, our understanding of the natural history of CIN is skewed, errors occur in defining appropriate screening practice, and inaccurate diagnosis results in incorrect treatment. The impression that CIN is more common on the anterior lip of the cervix is an artifact introduced by the inaccuracy of colposcopy. An unjustified enthusiasm for screening with visual inspection with acetic acid (VIA) occurred when the sensitivity of VIA for CIN3+ was inflated by screening studies using colposcopically-directed biopsy as the gold-standard for CIN3+. As the diagnosis of CIN3+ solely by endocervical curettage (ECC) is uncommon in women under age 25, the ECC may be omitted in women under age 25 years. If multiple cervical biopsies are performed, to limit discomfort, a bronchoscopy biopsy instrument which obtains 2-mm biopsies should be used (Figures 6-17)[19,20]. A novel technique uses a high-resolution microendoscope (HRME) to diagnose cervical dysplasia. HRME imaging reduces the limitations of existing cervical cancer screening methods currently in use in low-resource settings and so has the potential to contribute to cervical cancer prevention in the developing world[21,22].

PHASE THREE: TREATMENT AND FOLLOW-UP

Pre-cancerous lesions of cervix (CIN) are usually treated with excisional or ablative procedures. In the United Kingdom, the National Health Service cervical screening guidelines suggest that over 80% of treatments should be performed in an outpatient setting (colposcopy clinics). Treatment methods commonly used for precancerous lesions are conization,

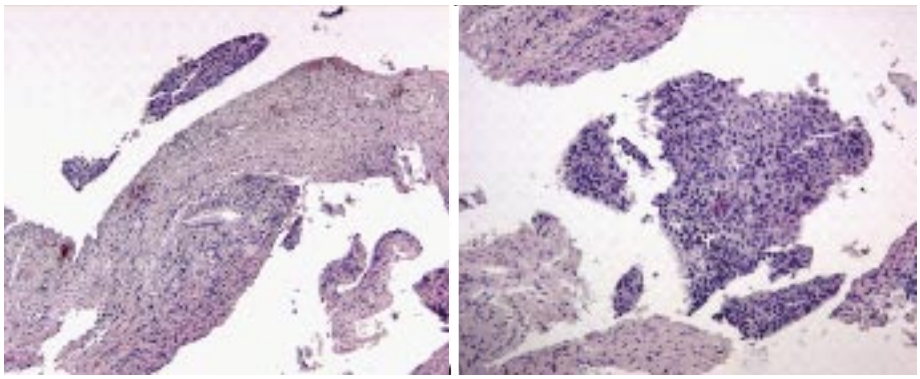

Figure 6 Dysplasia histologic samples.

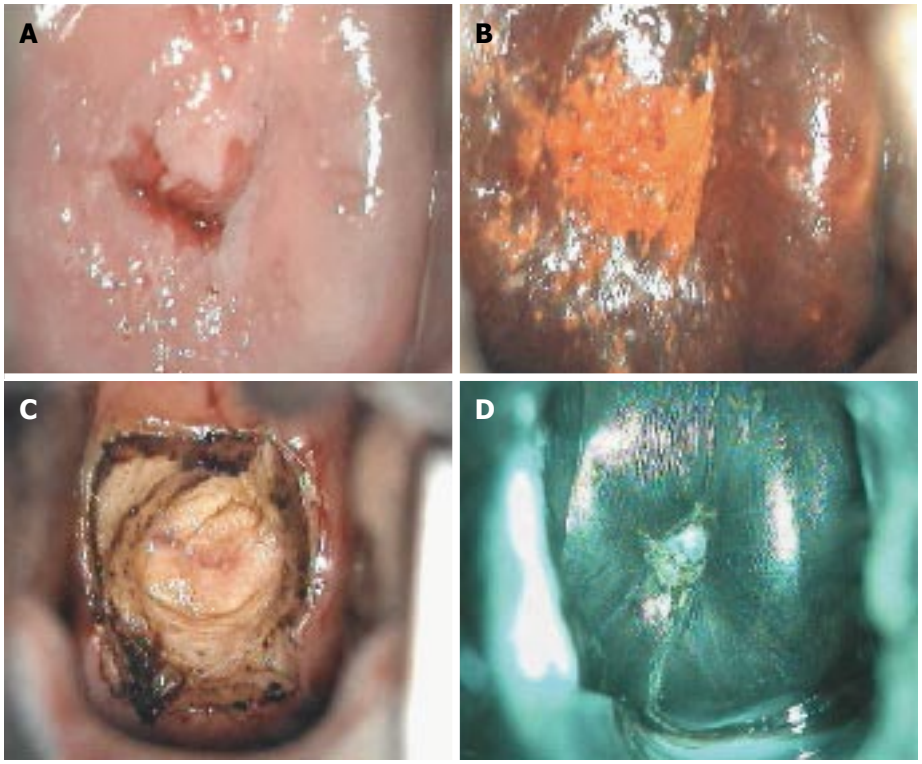

Figure 7 Cervical intraepithelial neoplasia grade 1 colposcopic appearance: (A) after acetic acid application; (B) after Lugol's iodine solution application; (C) after loop electrosurgical excision procedure; and (D) at 6-mo follow-up.

loop electrosurgical excision procedure (LEEP), laser ablation, and cryotherapy. Recently, outpatient LEEP has replaced cryotherapy in many countries. However, a greater awareness of the importance of cervical cancer in the developing world and a greater awareness of the long-term consequences of LEEP like cervical insufficiency, have renewed interest in cryotherapy. Among the trials, cure rates ranged from 56.8% to 96.6% in prospective controlled studies and from 70% to 95.5% in observational trials. Cryotherapy has very low rates of complication and serious complications that require medical therapy or affect the reproductive future results are extremely rare. Side effects include vaginal discharge and cramping which are temporary, usually self-limited, and well tolerated after preventive patient counseling. When surveyed, women highly accept cryotherapy. Compared to other methods of treatment, cryotherapy is very affordable and feasible to integrate screening programs and treatment for cervical cancer[23]. Often, due to improper judgment of interventional indications for cervical lesions, overtreatment to various degrees takes place, influencing patients' health and lives[24,25].

GUIDELINES

Cytopathology experts, interested stakeholders, and representatives from the College of American Pathologists (CAP), the Centers for Disease Control and Prevention, the American Society of Cytopathology

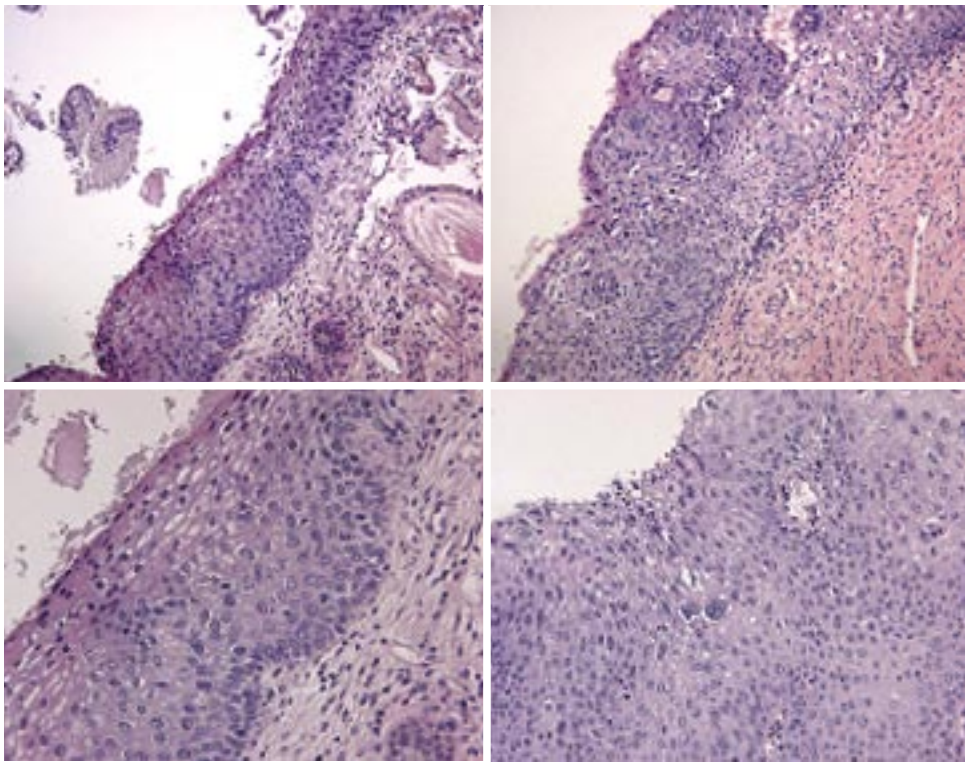

Figure 8 Cervical intraepithelial neoplasia grade 1 histologic samples.

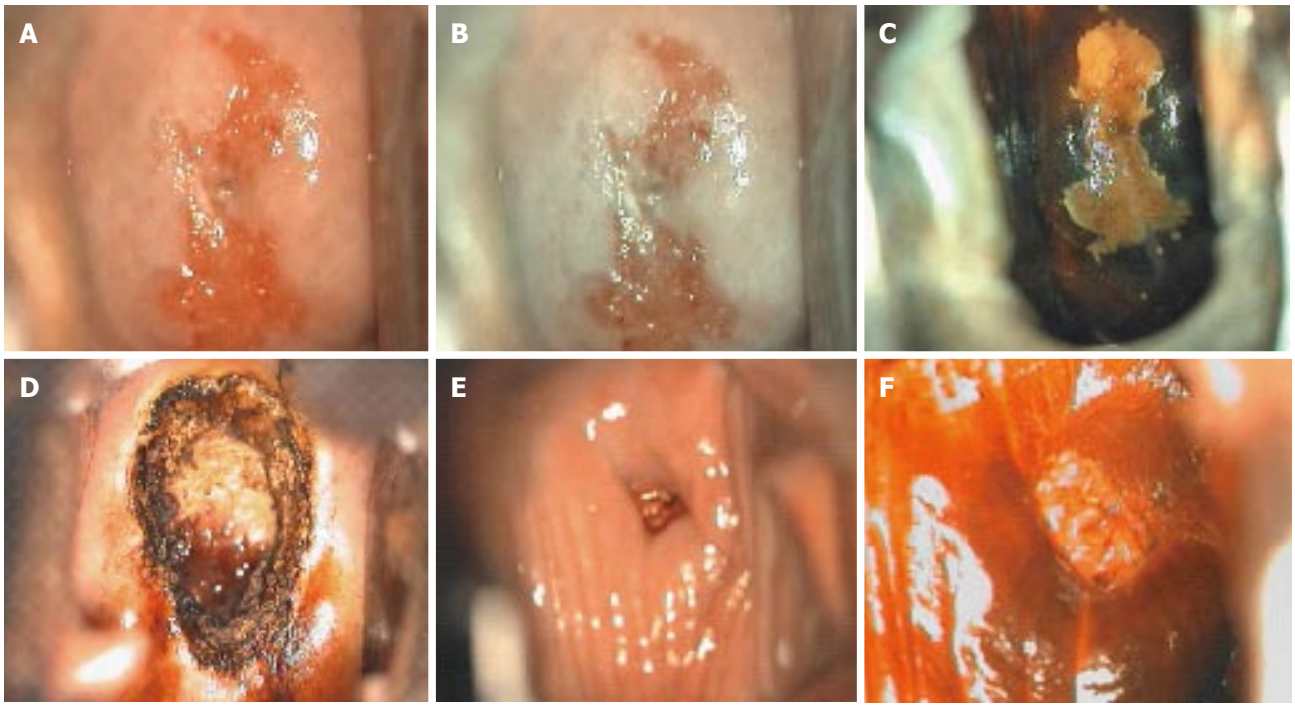

Figure 9 Cervical intraepithelial neoplasia grade 2 colposcopic appearance: (A) before application of any solution; (B) after acetic acid application; (C) after Lugol's iodine solution application; (D) after loop electrosurgical excision procedure; (E) at 6-mo follow-up before application of any solution; and (F) at 6-mo follow-up after acetic acid application.

(ASC), the Papanicolaou Society of Cytopathology, the American Society for Clinical Pathology, and the American Society of Cytotechnology convened the Gynecologic Cytopathology Quality Consensus Conference to present preliminary consensus statements developed by working groups, including the Cytologic-Histologic Correlations Working Group 4, using results from surveys and literature review. Conference

Table 1 The Bethesda system

Specimen type:
Conventional smear (Pap smear)
Liquid-based preparation
Other
Specimen adequacy:
Satisfactory for evaluation (describe presence or absence of endocervical/transformation zone component and any other quality indicators, e.g. partially obscuring blood, inflammation, *etc.*)
Unsatisfactory for evaluation… (specify reason)
Specimen rejected/not processed (specify reason)
Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)
General categorization (optional):
Negative for intraepithelial lesion or malignancy conventional smear (Pap smear)
Other: see interpretation/result (*e.g.*, endometrial cells in a woman ⩾ 40 yr of age)
Epithelial cell abnormality: see interpretation/result (specify "squamous" or "glandular" as appropriate)
Interpretation/result:
Negative for intraepithelial lesion or malignancy: when there is no cellular evidence of neoplasia, state this in the general categorization above and/or in the interpretation/result section of the report, whether or not there are organisms or other non-neoplastic findings
Organisms:
Trichomonas vaginalis
Fungal organisms morphologically consistent with Candida spp.
Shift in flora suggestive of bacterial vaginosis
Bacteria morphologically consistent with Actinomyces spp.
Cellular changes consistent with HSV
Other non neoplastic findings (optional to report; list not inclusive):
Reactive cellular changes associated with:
Inflammation (includes typical repair)
Radiation
IUD
Glandular cells status post hysterectomy
Atrophy
Other:
Endometrial cells (in a woman ⩾ 40 yr of age): specify if "negative for SIL"
Epithelial cell abnormalities:
Squamous cell:
ASC:
Of undetermined significance (ASC-US)
Cannot exclude H-SIL (ASC-H)
Low-grade SIL (L-SIL) (encompassing: HPV/mild dysplasia/CIN1)
High-grade SIL (H-SIL) (encompassing: moderate and severe dysplasia, CIS/CIN2 and CIN3):
With features suspicious for invasion (if invasion is suspected)
SCC
Glandular cell:
Atypical:
Endocervical cells (NOS or specify in comments)
Endometrial cells (NOS or specify in comments)
Glandular cells (NOS or specify in comments)
Atypical
Endocervical cells, favor neoplastic
Glandular cells, favor neoplastic
Endocervical adenocarcinoma in situ
Adenocarcinoma:
Endocervical
Endometrial
Extrauterine
NOS
Other malignant neoplasms (specify)
Ancillary testing: provide a brief description of the test methods and report the result so that it is easily understood by the clinician
Automated review: if case examined by automated device, specify device and result
Educational notes and suggestions (optional): suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included)

Adapted from: International Agency for Research on Cancer (IARC), 2013. AIS: Adenocarcinoma *in situ*; NOS: Not otherwise specified; SCC: Squamous cell carcinoma; CIN: Cervical intraepithelial neoplasia; CIS: Carcinoma *in situ*; IUD: Intrauterine contraceptive device; SIL: Squamous intraepithelial lesion; ASC: Atypical squamous cells.

participants voted on statements, suggested changes where consensus was not achieved, and voted on proposed changes. To document existing practices in gynecologic cytologic-histologic correlation (see

additional survey questions[26-30].

CONCLUSION

Vaccination against HPV is expected to decrease the incidence of cervical cancer in most countries. However, it is also expected to influence the effectiveness of screening. In the future, maintaining Pap test as the primary test for cervical screening may become too expensive. As the prevalence of cervical dysplasia decreases, the positive predictive value of citology also decrease, and consequently, more women will undergo unnecessary diagnostic procedures and follow-up. The HPV deoxy ribonucleic acid (DNA) test has recently emerged as the best tool to replace cytology as primary screening. It is less subjected to human errors and much more sensitive than the Pap test in detecting high-grade cervical lesions. By incorporating

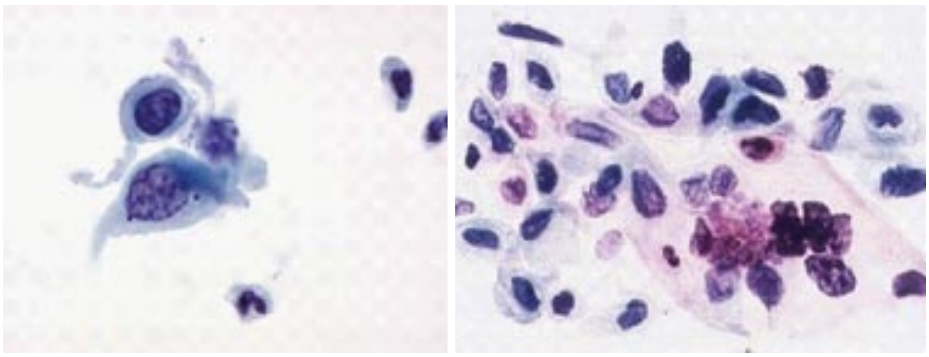

Figure 16 Squamous cells carcinoma.

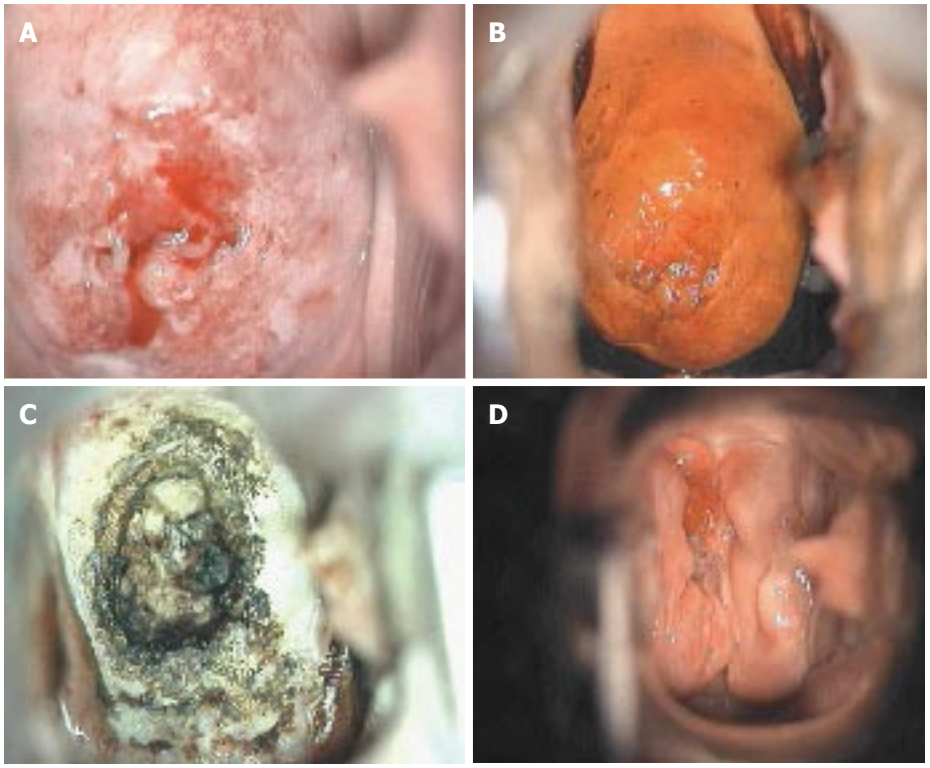

Figure 17 Adenocarcinoma *in situ* colposcopic appearance: (A) after acetic acid application; (B) after Lugol's iodine solution application; (C) after loop electrosurgical excision procedure; and (D) at 6-mo follow-up.

this test the overall quality of screening programs will improve and will allow spacing out the screening tests, while maintaining safety and reducing costs. Although HPV testing is less specific than Pap test, this problem could be solved by reserving the latter for triaging cases of HPV positivity. Since most HPV-positive smears contain significant anomalies, Pap cytology is expected to perform with sufficient accuracy in these cases. Pap triage of HPV-positive patients would also provide a low-cost strategy to monitor the effectiveness of the vaccine in the long term. Although HPV typing could be implemented as a screening tool for the population, further research is needed to determine the optimal age to begin screening, the role of the HPV test and other markers of disease progression, and adequate follow-up procedures for the HPV-positive and smear-negative women[31-33].

Abstract

Sustained clinical improvement is unlikely without appropriate measuring and reporting techniques. Clinical indicators are tools to help assess whether a standard of care is being met. They are used to evaluate the potential to improve the care provided by healthcare organisations (HCOs). The analysis and reporting of these indicators for the Australian Council on Healthcare Standards have used a methodology which estimates, for each of the 338 clinical indicators, the gains in the system that would result from shifting the mean proportion to the 20th centile. The results are used to provide a relative measure to help prioritise quality improvement activity within clinical areas, rather than simply focus on "poorer performing" HCOs. The method draws attention to clinical areas exhibiting larger between-HCO variation and affecting larger numbers of patients. HCOs report data in six-month periods, resulting in estimated clinical indicator proportions which may be affected by small samples and sampling variation. Failing to address such issues would result in HCOs exhibiting extremely small and large estimated proportions and inflated estimates of the potential gains in the system. This paper describes the 20th centile method of calculating potential gains for the healthcare system by using Bayesian hierarchical models and shrinkage estimators to correct for the effects of sampling variation, and provides an example case in Emergency Medicine as well as example expert commentary from colleges based upon the reports. The application of these Bayesian methods enables

all collated data to be used, irrespective of an HCO's size, and facilitates more realistic estimates of potential system gains.

Key words: Clinical indicators; Improvement; System gains; Bayesian; Statistical models

Core tip: The article's purpose is to bring attention to the increasing use of Bayesian methods in the clinical field to overcome shortcomings of previous analyses, and provide an application of how such methods are used in clinical management in Australia; in particular, on how to best report and use clinical indicator data for system improvement. The paper identifies flaws associated with traditional clinical indicator reporting techniques which are still often-used; describes part of current Australian clinical indicator reporting methods; and demonstrates how and why Bayesian methods are fundamental to the improved methods overcoming issues that would otherwise arise with such data.

INTRODUCTION

Healthcare accreditation systems and quality measurement systems are internationally used for the purposes of improving clinical care and organisational outcomes. Accreditation in healthcare reflects the systematic assessment of hospitals against explicit predetermined standards[1,2] and consists of multiple means of assessment such as self-appraisal, peer-reviewed interviews, scrutiny of documentation, checking of equipment and investigation of key clinical and organisational data[3]. These systems involve considerable levels of resources from the participating agencies and healthcare organizations (HCOs) and are believed to facilitate improved levels of quality in healthcare[4-7].

The Australian Council on Healthcare Standards (ACHS) has a well-established national healthcare accreditation program. It provides robust support for Australian healthcare and is one of the four most commonly cited national healthcare accreditation programs in the world[1,8,9]. In addition to providing a national accreditation scheme, the ACHS supports HCOs by providing sets of clinical indicators (CIs) which HCOs may opt to utilize. HCOs may simply collect their own data, or they may additionally submit their data *via* the ACHS's online performance indicator reporting tool for analysis and reporting[9-13]. CIs measure performance in a clinical setting; the reporting of CIs in HCOs aims to detect suboptimal care either in structure, process or outcome, and can be treated as a tool to assess whether a standard in patient care is being met. They may provide evidence for accreditation purposes and guide the process of quality improvement in healthcare[14].

There is world-wide interest in how to integrate clinical indicators within the accreditation process and mechanisms for their collection differ across countries[9]. A comparison of the four most often referenced national accreditation programs internationally[1,8,9] identified the following key points: (1) the Joint Commission (JC) in the United States and Accreditation Canada are examples of accreditation bodies that have integrated the mandatory requirement that hospitals provide core indicators as part of the accreditation process in order to help focus on-site survey evaluation activities in accreditation[9,15-22]. The JC has done so through its ORYX® program and through its integration of measurement data into its Priority Focus Process for the on-site survey[16,17]. Accreditation Canada has done so through its Qmentum program and combining indicator data with their "instrument" data obtained through questionnaires completed by representative samples of clients, staff, leadership and/or other key stakeholders[9,22]; (2) Haute Autorité de Santé, France, has mandatory accreditation for all its hospitals and has connected many of its accreditation standards to indicators. There are 13 criteria that must be satisfied to achieve certification, of which four are linked to indicators. In total, there are 14 indicators connected with accreditation criteria[9,23,24]; and (3) the ACHS, Australia, provides 6-monthly and trend reports to hospitals which have elected to submit their CI data. The contribution of these reports to a hospital's self-evaluation and quality improvement efforts are relied upon for instigating the CI data collection within hospitals and thus their inclusion in the accreditation process[9].

Taiwan was the fourth country, following the United States, Canada, and Australia, to implement a healthcare accreditation project and the first country in Asia to do so. The reporting of CIs is now required by law for hospitals in Taiwan, and many internal and several nationwide clinical indicator systems have been launched, including three nationwide quality measurement systems: Taiwan Healthcare Indicator Series, Taiwan Clinical Performance Indicators, and Taiwan Community Hospital Association indicators[25]. These three clinical indicator systems are optional for hospitals to utilize. Their target participants are varied and with the diversity of indicators collected there has been difficulty integrating CIs into Taiwan's accreditation process[26], which is governed by Taiwan's Joint Commission on Hospital Accreditation. Taiwan's Ministry of Health and Welfare is currently assessing how best to integrate the CIs from the varied agencies and government departments for enhancing the efficiency and effectiveness of CIs on quality improvement in healthcare.

Since 1993, Australian HCOs preparing for accreditation have submitted data on sets of CIs. The ACHS routinely collates the data in six-month periods and generates reports which are provided to HCOs, along with de-identified reports which are provided to accreditation surveyors, national medical colleges and government bodies. In 2012 the ACHS received data from 670 Australian and New Zealand HCOs on 338 CIs across 22 specialties, or clinical indicator sets[13]. This is the largest source of CI data in the world. The ACHS clinical indicators are not mandatory for any organisation to submit. HCOs select CIs that are relevant to them at that time and where there is a need within that clinical area; for example, high cost procedures, high patient thoroughfare, or a new clinical area to that HCO.

For a given CI, the i^{th} HCO provides the observed number of patients who incur the "event of interest" (O_i) and the number of patients at risk of the event (D_i). Traditional methods of analysis and reporting of such data have been flawed, failing to account for sampling variation and focusing on comparing individual HCO proportions with the mean proportion across all HCOs or with an externally set benchmark value determined by experts, with the primary intention of identifying "outliers". The approach employed in the reporting of the ACHS CIs, as part of the ACHS's Clinical Indicator Program, shifts the focus towards the potential benefits from system-wide improvements of clinical areas rather than simply comparing individual HCO performances within a clinical area which occurs with other traditional approaches. Further, the new approach has required the application of Bayesian hierarchical models to address issues of small samples, which arise in six-monthly data collection, and to preclude overestimation of the potential system improvements. Accounting for sampling variation through Bayesian hierarchical models additionally reduces HCOs' concerns of being misrepresented as extreme as a consequence of a small sample size in a given period.

This paper outlines flaws associated with traditional reporting techniques which are still often used elsewhere; describes part of the current ACHS CI reporting methods; provides examples of annual clinical comments and perspectives based on the reports; and demonstrates how and why Bayesian methods have been fundamental to the improved reporting methods overcoming issues that would otherwise arise with such data.

PROBLEMS WITH TRADITIONAL METHODS OF REPORTING CIS

The implementation of league tables which rank CIs within and across HCOs is a common practice which aims to establish an increased level of accountability and competition, and thus provoke individual strategies towards improved performance[27-29]. Deming's philosophy and systems theory identifies, however, how co-operation rather than competition is required to foster genuine quality improvement and how the system's components and the interdependencies of these components must be foremost in one's mind during the improvement cycle[29,30]. The increased focus upon "competition" between HCOs that occurs as a result of publishing league tables can lead to perverse incentives being created[31]. HCOs may, for example, be motivated towards manipulating their data or taking patients that are considered a "low risk" in order to improve their perceived performance, even if this is at the expense of other HCOs in the system[27,31-33].

There is limited, if any, value reporting league tables of HCO performances. Such presentations are likely to mislead[31,32,34,35] even when statistical techniques have been utilised that adjust for differences that arise due to varying sample sizes, as there will inevitably be a top-ranked HCO and bottom-ranked HCO even if all HCOs were providing outstanding service. Whilst confidence intervals are often introduced to determine where statistically significant differences in the ranks exist, the calculation of multiple intervals will increase the risk of identifying differences due to chance. Employing a conservative significance level to compensate will increase the confidence intervals' widths. In some cases the intervals for HCOs ranked first and last overlap rendering the publication of such tables meaningless[10,32,36,37].

Further, any variations in rank that may be observed with time may be a result of the "regression to the mean" phenomenon[38] rather than reflecting fundamental change in quality. Andersson *et al*[34] produced a measure of the "…expected change in the rank order if one were to repeat the study" to assess the validity of ranking and demonstrated the "…tremendous uncertainty in the ordering…"[34].

Fundamentally, the league table approach is flawed as it focusses attention on individual HCOs and, in particular, those deemed to be poorer performers requiring improvement rather than addressing issues that may help bring systemic advances to the system of HCOs[27,39]. Thus the analysis of clinical indicators must report more than a simple proportion and rank.

Setting thresholds and performing significance tests using p-values is also commonly practiced, and was previously employed by the ACHS. Comparing individual HCO proportions with a nominal threshold value provides minimal assistance to the HCO system as a whole since most HCOs will be within the tolerance level, potentially reducing motivation to undertake improvement, and HCOs with larger volumes of patients (larger sample sizes) are more likely to yield proportions, or rates, which are statistically significant. Consequently, the principal result of such analyses is the classification of individual HCOs as either satisfactory or not[10,27], rather than highlighting system variation or focusing attention on necessary system-wide improvements.

AN IMPROVED APPROACH FOR ANALYSING AND REPORTING CLINICAL INDICATORS

Focusing upon the system of HCOs helps with identifying clinical areas where investigation and improvement activity may produce the most benefit. An approach was applied that uses the data arising from the system of HCOs to identify a potentially achievable mean proportion and identifies clinical areas with large "potential gains" resulting from achieving such a mean proportion. The ACHS reports achieved this by introducing, for each CI, a measure of the gains (or reduction in the number of undesirable events) that could be achieved if the mean proportion was shifted to the 20th centile. The calculation of these potential gains is based on the amount of variation in the system (represented by the difference in the mean proportion, π, and 20th centile proportion, p_{20}, across all HCOs) and the impact upon the system, or volume effect, (represented by the summed D_i, where D_i represents the number of patients at risk of the event at the i^{th} HCO, across all n HCOs providing data for the CI) as shown in equation (1).

$$\text{Potential Gains} = (\pi - p_{20}) \sum_{i=1}^{n} D_i \quad (1)$$

The estimated potential gains facilitates and motivates scientific investigation within clinical areas by providing a relative measure between CIs of the potential improvement. Smaller variation and smaller potential for system impact [in terms of potential for events occurring, represented by ΣD_i in equation (1)] are reflected in a smaller value for the potential gains. Reported as part of the annual Australasian Clinical Indicator reports, this measure enables comparisons of clinical areas for improvement activity rather than allocating responsibility solely to individual HCOs[11].

The use of the 20th centile to calculate potential gains in the system has great appeal as the estimated gains don't rely upon a subjective target but instead is influenced by the system and the data it has produced; the estimated gains are being guided by the existing between-HCO level of variation in proportions. The 20th centile is approximately one standard deviation from the overall mean proportion and may be considered a practicable goal[10]. Since the distribution of proportions is often not symmetric, using standard errors is less useful.

The potential gains as a measure considers the HCOs as part of an holistic system that may have potential for improvement rather than focusing on individual HCOs' performances. Such an approach enables healthcare professionals and governing bodies "…to determine those clinical areas where there are potentially greater gains and hence funding for quality improvement activity would be of a higher priority"[10].

In the case of CIs where higher proportions are desired, potential gains are calculated using the 80th centile, p_{80}, as $(p_{80} - \pi) \Sigma D_i$. This represents the number of additional events that would occur if the mean proportion were equal to p_{80}.

The 20th (or 80th) centile and ensuing calculation of the potential gains, however, should not be obtained simply by using the observed proportions (O_i/D_i) since they are affected by sampling variation. Further, since the HCOs report their data across six-month periods the observed proportions will be based on large and small sample sizes, affecting the precision and reliability of the estimated proportions[10]. Consider for example an HCO that reports only three individuals at risk of a particular event in a given period. A difference of one in the number incurring the event of interest would correspond in a change in the estimated proportion of 33%. Additionally, it would be more likely that HCOs with such small D_i will report the extreme proportions (0% and 100%) despite this most likely not reflecting the true underlying proportion at the HCO.

Rather than exclude HCOs with small data, and thus lose data, a statistical technique known as Bayesian hierarchical modelling and the associated empirical Bayesian shrinkage estimator have been used to better estimate the proportions for the HCOs in a given six-month period. The approach essentially utilizes and combines an individual HCO's proportion and the summary results from the system of HCOs to produce a better estimate of the individual HCO's true underlying proportion.

Empirical Bayes models

"Medical research applications often involve hierarchical data structures as data are collected on random samples of patients nested within each hospital"[10]. When data are collected from many HCOs there is usually substantial variability among the HCOs in addition to variability within the HCOs due to sampling.

Many readers would be more familiar with the non-Bayesian approach to analyses, known as the frequentist or classical approach, which uses only the information provided by the sample data to make wider inference. In contrast, the Bayesian methodology uses additional prior knowledge or belief, presented in the form of probability distributions, in making wider inference. Bayesian methods essentially assess the appropriateness of the prior knowledge given the new data and quantifies this in the form of probability statements or density functions for the values we are wishing to estimate[40,41]. The "Bayesian methodology has been shown to be particularly useful in both the clinical setting and the area of public health policy when the results of a study must subsequently be used to facilitate a decision"[10]. In the Bayesian paradigm, a two-stage hierarchical model representing the nesting of the patients within HCOs may be used to make inferences[42-48], with the first stage representing the distribution of the HCO-specific proportions (CI proportions among HCOs) and the

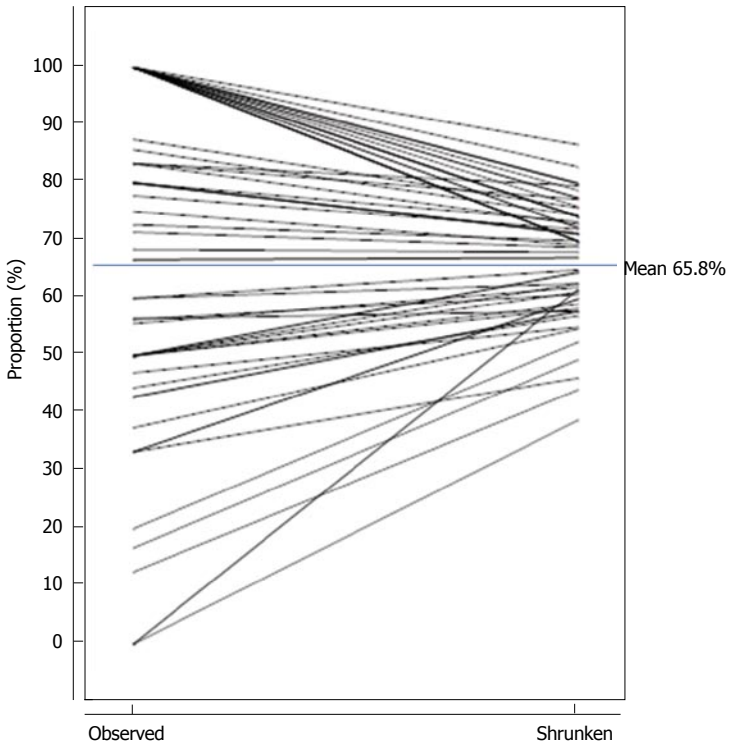

Figure 1 Shrinkage Plot showing Observed and Shrunken Proportions for 62 Healthcare Organisations.

second stage modelling the additional sampling variation associated with what we observe for the patients within HCOs.

The approach borrows strength from the ensemble[49] of HCOs to estimate any individual HCO's true proportion better than an individual HCO's data alone. Essentially the approach uses statistical models for: (1) the conditional probability of the observed counts of events given the unknown true CI proportions (we are attempting to estimate the latter); and (2) a *prior* distribution for the true CI proportions given their overall mean and variance (the latter may be estimated from the data, in which case the approach is referred to as an *empirical* Bayes approach). The two statistical models combine *via* Bayes' rule[45,50] to produce the probability distribution for the unknown true CI proportions given the observed counts and overall mean and variance; this is known as the posterior distribution.

The expectation of this posterior distribution is the empirical Bayes shrinkage estimator for an HCO's CI proportion. The estimated proportion for a given HCO is effectively a weighted average of the individual HCO's observed proportion and the overall mean proportion across all HCOs. The weighting depends upon the systematic variation between HCOs and sample size of the individual HCO, as well as the particular two-stage model's family of distributions.

To reflect the between-HCO and within-HCO sources of variation in the CI proportions, the ACHS reports use the gamma-Poisson hierarchical model. This model was applied since the gamma distribution could represent the distribution of the ratios of observed to expected numbers of events[10]. Further, using the gamma-Poisson model instead of a beta-binomial model for proportions was shown to result in more conservative estimates of the 20th centile-based potential gains due to a relatively greater shrinkage using the former rather than the latter model[10].

The gamma-Poisson model assumes that the O_i follow a Poisson distribution with mean $\lambda_i E_i$, where E_i is the expected number of events at the i^{th} HCO obtained by multiplying D_i by the mean proportion, π, and the true ratios of observed and expected numbers of events, λ_i, are obtained from a gamma distribution with mean, μ, and variance, S_r^2. That is, we have $O_i \sim Poisson\ (\lambda_i E_i)$ and $\lambda_i \sim Gamma\ (\mu, S_r^2)$ which combine using Bayes' rule[45,50] to provide the estimated ratios of an HCO, which are interpretable as proportions by multiplying a ratio by the mean proportion.

The effects of empirical Bayesian shrinkage estimators

Figure 1 visually demonstrates the changes to the individual HCOs' estimated proportions and the distribution of proportions following "shrinkage" for a particular clinical indicator having 62 HCO submissions of data; for this indicator a high proportion was desirable. Each HCO returned data enabling the observed proportion (O_i/D_i) to be obtained and a shrunken proportion was calculated by the afore-mentioned two-stage models and Bayesian methods and multiplying by π (the overall mean proportion). Figure 1 joins each HCO's corresponding observed and shrunken proportions. Several HCOs had common observed and shrunken proportions, hence Figure 1 does not show 62 distinct lines.

The D_i for the CI ranged from 1 to 78. The observed proportions ranged from 0% to 100%. There were 20

CI: Clinical indicator; HCO: Healthcare Organisation.

HCO submissions with observed proportions equaling 100%; the D_i for these HCOs ranged from 1 to 7. There were 3 HCO submissions with observed proportions equaling 0%; the D_i for these HCOs ranged from 1 to 8. The 20th and 80th centiles of the observed proportions were 43.8% and 100% respectively. The 20th and 80th centiles of the shrunken proportions were 58.6% and 74.9% respectively. The mean proportion was 65.8%.

The key points to observe for this example are: (1) HCOs with extreme observed proportions (0% and 100%) are shrunken more greatly towards the mean; a consequence of having smaller D_i; (2) not all HCOs having the same observed proportion will have the same shrunken proportion; a consequence of having differing D_i; (3) the spread of the distribution of shrunken proportions is far less than the spread of the distribution of observed proportions, reflecting the spread of the true underlying proportions; and (4) the 20th and 80th centiles of the shrunken proportions are closer to the mean proportion than the respective centiles of the observed proportions and hence facilitate better estimates of the potential gains.

The potential gains for a CI are then calculable using the shrunken proportions and 20th or 80th centiles using equation (1), or its equivalent for the 80th centile, and are presented along with other summary information for CIs. Table 1 presents an example of such a report for the clinical area Emergency Medicine.

The potential gains provided in Table 1 provide a measure to help prioritise investigation and improvement activity. Consider CIs 1.2 and 2.1; each are desired to have a high proportion. CI 1.2 has a mean proportion of 79.8% whilst 2.1 has a mean proportion of 65.8%. On this alone, it may seem 2.1 should be the priority for improvement; however, the potential gains incorporates the variation between HCOs as well as the size of the potential impact upon the system represented by "Denominator" which is the total number at risk of an event across all HCOs. When this information is considered we observe potential gains for 1.2 that is some 1360 times the potential gains for 2.1, reprioritising where investigation and improvement activity may be best undertaken.

Other estimated gains and funnel plots

In addition to the 20th centile-based potential gains, the ACHS reports present estimates of stratum gains and outlier gains, as shown in Table 1. Stratum gains represent the gains that would be achieved from moving the mean proportions of the poorer performing strata to the mean proportion of the best performing stratum. The strata for the HCOs are: public or private; metropolitan or non-metropolitan; and State (region of Australia).

Outlier gains present the gains that may be achieved from improving the outlier HCO proportions to equal the overall mean proportion. Outlier HCOs have differences in observed and expected numbers of events exceeding three times the standard error of the difference, after shrinkage. A funnel plot, as shown in Figure 2, plots for a given CI the HCOs' differences in observed and expected counts, or *Excess* count, ordered by D_i. Doing so allows a visual check for any patterns that would suggest a volume effect (a pattern due to D_i). In this particular case there were no outliers or an effect due to sample size. Whilst traditional methods may have resulted in little more than the reporting of no outliers,

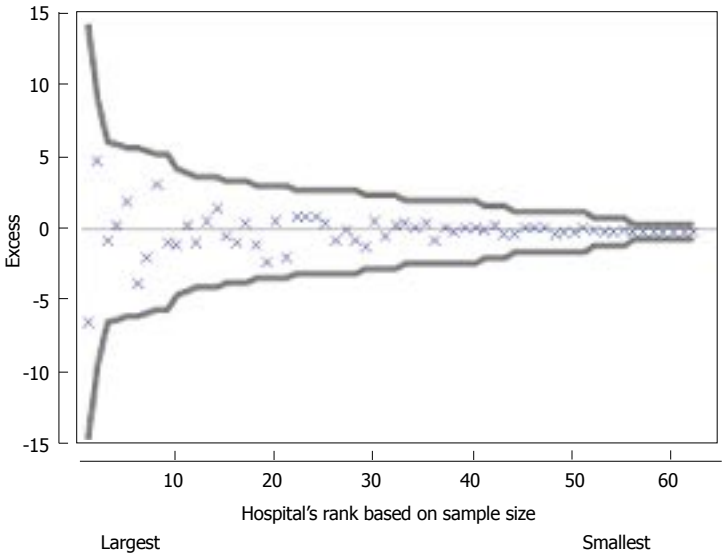

Figure 2 Funnel Plot of Shrunken Estimates of Excess (difference in Observed and Expected) counts for 62 healthcare organisation submissions for clinical indicator 2.1.

the 20th centile gains and stratum gains presented in the ACHS reports focus attention on potential for improvement in the system.

How the reporting system is used

The annual reports described in this paper are part of a two-tiered reporting system. In addition to these annual reports, HCOs receive individual six-monthly reports which identify the individual HCO's performance (rate) compared with both the entire system's rate and themselves based on trend analysis of their six-monthly rates. The latter reports are used by individual HCOs to self-assess whilst the annual report is provided to the relevant Colleges before being published and the Colleges are invited to comment on their set of CIs. In earlier editions of this report the response was less than hoped for, but the annual edition, currently in its 15th year, has more recently received and incorporated clinical comments and perspectives on all results.

Vignettes of the types of comments are provided below[12]. Importantly, Colleges and State Governments are reading reports and thus engaging more with the data.

Example 1: Response from the College of Nursing to the CI representing falls for those aged 65 years or more: "There is no significant change to the data reported in 2013 compared to 2012, despite the fact that the HCO population is aging, with higher numbers of complex and higher acuity patients–particularly within the public HCOs….HCOs with outlier rates within this CI need to review their falls management protocols and falls prevention education, to reduce the current rate of falls–which is nearly double the fitted rate for all reporting HCOs"[12].

Example 2: "The Australian Faculty of Rehabilitation Medicine (AFRM) and the Australasian Rehabilitation Outcomes Centre (AROC) are proud of the continued high standard of compliance with the ACHS CIs by all participating HCOs. The AFRM has included the ACHS CIs in the AROC dataset to encourage HCOs to participate in this important collection and thereby promote continued improvement in these processes and outcomes. The quality of the data collected is of a high standard, with well-established, nationally consistent education programs *in situ*. On that basis, the AFRM and the AROC are confident about the results reported here. HCOs are encouraged to continue reviewing their CI collections to help inform processes and practices in order to maintain the high rates achieved in previous years"[12].

Example 3: Expert commentary from Royal Australian and New Zealand College of Obstetricians and Gynaecologists (RANZCOG) on outcome of selected primipara: "There has been a small increase in the number of spontaneous vaginal births in the selected primipara (CI 1.1), but it remains at around 45.0%. There are several reasons why the number of spontaneous vaginal births will be expected to continue to lessen: (1) women becoming more risk averse and therefore more often requesting obstetric procedures in order to minimize risk. This applies to all women, but particularly in relation to common issues such as how long to tolerate pregnancy progressing beyond the due date; (2) increasing maternal age; and (3) Reducing maternal parity with the consequential reduced morbidity from caesarean section in subsequent pregnancies.

Stratum differences were demonstrated in relation to private and public HCOs (36.4% *vs* 50.8% respectively). This is expected as the above factors are more prevalent in the private sector than public sector"[12].

Example 4: Expert commentary from RANZCOG on Intrauterine growth restriction: "The rate of CI 8.1 has been steadily improving, but this appears to have plateaued at around 1.64%. Failure to diagnose intrauterine growth restriction remains the most obvious

preventable factor in perinatal mortality at term. It has been rewarding to see this statistic fall over the 5 year period and it could be suggested that introducing this CI is partly responsible for this highly desirable improvement"[12].

Example 5: Expert commentary from the Australian and New Zealand College of Ophthalmologists on Cataract Surgery: "Unplanned overnight admission rates following cataract surgery were lower in 2013 with a reduction in the annual rate (CI 1.3). There are known factors such as older age groups, medical co-morbidities and surgery in the latter part of the day that may be contributing. In 2013, there were eleven outlier submissions from eight different HCOs. The outlier organisations can consider a grading/points system based on case complexity to identify cases that should be done in the morning or by an experienced surgeon"[12].

Example 6: Expert commentary from the Australian College of Midwives: General Comment, "The number of services reporting for each CI indicates the ease or difficulty of recording and reporting data defined and possibly the usefulness of the measure to local monitoring. Comparison of local results with the mean and stratified groups would enable health services and professionals to determine areas for policy, practice and research attention"[12].

DISCUSSION

The ACHS CIs aim to get refined data, controlling for casemix, *e.g.*, infection control for each of coronary-artery bypass, hip replacement, knee surgery, *etc.* Since there are 22 specialties (sets of indicators) representing the main Colleges in Australia, and hence some 338 CIs, an individual HCO has to select those sets, or subsets of CIs, that are appropriate to their needs. For example, sets based upon paediatrics, obstetrics, oncology, gynaecology or day only procedures or patients will not be relevant to many HCOs. Even for sets that are relevant some of the CIs within the set may not be collected due to costs of obtaining the data from the medical records, or the CI may not be seen as important to the individual HCO. The non-mandatory nature of the CIs is consistent with the non-punitive and non-invasive nature of the reporting methods described. The data collection and reporting method is designed to assist the healthcare system, not place greater burdens upon the system or HCOs unable to sustain the costs of widespread data collection. Whilst the CIs provide a means for HCOs to more easily provide necessary evidence to warrant accreditation, the aforementioned reasons along with nuances that exist within any HCO warrants the optional nature of their use. This further attracts some HCOs towards the ACHS accreditation process and to provide data honestly rather than be forced to provide data and be motivated towards manipulating their data or taking patients that are considered a "low risk" in order to improve their perceived performance, even if this is at the expense of other HCOs in the system[27,31-33].

The simplistic ranking of HCOs does not quantify the gains that could be achieved and has many disadvantages. The reporting of indicators which measure clinical and healthcare processes should quantify the potential gains to encourage action. Estimating the gains across many indicators enables the comparison and identification of areas with greater potential improvement and thus prioritisation of resources for investigation and improvement efforts. The required tools and resources to investigate and address those areas with the greatest gains must then be provided.

Bayesian hierarchical models and empirical Bayes shrinkage estimators borrow strength from the collection of HCOs to estimate any individual HCO's true proportion better than an individual HCO's data alone, accounting for sampling variation and addressing issues surrounding small sample sizes[49]. Shrinkage estimators are more beneficial in situations where denominators vary in size and some are small[10,51], as is the case for the CI data.

The shrinkage estimator effectively modifies an individual HCO's observed proportion by drawing it closer to the prior mean. The amount of modification (shrinkage) is less for those HCOs having larger sample sizes (reflecting the increased information being reported by those individual HCOs reducing the effects of sampling variation) and for systems exhibiting large systematic, or between-HCO, variation (reflecting lower strength of knowledge about the prior mean since the prior variance is large in such cases). Thus HCOs having smaller denominators will have their observed proportions shifted more closely towards the overall mean than HCOs having larger denominators. The implementation of the shrinkage estimators not only provides better estimates for each HCO, in particular those that would otherwise be identified as extreme due to small sample sizes, but additionally enables all HCOs to be included in the reports irrespective of size. Further, the approach is reflecting the reality that there is a level of dependence between the HCOs as they are all part of the one system.

The use of CIs as flags for required investigation towards system improvement is a valuable area of research. The development and application of appropriate statistical methods for analysing and reporting CIs is important and should focus on improving the healthcare system. Estimating the potential gains achievable through investigation and quality improvement that reduces the mean proportion to the 20th centile focusses efforts on system-wide improvements rather than assigning blame and onus on individual HCOs. In combination with the empirical Bayesian shrinkage estimators, the estimated potential gains support practicable reports on CIs for healthcare providers.

CIs are screening tools, so just as positive blood tests or breast cancer screening result in review and

further investigation so too positive results from the CI analysis must result in further investigation. There are three types of positive results, namely, large variation between HCOs, large variation between strata and outlier HCOs (large variation from expected). This paper has described the use of the difference between the mean and 20th centile proportions to estimate the impact of between HCO variation and stratum and outlier gains which estimate the impact of between stratum variation and variation from expected for individual HCOs. These gains are reported by the ACHS for all 338 CIs[13]. Bayesian methods play a key role in ensuring such measures are not overestimated.

The presented potential gains quantify reductions, or increases for certain CIs, in the numbers of "events of interest". Whilst it is possible to attribute monetary costs to each event in order to estimate potential financial changes, the problem remains of comparing the vast range of outcomes such as delays due to intensive care unit (ICU) access block, readmissions and out of hours discharges from ICU, adverse events related to medication errors, wound infections and failure to administer venous thromboembolism prophylaxis. Whilst the measures may be converted to indicate potential costs to the healthcare system doing so would take a restricted view of these measures of quality. Further, there remains the issue of how one may compare losses of life with additional waiting times. The simplest approach involves identifying CIs where significant numbers of patients were not receiving the standard of care implied by the CI as being acceptable; however, this remains an area of ongoing research.

Abstract

Intra-partum foetal death has been variously defined. However, a definition adopted at a technical consultation in 2006 is employed in this review. The quality of intra-partum care is a crucial factor for pregnancy outcome for both mothers and new-borns. Intra-partum stillbirth is defined as late foetal death during labour, which clinically presents as fresh stillbirth. The largest proportion of the world's stillbirths occurs in the late preterm, term and intra-partum periods. The Western Pacific region has the greatest reduction in stillbirth with a 3.8% annual decline between 1995 and 2009; however, the annual decline in the African region is less than 1%. Caesarean delivery is still uncommon, especially in rural areas: 1% of births in rural Sub-Saharan Africa and 5% in rural South Asia are by caesarean delivery; 62% of stillbirths occurred during the intra-partum period; 61.4% of stillbirths are attributable to obstetrical complications. Preventive measures aimed at reducing the incidence of intra-partum foetal death entail all measures aimed at improving quality antenatal care and preventing intra-partum asphyxia. This review discusses intra-partum foetal deaths from a Sub-Saharan African perspective. It explores the contribution of research within the region to identifying its impact on new-born health and potential cost-effective policy interventions.

Key words: Intra-partum; Foetal; Death; Sub-Saharan; Africa

Core tip: Intra-partum foetal death includes intra-uterine deaths that occur within 12 h of delivery of a new-born weighing more than 1000 g, or that had more than 28 wk of gestation, but could not be resuscitated. Sub-Saharan Africa has the lowest recorded decline of intra-partum foetal deaths; however, this region recorded a doubling of her annual rate of reduction to 3.1% during 2000-2011, from 1.5% during 1990-2000. Impacts of research within the region towards improved new-born health and cost-effective policy interventions are examined.

Adekanbi AOA, Olayemi OO, Fawole AO, Afolabi KA. Scourge of intra-partum foetal death in Sub-Saharan Africa. *World J Clin Cases* 2015; 3(7): 635-639 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i7/635.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i7.635

INTRODUCTION

Intra-partum foetal death is a subset of perinatal mortality: macerated stillbirths; lethally and congenitally malformed neonates as well as new-borns that died after the first 24 h of life are excluded. It basically refers to intra-uterine foetal deaths that occurred within 12 h of delivery of a new-born whose weight is more than 1000 g or which has gone beyond 28 wk of gestation[1]. It is a health indicator which measures the quality of obstetric care on one hand, and the association between maternal and neonatal health on the other hand; it is a determinant of the quality of intra-partum care.

According to the International Classification of Diseases, Revision 10, a stillbirth or late foetal death is that which occurs after 22 wk of gestation, or when the crown-heel length is 25 cm or more, and the weight is at least 500 g[2]. For the purpose of international comparison, stillbirth is better described as foetal death at a gestational age of 28 completed weeks or a crown-heel length of 35 cm or more and birth weight is at least 1000 g[3]. Gestational age measures are not as reliably documented as birth weight, especially in the low resource countries.

The greatest risk to life for the mother and baby is noted during childbirth[4]. Intra-partum related death accounts for over 2/5 of the world's annual maternal deaths; the death of 1.02 million babies during labour, and 904000 neonatal deaths around delivery are interrelated[1,4,5].

The quality of intra-partum care is therefore a crucial factor for the pregnancy outcome for both mothers and new-borns. Timely and appropriate care rendered by skilled attendants in an atmosphere that is conducive will prevent or at least reduce morbidity for both mothers and newborns.

The foetal mortality rate for gestations of at least 20 wk (6.2 foetal deaths per 1000 live births)[6] and infant mortality rate (6.9 infant deaths per 1000 live births)[7] in the United States in the year 2005 were similar. Depending on the definition used, 40% to 60% of perinatal mortality is due to foetal mortality[8]. According to the World Health Organization (WHO)[9], 8 out of every 1000 babies die during labour worldwide. In 2000, intra-partum mortality rate was estimated at 15 per 1000 births in Middle and Western Africa, while it was only 0.6 per 1000 births in developed countries[9].

Annually, there are 287000 maternal deaths[10] and over 3 million stillbirths, of which about a million die in the course of labour and about four million neonatal deaths, half of which happen on the day of birth[11].

Although stillbirths are underreported in developing countries, 97% of the cases occur in the region, and it accounts for 50% of worldwide perinatal deaths. It is hoped that the problem of stillbirths will be given due attention in these regions with a view to reducing the effect on the society[9,12]. A Nigeria based study posited that of the recorded perinatal deaths, 51.2% were fresh stillborns, while 39.1% were macerated[13]. This finding conforms to the Wigglesworth classification of perinatal death (Table 1). The high proportion of intra-partum foetal death is a reflection of poor-quality intra-partum care in the study-country, however, another study conducted in Nigeria recorded 73% macerated and 27% fresh stillbirths[14], which reflects variations noted from one centre to the other, even within the same country.

The neonatal period is a crucial part of the infant's life, as up to 40% of deaths of children younger than 5 years occurred within the period; also, neonatal death was observed to increase in relation to a rapid fall in postnatal deaths[1,15]. The need for concerted efforts from health practitioners and policy makers can never be overemphasized.

Twenty-five percent of neonatal deaths in low income countries and 8% of all deaths among children younger than 5 years during the 4-year period of 2000 to 2003, were attributed to birth asphyxia by the WHO[16]. A major focus on birth asphyxia is important in reducing child mortality; this will immensely contribute to the attainment of the Millennium Development Goal[17]. Tracking of stillbirths, however, is often incomplete and variable.

The global burden of disease literature gives insight into the prevalence of death during the peri-partum period[17]. The relatively insufficient resource allocation to the health sector, especially in Africa, which is identified as a bane, was addressed by the World bank in 1993; the bank issued a guide on resource allocation in the health sector to assist the developing countries in that perspective.

Intra-partum related neonatal death deserves prominence in global health programming and policy because it has a significant contribution to the under-5 child mortality rate. Early neonatal deaths are intertwined with maternal health, therefore, effective maternal cum neonatal health services are key to reversing the poor outcomes. The reduction of intra-partum-related neonatal deaths is a daunting challenge and success will depend on provision of effective and efficient care delivery[3,11,16].

Vital registration systems are weak in developing countries where more than 97% of neonatal deaths occur[12], therefore little is known about the causes of most of these deaths. Furthermore, autopsies on the dead foetuses, as well as placenta histological studies are rarely carried out in the region. This review discusses intra-partum foetal deaths from a Sub-Saharan African perspective. It explores the contribution of research within the region to identifying its impact on new-born health and potential cost-effective policy interventions.

Table 1 Perinatal deaths by Wiggles worth classification[a]

Birth weight (g)	No. of perinatal deaths					Total (%)
	Macerated stillbirths	Congenital malformations	Immaturity	Asphyxia	Other	
1000 (n = 34)	18	2	14	0	0	34 (5.2)
1001-1500 (n = 42)	16	7	16	3	0	42 (6.4)
1501-2000 (n = 65)	35	4	18	8	0	65 (9.9)
2001-2500 (n = 55)	20	7	11	16	1	55 (8.3)
N2500 (n = 464)	151	5	49	250	9	464 (70.3)
Total (%)	240 (36.4)	25 (3.8)	108 (16.4)	277 (41.9)	10 (1.5)	660 (100.0)

[a]Birth weight data missing for 61 neonates. Adapted from Fawole *et al*[13], Determinant of Perinatal Mortality in Nigeria.

PATHOLOGIC CONSIDERATIONS AND TERMINOLOGIES

Most foetal deaths, intra-partum or immediately post-partum, are caused by birth asphyxia, which is mainly due to mismanaged obstetric conditions. The causes of foetal deaths are: obstructed labour, infections, asphyxia, maternal haemorrhage, severe pre-eclampsia and eclampsia, maternal/foetal malnutrition, congenital anomalies and umbilical cord complications[18,19].

Congenital anomalies, diabetes, and infections associated with preterm birth and post-term pregnancy, which are preventable causes of stillbirth, contribute immensely to a high foetal death rate, however, the causes have been virtually eliminated in high income countries (HIC)[20]; the contributions from these important causes in the Sub-Saharan Africa region are scarcely documented.

"Birth asphyxia" according to WHO in 1997, is a condition in new-borns who had breathing abnormality at birth[21]. Non-specific terminologies such as foetal distress, Apgar score and foetal acidosis are not favoured; these terminologies are not predictive of outcome on the long run[22].

Post–asphyxia encephalopathy, birth asphyxia, hypoxic-ischaemic encephalopathy, foetal distress or perinatal asphyxia should not be used loosely, except when there is evidence of acute intra-partum causation[22-24]. Intra-partum stillbirth presents as fresh stillbirth when it is due to intra-partum hypoxic injury[25].

Intra-partum neonatal death is the death of a baby born alive within 28 d of life from evidenced intra-partum injury, with or without neonatal encephalopathy[3,11,20,21]; acute hypoxia superimposed on chronic hypoxia in a growth restricted foetus could easily lead to foetal death[22]. There is a limit to the ability of the foetus to tolerate excessive reduction in oxygen partial pressure, though a healthy foetus is conditioned to physiological hypoxia that regulates foetal circulation through unhindered oxidative metabolism[26].

The immediate response to acute hypoxia by the foetus and the new-born is shallow breathing followed by cessation of respiration, called primary apnoea, which leads to deep gasping and irregular respirations. It progresses to terminal apnoea when all respiratory efforts cease[26].

In the course of apnoea, the heart rate progressively decreases to a halt few minutes after the onset of secondary apnoea. Primary and secondary apnoea presents with bradycardia and dyspnoea[26].

Prompt tactile stimulation and/or assisted ventilation always lead to a restoration of the heart rate to normalcy; any delay in resuscitation is accompanied by slow recovery. The importance of institutionalization of the concept of emergency obstetric care (EMOC), increased skilled birth attendance and neonatal intensive care in all facilities charged with pregnancy care cannot be over-emphasized.

DEMOGRAPHIC TRENDS

Over 1 million stillbirths occur during labour[23]; a number of studies from some low income countries showed that up to 70% of stillbirths occur in the intra-partum period and are due to obstetric emergencies[4,22], while in advanced countries, half of all stillbirths occur in non-anomalous babies at > 28 wk gestation[20]. A WHO review of vital registration showed that the estimated number of global stillbirths was 2.6 million in 2009 and 3.0 million in 1995[27]. The worldwide stillbirth rate has declined by 14% between 1995 and 2007[27].

The Western Pacific region recorded the greatest reduction in stillbirths, with a 3.8% annual decline between 1995 and 2009, while the African region posted only an annual decline of less than 1% (0.7%)[24]. There is a wide variation in stillbirth rates among countries; South-East Asia and Africa had two-thirds of all stillbirths.

In advanced countries, the third-trimester stillbirth rate is less than 4 per 1000 total births, and this amounts to 25% of the worldwide average and 11% of the average in South Asia and Sub-Saharan Africa[25]. Finland has the lowest reported rate of 2.0 per 1000 total births, while Nigeria reported 41.9 per 1000 total births and Pakistan at 46.1 per 1000 total births, had the highest rates[24].

Sub-Saharan Africa registered a 39% decline in the under-five mortality rate. However, the region had an annual rate of reduction to 3.1% during 2000-2011, from 1.5% during 1990-2000[26]. There was a dramatic acceleration in the rate of decline in Eastern and Southern Africa; this coincided with a recorded sub-

stantial improvement in effective interventions to combat major diseases, especially HIV, and also measles and malaria[27].

RISK FACTORS

Utilization of emergency obstetrics care where available, remained low and even worse in the remote areas; 5% of births in rural South Asia and 1% in rural Sub-Saharan Africa are by caesarean delivery[28]. Sixty-two percent of stillbirths occurred in the intra-partum period; obstetrical complications accounted for 61.4% of stillbirths. The following significant maternal risk factors were documented: un-booked status, illiteracy, age of 35 years and above in pregnancy, extremes of reproductive age groups, multiple pregnancies and prolonged labour; the foetal risk factors associated with stillbirth are mal-presentation, decreased foetal movement, foetal distress, prematurity, small for gestational age, and neonatal infection[28-30]. The following independent risk factors were identified: congenital malformations, true knot of cord, meconium stained amniotic fluid, oligo-hydramnios, poly-hydramnios, previous adverse perinatal outcome, placental abruption, advanced maternal age, and hypertensive disorders[30]. Jewish ethnicity, gestational diabetes, previous caesarean section, and recurrent abortions were negatively associated with intra-uterine foetal death[31].

An Africa based study identified the following risk factors for perinatal death: un-booked status, lack of prenatal care, duration of schooling, maternal age above 35 years, asphyxia, and prematurity[12]. However, the researchers found that when maternal and neonatal factors were considered together, the following are the determinants of perinatal mortality: un-booked status, free maternity service, mother's level of education, mother's age within the range of 26 and 30 years, and mothers older than 40 years, prematurity, asphyxia, lack of prenatal care, mode of delivery and so on[12]. Some of the risk factors peculiar to the Sub-Saharan African society are lack of prenatal care, un-booked status, and lack of quality care to mention a few.

The most common patient-related avoidable factors found in a South African study were un-booked patients, patients booked late in pregnancy, patients who delayed before seeking medical assistance, and patients with inappropriate responses to poor foetal movements[32]; whereas the most common avoidable factors related to medical care were underestimation of foetal size and lack of response by staff to patients with poor obstetric histories. However, the common administration-related avoidable factors were unavailable operating theatres and lack of transportation between institutions[32].

In a number of countries in the Sub-Saharan Africa, a considerable percentage of deliveries are not supervised by skilled workers, there is a dearth of nurses and midwives, the database in these places is weak for setting priorities, and political willingness to address the issue is suboptimal.

It is implied by these identified risk factors that developing an algorithm for the management of such conditions, especially for use in the Sub-Saharan African countries, will be a good step towards reducing the scourge.

PREVENTION

Preventive measures aimed at reducing the incidence of intra-partum foetal death entail all measures aimed at improving quality antenatal care and preventing intra-partum asphyxia.

Appropriate obstetric care in the prenatal and intra-partum periods is vital. Also, close monitoring with readily available appropriate care during labour to enable obstetrical providers recognize conditions such as prolonged labour, placental abruption, placental previa, foetal mal-position, and foetal distress, will allow for rapid intervention through caesarean section to further reduce the rate of intra-partum foetal deaths.

Every death counts; a version of mortality audit in South Africa focuses on saving mothers, babies and children[33]. Replication of the exercise in all African countries, with the intention of putting to use lessons learnt from the exercise, will help stem the tide of the repugnant scourge.

Intermittent auscultation for monitoring foetal heart rate in labour is preferred and should be promoted in the low and medium income countries, rather than continuous foetal heart rate monitoring devices which might appeal to policy makers in such climes. This recommendation is based on the outcome of a Dublin based study, which concluded that there is no difference in intra-partum stillbirth rates, as well as long term outcome between the intermittent auscultation group and the continuous foetal heart rate monitored group[33].

CONCLUSION

The high rates of intra-partum foetal death in Sub-Saharan Africa should be a cause for concern for all stakeholders.

Urgent and effective steps are needed to promote equitable distribution of health facilities, providing maternal and newborn health care with optimal capacity for EMOC.

Initiatives that seek to increase rates of facility births in Sub-Saharan Africa must address the issues of quality of maternity care and socio-cultural determinants of access to health care.

It is important that health systems identify the causes of intra-partum foetal deaths peculiar to their location and endeavour to audit all stillbirths with a view to improving pregnancy outcomes for both mothers and new-borns.

Increased research attention focusing on this subject in the region is also advocated.

Abstract

AIM: To investigate the differentiation of human Wharton's jelly derived mesenchymal stromal cells (WJ-MSCs) to insulin producing clusters (IPC) this study was conducted.

METHODS: The umbilical cords samples were collected from full term caesarian section mothers and the WJ-MSCs were cultured from tissue explants in High glucose-Dulbecco's Modified Eagle Medium (H-DMEM); H-DMEM supplemented with 10% fetal bovine serum (FBS) and antibiotics. The expression of CD90, CD44, CD105, CD34 and CD133 as well as osteogenic and adipogenic differentiation of cells in appropriate medium were also evaluated. The cells were differentiated toward IPC with changing the culture medium and adding the small molecules such as nicotinic acid, epidermal growth factor, and exendin-4 during 3 wk period. The gene expression of *PDX1*, *NGN3*, *Glut2*, insulin was monitored by reveres transcription polymerase chain reaction method. The differentiated clusters were stained with Dithizone (DTZ) which confirms the presence of insulin granules. The insulin challenge test (low and high glucose concentration in Krebs-Ringer HEPES buffer) was also used to evaluate the functional properties of differentiated clusters.

RESULTS: WJ-MSCs were positive for mesenchymal surface markers (CD90, CD44, CD105), and negative for CD34 and CD133. The accumulation of lipid vacuoles and deposition of calcium mineral in cells were considered as adipogenic and osteogenic potential of WJ-MSCs. The cells also expressed the transcriptional factors such as Nanog and OCT4. During this three step differentiation, the WJ-MSCs morphology was gradually changed from spindle shaped cells in to epithelioid cells and eventually to three dimensional clusters. The clusters expressed PDX1, NGN3, Glut2, and insulin. The cells became bright red color when stained with DTZ and the insulin secretion was also confirmed. In glucose challenge test a significant increase in insulin secretion from 0.91 ± 0.04 μIu/mL (2.8 mmol/L glucose) to to 8.34 ± 0.45 μIu/mL (16.7 mmol/L glucose) was recorded ($P < 0.05$). The insulin secretion of undifferentiated *WJ-MSCs* was not changed in this challenge test.

CONCLUSION: WJ-MSCs have the ability to differentiate in to islet-like cells *in vitro*. However, this process needs further optimization in order to generate efficient and functional IPCs.

Key words: Mesenchymal stromal cells; Umbilical cord; Beta cell; Islet

Core tip: Diabetes is a major chronic metabolic disorder in the world. Mesenchymal stromal cells (MSCs) has the ability to differentiate in to functional insulin producing cells.In this study, human Wharton's jelly derived MSCs (The clusters expressed *PDX1*, *NGN3*, *Glut2*, and insulin. The cells became red color when stained with DTZ and the insulin secretion was confirmed Wharton's jelly derived MSCs were differentiated to insulin producing clusters (IPCs). More efficient differentiation protocoles for generation of functional IPCs will be a potential new source for cell transplantation in diabetic patients.

Nekoei SM, Azarpira N, Sadeghi L, Kamalifar S. *In vitro* differentiation of human umbilical cord Wharton's jelly mesenchymal stromal cells to insulin producing clusters. *World J Clin Cases* 2015; 3(7): 640-649 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i7/640.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i7.640

INTRODUCTION

Diabetes mellitus is characterized by an absolute or relative lack of blood insulin and associated the impaired metabolism of carbohydrates, fats and proteins. Recent study reported that 382 million people had diabetes in the world; and by 2035, this number is expected to be increased to 592 million[1]. Pancreas or islet cell transplantation is considered as an effective therapy for diabetic patients[2]. However, the limited number of cadaveric donors and immunological rejection are two major obstacles to achieve effective long term results[3].

Human embryonic stem cell (ESC) is a good promising source for treating diabetes[4]. However, ethical concerns about the use of human embryos and the risk of tumourigenicity are problems regarding the use of these cells for clinical use[4]. Other studies have made efforts to differentiate pancreatic beta cells from other sources such as induced pleuripotent stem cells (IPSs)[5,6], bone marrow-derived mesenchymal stromal cells[7,8], or umbilical cord blood cells[9].

Mesenchymal stromal cells (MSCs) are isolated from the Wharton's jelly or umbilical cord, are easily obtained and processed compared to ESCs and bone marrow derived MSCs[10]. The cells have differentiated into adipogenic, chondrogenic, and osteogenic lineage and also have expressed the CD105, CD44 and CD90 and negative for hematopoietic and vascular markers such as: CD33, CD56, CD31, CD34, CD45[10]. Wharton's jelly derived MSCs (WJ-MSCs), have high proliferation capacity and do not induce teratomas after transplantation[10].

The potential of these postnatal stem cells to differentiate toward insulin-producing cells has been evaluated previously. However, the current protocols are not optimized for efficient transdifferentiation. Here, we describe the three step modified protocol for direct differentiation of WJ-MSCs into insulin producing clusters (IPC). These clusters produce insulin in response to different glucose concentration.

MATERIALS AND METHODS

Preparation of human umbilical cord

Human umbilical cord samples were aseptically collected from full-term delivery by cesarean section at the Hafez Hospital affiliated to Shiraz University of Medical Sciences. Informed consent was received from mothers and the study design was approved by ethical committee of our university.

Preparation of WJ-MSCs

Umbilical cord Wharton's jelly was processed within 2 h after aseptic collection and cut into pieces of 0.5-1 mm^2. These pieces were placed in 10 cm plates and cultured in High glucose-Dulbecco's Modified Eagle Medium; H-DMEM supplemented with 10% fetal bovine serum (FBS) and penicillin 100 U/mL, streptomycin 100 μg/mL. The plates were placed in an incubator with saturated humidity at 37 ℃ containing 5% CO_2. The medium was changed every three days; the cell migrated from the margins of explants. After reaching 70%-80% confluence, the adherent cells were harvested with 0.05% trypsin-Ethylene diamine tetra acetic acid (EDTA), (Gibco, Germany) and the cell suspension was used for subsequent experiments. The presence of transcription factors that regulate maintenance of pluripotent

state in ESC (OCT4, Nanog) were studied by reveres transcription polymerase chain reaction (RT-PCR).

Flow cytometry analysis

The WJ-MSCs was stained with monoclonal antibodies: CD90, CD44, CD105, CD34 and CD133 (BioLegend, San Diego, Calif., United States) and analyzed using the FACS Calibur flow cytometer (Becton Dickinson, NJ, United States).

In vitro osteogenic and adipogenic differentiation

To investigate their capacity for mesodermal differentiation adipogenic and osteogenic differentiation was carried out by culturing cells with appropriate differentiation medium. For adipocytes differentiation, the WJ-MSCs were cultured in L-DMEM supplemented with 10% FBS, 10 nmol/L dexamethasone, 0.5 μg/mL insulin, 2 mmol/L glutamine for 15 d. Then the cells were fixed with 0.4% paraformaldehyde (PFA) and stained with oil-red-O (Sigma). For osteoblastic differentiation, the WJ-MSCs were cultured L-DMEM supplemented with 10% FBS, 10 nmol/L dexamethasone (Sigma), 10 mmol/L b-glycerol phosphate (Sigma) and 50 mg/mL ascorbic acid-2 phosphate (Sigma). After fixation, the differentiated cells were stained with alizarin red stain and calcium deposition was confirmed.

In vitro differentiation of WJ-MSCs to insulin producing clusters

The cultured WJ-MSCs from 4th passage with 80% to 90% confluency were induced to differentiate into IPC in three separate stages.

In first sage, the MSC monolayer was treated for 24 h with high glucose Dulbecco modified Eagle medium-F12 (DMEM-F12) supplemented with10% FBS, 10^{-6} mol/L of retinoic acid (RA; Sigma-Aldrich) and 1% antibiotic; then the medium was switched to DMEM-F12 containing only 10% FBS for 2 d.

In second stage, the cells were detached with 0.5% trypsin-EDTA and seeded in 0.1% gelatin (Sigma-Aldrich) coated plates. The medium was switched to DMEM-F12, supplemented with 10% FBS, 10 mmol/L nicotinic acid (Sigma-Aldrich), and 20 ng/mL epidermal growth factor (EGF, Sigma-Aldrich) for one week.

In third stage, in order to mature the insulin-producing cells, the DMEM-F12 medium was supplemented with 10% FBS and exendin-4 (Sigma-Aldrich) for one week. Glucagon-Like Peptide-1 or Exendin-4 is an insulin secretagogue, with glucoregulatory effects.

The formation of islet like clusters was daily monitored and the DTZ staining confirmed the presence of insulin granules. The genes expression of pancreatic endocrine cell development was monitored in the end of each step. The cells which were cultured in L-DMEM containing only 10% FBS was considered as a control group.

RT-PCR

The total RNA was extracted from WJ-MSCs s before and after third stage of differentiation by using Mini-RNease RNA extraction kit (Cinnagen, Iran). The cDNA was synthesized using MMULV reverse transcriptase (Cinnagen, Iran). The reaction condition for cDNA synthesis was: pre-heating at 42 ℃ for 90 min; followed by annealing at 85 ℃ for 5 s. The synthesized cDNA was used to examine the expression of pancreatic specific transcription factors as listed in Table 1. Amplification used a fluorescence-quantitative PCR instrument (ABI Prism7500, step one plus) by using SYBER Green (TAKARA, Japan) following the manufacturer's instructions. Amplification was carried out as follows: denaturing at 95 ℃ for 5 min; followed by 40 cycle denaturation at 95 ℃ for 1 min; annealing for 1 min. The final stage was run to generate a melting curve for verification of amplification product specificity. Beta actin gene was used as a control. The products were also visualized by gel electrophoresis.

Dithizone staining

Diphenylthiocarbazone, Dithizone (DTZ), (Sigma, United States) is a zinc-chelating substance which is used for identification of insulin granules in pancreatic beta-cells as bright crimson red. The Acinar cells remain unstained.

In order to evaluation insulin production in IPC at the end of 3rd week, the differentiated clusters were examined.

Insulin secretion

The clusters, were rinsed twice in Krebs-Ringer HEPES (KRH) buffer (125 mmol/L NaCl, 4.74 mmol/L KCL, 1 mmol/L $CaCl_2$, 1.2 mmol/L KH_2PO_4, 1.2 mmol/L $MgSO_4$, 5 mmol/L $NaHCO_3$, 25 mmol/L HEPES, 0.1 mmol/L 0.1%BSA, pH = 7.4) containing 2.8 mmol/L glucose (Low glucose concentration) (Sigma-Aldrich, United States).

After 1 h incubation, the medium was collected for insulin assay and the cells were stimulated with KRH buffer containing 16.7 mmol/L glucose for 1 h (High glucose concentration). The insulin level was determined by Enzyme linked Immunoassay kit and the results were compared with undifferentiated MSC cells as control group.

Statistical analysis

The data were presented as means ± SD. Each experiment was repeated 3 times. Data was assessed by one-way ANOVA followed by Tukey's test for pair wise comparison. $P < 0.05$ was considered as statistically significant. The statistical analysis was performed using Graph Pad Prism 5 software.

RESULTS

Cell morphology and Immunophenotyping of WJ-MSCs

WJ-MSCs formed a homogenous monolayer of adherent spindle shaped cells (Figure 1). Flow cytometry ana-

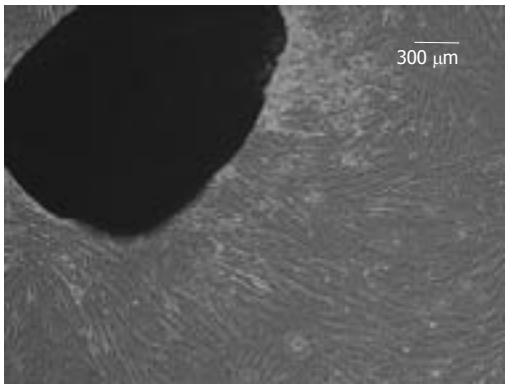

Figure 1 The Wharton's Jelly mesenchymal stromal cells were grown from the edge of tissue explants (× 100).

lyses showed that the WJ-MSCs were positive for mesenchymal markers (CD90, CD44, CD105), and negative for CD34 and CD133 (Figure 2). The ESCs transcriptional factors such as Nanog and OCT4, also expressed.

In vitro osteogenic and adipogenic differentiation of WJ-MSCs

The accumulation of lipid vacuoles (Stained red color in Oil Red O) in cells was considered as adipogenic differentiation. Deposition of calcium minerals (stained as orange red color with Alizarin Red) was also considered as osteogenic potential of these cells (Figures 3 and 4).

Morphological Changes before and after differentiation of WJ-MSCs

In passage 4 (P4), the WJ-MSCs were step wise differentiated toward insulin producing cells.

In stage 1, the cells have shown spindle-shaped morphology (Figure 5A). Cell morphology was gradually changed into round epithelioid cells and by addition of beta cell maturation factor such as nicotinamide in stage 3, three dimensional clusters were formed (Figure 5B-D). These clusters were stained red color with DTZ (Figure 6).

Gene expression analysis

After differentiation, mRNA expression of pancreatic development transcription factors and beta cell specific gene such as *PDX1*, *NGN3*, *Glut2* and insulin were detected. Expressions of the mentioned genes led to *in vitro* production of functional IPCs. Results represent three separate experiments (Figure 7A and B).

Insulin secretion after glucose challenge test

In respect of insulin secretion, a significant increase in insulin secretion from 0.91 ± 0.04 μIu/mL (2.8 mmol/L glucose) to to 8.34 ± 0.45 μIu/mL (16.7 mmol/L glucose) was recorded ($P < 0.05$). The insulin secretion was detected in undifferentiated *WJ-MSCs* (0.3 ± 0.03 μIu/mL) which was not changed in glucose challenge test.

DISCUSSION

Type 1 diabetes mellitus is caused by an autoimmune destruction of pancreatic beta cells. Although the insulin therapy remains the routine treatment for diabetes, but whole pancrease organ transplant or transplantation of pancreatic islets of Langerhans provides a cure for this disorder[2,3]. Various types of stem cells such as ESCs, induced pleuripotent stem cells (IPs) and mesenchymal stromal cells have been differentiated into IPCs by genetic modification and/or modification in culture conditions[7,8,11,12]. Using of ESCs has several limitations such as ethical problem, immune rejection, and risk of tumorigenesis.

To overcome these problems, human IPS is ideal for personalized therapy. However, epigenetic changes, and chromosomal instability during reprogramming remain the obstacle[6] .

Generation of IPCs from MSCs from a variety of tissues such as bone marrow, umbilical cord, and adipose tissue represents an alternative therapy. MSCs can also be used as a cellular vehicle for the expression of human insulin[6,13-15].

The MSC numbers in bone marrow and umbilical cord blood are low and require multiple *ex vivo* expansion. Extra-embryonic tissue such as fetal membrane and umbilical cord Wharton's jelly has the stemness phenotype, immunoprivileged properties, and faster proliferation than adult MSCs and is considered as unlimited source for tissue engineering and regenerative medicine[13]. The WJ-MSCs express HLA-G6 isoform, the unique ability which is important in immune modulation. Therefore, these cells are particularly suitable for cell based therapy. These tissues are normally discarded

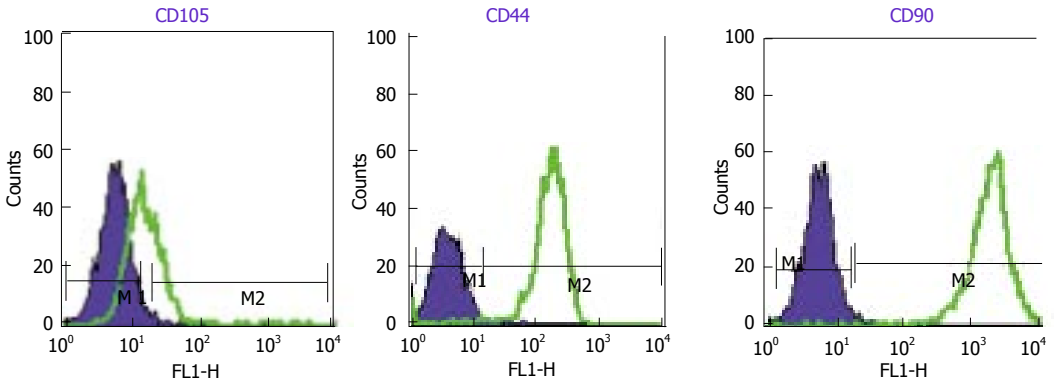

Figure 2 Flow cytometry histogram of Wharton's jelly derived mesenchymal stromal cells (CD90, CD105, CD44). WJ-MSCs are positive for these markers. Dark Blue lines indicate background fluorescence obtained with isotype control. WJ-MSCs: Wharton's jelly derived mesenchymal stromal cells.

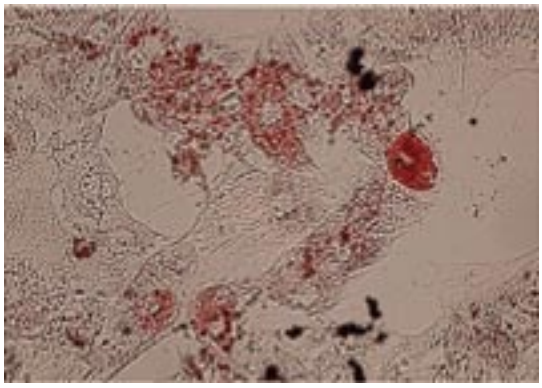

Figure 3 Fat droplets confirmed the adipogenic potential of Wharton's jelly derived mesenchymal stromal cells (Oil Red O staining × 400).

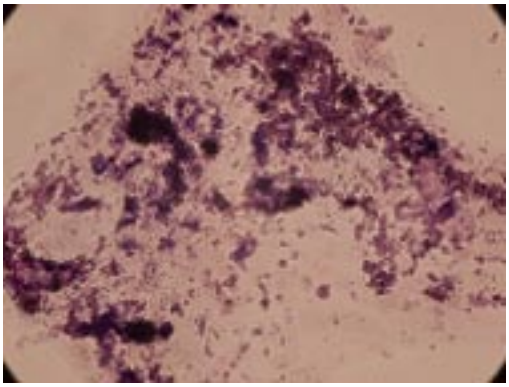

Figure 4 Calcium deposition confirmed the osteogenic potential of Wharton's jelly derived mesenchymal stromal cells (Alizarin Red staining × 100).

after birth and using them is not associated with ethical problem[16,17].

In this study, WJ-MSCs were isolated and their differentiation into adipocytes, and osteocytes confirmed their multilineage potentials. The retinoic acid we used to start the differentiation process. RA is an essential molecule for dorsal pancreas development in mouse. The effects of RA are achieved through RA binding and activation of retinoic acid receptors such as RARα, RARβ, and RARγ. Over expression of RARβ was detected in early stage of pancreases differentiation and absence of RARβ impaired the terminal differentiation of α and β-cells[18,19]. In vitamin-A deficiency, pancreatic islet function was Impaired. RA directly induces Pdx1 expression in ESCs and Pdx1 is an important transcription factor in the early development of pancreatic progenitors and bud expansion[20,21]. The retinoic acid response element is located at upstream of the transcription start site of Pdx1. Retinoie Acid Receptor (RARβ) expression is depended on epigenetic regulation[18,19]. Hyper methylation of the RARβ2 promoter was reported in pancreatic cancer, and diabetes. Therefore, it is postulated that the epigenetic silencing of RARβ, combined with vitamin A deficiency, may play a role in pathogenesis of diabetes[18,19]. Glucose is considered as a growth factor for β-cells replication both *in vitro* and *in*

vivo[22]. Subsequently, using of EGF was associated with proinsulin biosynthesis and 3H-thymidine incorporation in experimental model[23,24]. Nicotinamide was used during the second stage of differentiation. Various published protocols reported this substance as an effective inducer in pancreatic differentiation. Nicotinamide preserve islet viability through poly-ADP-ribose polymerase[25].

Glucagon-like peptide 1 (GLP-1) and its long acting mimetic exendin-4 are usually used for treatment of type 2 diabetes. Exendin 4 simultaneously stimulates beta cell secretory capacity as well as maintains insulin stores by translational control of proinsulin biosynthesis. Exendin-4 can also stimulate b-cell replication in human islets from young donors[26-28].

In our study, at the end of *in vitro* differentiation protocols, pancreatic endocrine genes and insulin were expressed. However, the insulin secretion after glucose challenge test was very low. As mentioned previously, incomplete beta cell phenotype and consequently poor insulin release in response to glucose challenge test might explain this problem[29,30].

In the literature, various sources of mesenchymal stem were differentiated into insulin secreting cells with different efficacy[31-43] (Table 2). However, the insulin secretion capacity of the cells was variable. The insulin challenge test was done with different protocols; the concentration of insulin was measured with different assays and reference range. Therefore, the comparison of data was not easily performed.

In our experience, differentiation of WJ-MSCs to form IPCs needs further optimization for clinical practice. To overcome this problem, addition of growth factors, extracellular matrix and/or culturing the cells in three dimensional environments are suggestive.

ACKNOWLEDGMENTS

The present article was adopted from Masumeh Nekoui MsC thesis in Embryology and development. The authors are also grateful to Mrs Elaheh Esfandiari and Mrs Masoumeh Darai for their assistance in cell culture and PCR.

COMMENTS

Background

Different types of stem cells such as embryonic stem cells (ESCs), induced pleuripotent stem cells and mesenchymal stromal cells have been differentiated into insulin producing cells by modification in cell culture conditions and addition of small molecules. Umbilical cord Wharton's jelly derived stromal cells has the stemness phenotype, with faster proliferation than adult mesenchymal stromal cells (MSCs) and is considered as a good source for generation of insulin producing cells.

Research frontiers

In this research, insulin producing clusters (IPC) was differentiated from Wharton's jelly MSCs (WJ-MSCs) without any genetic manipulation.

Innovations and breakthroughs

The IPCs was differentiated from WJ-MSCs by changing the cell culture medium and growth factors without genetic manipulation. However, the insulin release in response to glucose challenge test was not sufficient. Similar studies used various sources of mesenchymal stem and differentiated into insulin secreting cells with different efficacy and variable insulin secretion capacity. The insulin challenge test was done with different protocols; the concentration of insulin was measured with different assays and reference range. Therefore, the comparison of data was not easily performed.

Applications

Differentiation of WJ-MSCs to form IPCs needs further optimization for clinical practice.

Peer-review

The authors have performed a good study, the manuscript is interesting.

Abstract

Perifollicular granuloma is a unique histologic feature and whether it is associated with immunoglobulin G4 (IgG4)-related disease is controversial. We report a case of a 38-year-old man who presented with worsening left eye pain, proptosis, tearing, gritty sensation, blurred vision and multiple lymphadenopathy. An axillary lymph node resection showed reactive follicular and interfollicular lymph node hyperplasia, and increased eosinophils and plasma cells (at least 80% of IgG^+ plasma cells were positive for IgG4). A distinct feature was the presence of multifocal, perifollicular histiocytic granulomas, which formed a wreath around the entire follicles. The human herpes virus 8 was not detected by immunohistochemistry. In addition, an extensive panel of special stains, immunohistochemistry, and flow cytometry was negative for lymphoma, fungal, or mycobacterial infection. The findings were suggestive of IgG4-related sclerosing disease-associated lymphadenopathy. Further laboratory testing showed a significant increase of serum immunoglobulin E (> 23000 IU/mL) and slight increase of total IgG, but normal serum IgG4. Even though perifollicular granuloma is a nonspecific histopathologic feature and can be seen in other diseases, such as nodular lymphocyte predominant Hodgkin lymphoma, IgG4-related lymphadenopathy should be listed in the differential diagnoses of benign reactive lymph nodes, especially when perifollicular granuloma and plasmacytosis coexist.

Key words: Immunoglobulin G4-related disease; Lymphadenopathy; Plasma cells; Granuloma

Core tip: We report a case of a 38-year-old man who

presented with worsening left eye pain and multiple lymphadenopathy. An axillary lymph node resection showed increased eosinophils and plasma cells (at least 80% of immunoglobulin (Ig)G$^+$ plasma cells were positive for IgG4 and the presence of multifocal, perifollicular histiocytic granulomas, which formed a wreath around the entire follicles. An extensive workup was negative for lymphoma, fungal, or mycobacterial infection. The findings were suggestive of IgG4-related sclerosing disease-associated lymphadenopathy. Thus, IgG4-related lymphadenopathy should be listed in the differential diagnoses of benign reactive lymph nodes, especially when perifollicular granuloma and plasmacytosis coexist.

INTRODUCTION

Immunoglobulin G4 (IgG4)-related disease is a recently recognized fibro-inflammatory condition that can involve multiple organs and cause tumor-like enlargement[1,2]. It is characterized by a lymphoplasmacytic infiltrate enriched in IgG4-positive plasma cells, while elevated serum concentrations of IgG4 are found in 60% to 70% of patients[3]. IgG4-related disease has a male predilection (male to female ratio 8:1)[4].

According to the consensus statement from a multinational, multidisciplinary group of experts, the major histopathological features to make the diagnosis of IgG4-related disease include a dense lymphoplasmacytic infiltrate, plasma cells, storiform fibrosis, and obliterative phlebitis[5]. However, these features are usually uncommonly seen in certain organs, such as lymph nodes.

We describe a case of a 38-year-old man with swelling of soft tissue surround the eye and multiple lymphadenopathy and an axillary lymph node resection showed reactive follicular and interfollicular lymph node hyperplasia, increased eosinophils and plasma cells (at least 80% of immunoglobulin IgG$^+$ plasma cells were positive for IgG4) and multifocal, perifollicular histiocytic granulomas, which formed a wreath around the entire follicles. Review of literature also found our findings may add to the knowledge of IgG4-related disease.

CASE REPORT

Clinical history

We report a case of a 38-year-old man who presented with worsening left eye pain, proptosis, tearing, gritty sensation, and blurred vision. Magnetic resonance imaging of orbits confirmed enlargement of the left medial rectus, superior oblique and inferior rectus muscle, and enhancing soft tissue signal encasing the left optic nerve sheath. Computed tomography scan of chest and abdomen showed multiple lymphadenopathy. Clinically, lymphoma was suspected. Patient's rheumatology work up was negative, including anti-neutrophil cytoplasmic antibodies, anti-double stranded DNA, anti-nuclear antibodies, anti-Smith, anti-ribonucleoprotein, anti-complement C3 and C4. Complete blood count shown mild eosinophilia, otherwise, it was unremarkable.

Microscopic and immunohistochemical features

An axillary lymph node resection showed reactive follicular and interfollicular lymph node hyperplasia, and increased eosinophils and plasma cells (at least 80% of IgG$^+$ plasma cells were positive for IgG4). A distinct feature was the presence of multifocal, perifollicular histiocytic granulomas, which formed a wreath around the entire follicles (Figure 1A). Increased plasma cells were marked by CD138 immunohistochemical stain (Figure 1B). IgG4$^+$ plasma cells are markedly increased (Figure 1D), compared with total IgG stain (Figure 1C). EBER (EBV encoded small RNA by *in situ* hybridization) was negative. The human herpes virus 8 was not detected by immunohistochemistry. In addition, an extensive panel of special stains, immunohistochemistry, and flow cytometry was negative for lymphoma, fungal, or mycobacterial infection. The findings were suggestive of IgG4-related sclerosing disease-associated lymphadenopathy.

Follow-up

Further laboratory testing showed a significant increase of serum IgE (> 23000 IU/mL) and slight increase of total IgG (1802 mg/dL), but normal serum IgG4 (27 mg/dL). The patient was started on prednisone and methotrexate with reduction in proptosis and in the size of orbital mass by computerized tomography (CT) scan. While patient was maintained with methotrexate and tapering on steroid, he was noted to have left eye redness and itching. Rituximab was added and methotrexate was discontinued. The patient's symptom subsided.

DISCUSSION

According to the consensus statement from a multinational, multidisciplinary group of experts, the major histopathological features to make the diagnosis of IgG4-related disease include a dense lymphoplasmacytic infiltrate, plasma cells, storiform fibrosis, and obliterative phlebitis[5]. However, these features are usually not seen in certain organs, such as lymph nodes. Fibrosis and obliterative phlebitis are usually not present in lymph nodes.

Lymph nodes in IgG4-related disease may show variable histopathologic features. Cheuk *et al*[4] divided it into five different categories, including multicentric

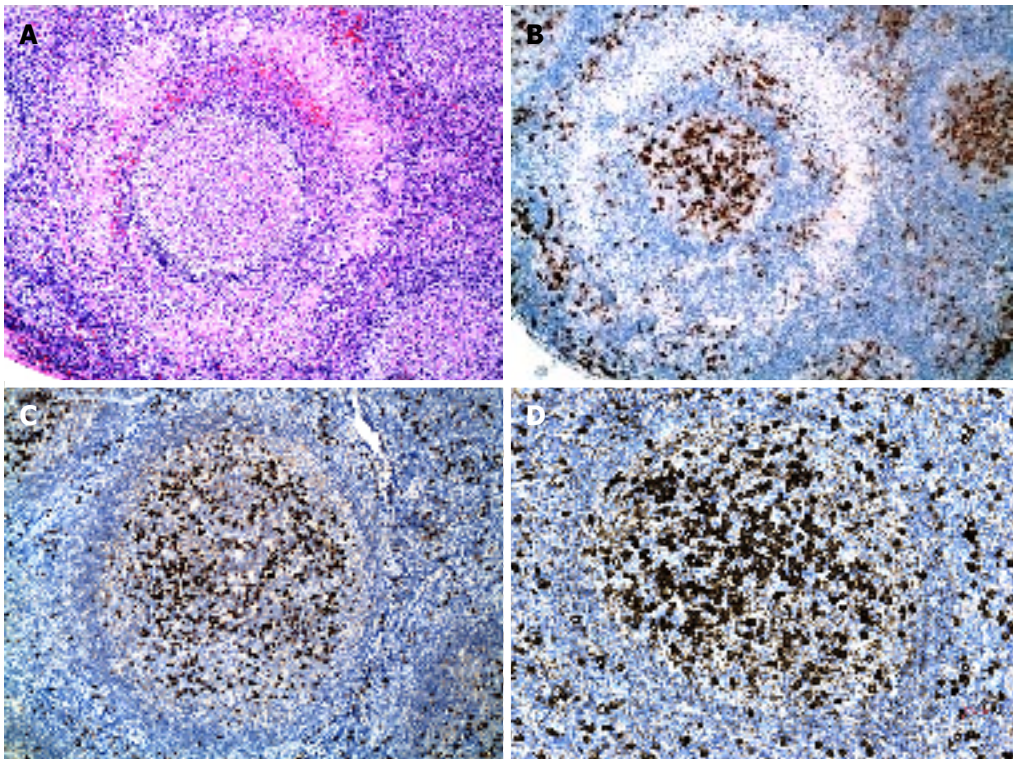

Figure 1 Perifollicular histiocytic granulomas that formed a wreath around the entire follicle. A: Hematoxylin and eosin stain; B: CD138 immunohistochemical stain highlights the plasma cells; C: Immunoglobulin G (IgG) immunohistochemical stain; D: IgG4 immunohistochemical stain demonstrated that more than 80% of IgG^+ cells were positive for IgG4.

Castleman disease-like (type Ⅰ), follicular hyperplasia (type Ⅱ), interfollicular expansion (type Ⅲ), progressive transformation of germinal centers (type Ⅳ), and inflammatory pseudotumor-like (type Ⅴ). Nevertheless, an increase in $IgG4^+$ plasma cells with an IgG4/IgG plasma cell ratio exceeding 0.4, and/or an absolute number of $IgG4^+$ plasma cells of more than 50/high-power field (hpf) are the currently accepted cutoff for IgG4-related disease. However, presence of $IgG4^+$ plasma cells in isolated reactive lymphadenopathy is not exclusively specific for IgG4-related disease[6]. Martinez *et al*[6] reported seven of the 55 solitary reactive lymph nodes with increased IgG4/IgG plasma cell ratio of more than 0.4, and six of them showed more than 50 $IgG4^+$ plasma cells per high power field, but none of these patients had history of IgG4-related disease. On the other hand, Uehara *et al*[7] reported that presence of fibrosis in lymph nodes, together with increased IgG4 ratio and other features of IgG4-related disease, may suggest the diagnosis of IgG4-related lymphadenopathy.

Even though epithelioid cell granulomas is usually not considered a feature of IgG4-related disease at extranodal sites, it has been described in lymph nodes. Siddiqi *et al*[8] described seven cases with perifollicular granuloma in a concentric or crescent-like arrangement encircling lymphoid follicles and associated with a marked elevation of intra-germinal center $IgG4^+$ plasma cells. However, the specificity of these findings were debated by Cheuk *et al*[4]. Grimm *et al*[9] reported histiocytic proliferation in 11 of 29 cases of lymphadenopathy with increased IgG4 plasma cells, and a prominent ringing of follicles by epithelioid histiocytes in 3 patients (Table 1). In addition, Takahashi *et al*[10] reported a case of IgG4-related lymphadenopathy with prominent granulomatous inflammation, most likely due to reactivation of Epstein-Barr virus. Takeuchi *et al*[11] performed Epstein-Barr virus (EBV)-encoded RNA (EBER) in situ hybridization and identified EBER-positive cells in 18 of 31 cases (58%) of IgG4-related lymphadenopathy, significantly higher rate than non-IgG4-related reactive lymphoid hyperplasia. However, EBER was negative in our case, and either negative or rarely positive in the two cases with EBER performed in Grimm group's study (Table 1). Further study is needed to determine whether there is a causal relationship.

IgG4-related disease is a great mimicker. One of the differential diagnoses is multicentric Castleman's disease. However, $IgG4^+/IgG^+$ plasma cell ratio is usually less than 0.4 in multicentric Castleman disease. Furthermore, elevated serum levels of interleukin-6 and vascular endothelial growth factor favor the diagnosis of multicentric Castleman's disease[12]. Rosai-Dorfman disease can also show increased IgG4-positive plasma cells, as well as other autoimmune diseases including rheumatoid lymphadenopathy, are also in the differential diagnosis[13,14]. Moreover, bacterial, viral, fungal and parasitic infections have to be carefully ruled out. In our case, special stains and cultures were performed and the results were negative. The patient

Table 1 Perifollicular granulomatous inflammation and immunoglobulin G4-related disease

recovered quickly after immunosuppressive therapy, which was not consistent with infectious lymphadenitis. Other diseases with perifollicular granuloma have been reported, including reactive lymph nodes of unknown etiology, progressive transformation of germinal centers, and nodular lymphocyte predominance Hodgkin lymphoma[4]. However, in our case, morphologic features, immunohistochemistry and flow cytometry results were not consistent with lymphoma.

In our case, the pathologic evaluation is based on lymph node resection specimen. Even though biopsy of the orbital lesion was considered in initial evaluation, it wasn't performed based on the decision of multidisciplinary team, because this invasive procedures carried a significant risk. In addition, our patient had a normal serum level of IgG4. It is a not uncommon finding and is seen in up to 40% of patients with IgG4-related disease[3]. Our patient was treated with prednisone, methotrexate and Rituximab. His eye symptoms subsided dramatically and a post-treatment imaging study showed shrinking of the orbital mass. Thus, clinical presentations and histopathologic findings in this case supported of a diagnosis of IgG4-related disease.

According to the most recently published International consensus guidance statement, the first line treatment of active IgG4-related disease are glucocorticoids, but a combination of glucocorticoids and a steroid-sparing immunosuppressive agent (*e.g.*, azathioprine, methotrexate or mycophenolate) may be beneficial for some patients[15]. In addition, Rituximab has been reported to be an effective drug to treat patients with IgG4-related ophthalmopathy, especially those intolerant of steroid or with recurrent or refractory disease[16].

In summary, we described a case of IgG4-related disease with distinct features of perifollicular granulomas and literature reviews. This may expand our knowledge of pathologic findings of IgG4-related disease in a lymph node, although clinical history, lab results and radiological findings must be taken into consideration when making the diagnosis.

COMMENTS

Case characteristics

A 38-year-old man who presented with worsening left eye pain, proptosis, tearing, gritty sensation and blurred vision.

Clinical diagnosis

Multiple lymphadenopathy was identified.

Differential diagnosis

Lymphoma, Castleman's disease, fungal or mycobacterial infection, autoimmune disorders, *etc*.

Laboratory diagnosis

Serum immunoglobulin E (> 23000 IU/mL) and slight increase of total immunoglobulin G (IgG), but normal serum IgG4. An extensive panel of special stains, immunohistochemistry, and flow cytometry was negative for lymphoma, fungal, or mycobacterial infection.

Imaging diagnosis

Magnetic resonance imaging of orbits showed enlargement of the left medial rectus, superior oblique and inferior rectus muscle, and enhancing soft tissue signal encasing the left optic nerve sheath. Computed tomography scan of chest and abdomen showed multiple lymphadenopathy.

Pathological diagnosis

An axillary lymph node resection showed reactive follicular and interfollicular lymph node hyperplasia, and increased eosinophils and plasma cells (at least 80% of IgG^+ plasma cells were positive for IgG4). A distinct feature was the presence of multifocal, perifollicular histiocytic granulomas, which formed a wreath around the entire follicles.

Treatment

The patient was started on prednisone and methotrexate with reduction in proptosis and in the size of orbital mass by computerized tomography scan. While patient was maintained with methotrexate and tapering on steroid, he was noted to have left eye redness and itching. Rituximab was added and methotrexate was discontinued. The patient's symptom subsided.

Related reports

Perifollicular granuloma is a unique histologic feature and whether it is associated with IgG4-related disease is controversial. Very few cases have been reported in the English literature.

Term explanation

IgG4-related disease is a recently recognized fibro-inflammatory condition that can involve multiple organs and cause tumor-like enlargement, which is characterized

by a lymphoplasmacytic infiltrate enriched in IgG4-positive plasma cells.

Experiences and lessons

IgG4-related lymphadenopathy should be listed in the differential diagnoses of benign reactive lymph nodes, especially when perifollicular granuloma and plasmacytosis coexist.

Peer-review

The authors have performed a good study, the manuscript is interesting.

Abstract

Postural orthostatic tachycardia syndrome (POTS) is a relatively rare syndrome recognised since 1940. It is a heterogenous condition with orthostatic intolerance due to dysautonomia and is characterised by rise in heart rate above 30 bpm from base line or to more than 120 bpm within 5-10 min of standing with or without change in blood pressure which returns to base line on resuming supine position. This condition present with various disabling symptoms such as light headedness, near syncope, fatigue, nausea, vomiting, tremor, palpitations and mental clouding, *etc*. However there are no identifiable signs on clinical examination and patients are often diagnosed to have anxiety disorder. The condition predominantly affects young female between the ages of 15-50 but is rarely described in older people. We describe an older patient who developed POTS which recovered over 12 mo. Recognising this condition is important as there are treatment options available to alleviate the disabling symptoms.

Key words: Postural; Orthostatic; Tachycardia; Dysautonomia; Hypotension; Postural tachycardia syndrome; Older person

Core tip: This is a short report and literature review on postural orthostatic tachycardia syndrome (POTS). POTS commonly affects younger patients and is rarely reversible. Here we describe an older patient who presented with disabling POTS which was reversed. Although rare, it is now being recognised in older people and increasing awareness among geriatricians is important as early diagnosis and treatment may alleviate the disabling symptoms. Reviewing the literature we argue whether hypotension should be considered as a feature of POTS.

INTRODUCTION

Postural orthostatic tachycardia syndrome (POTS) is an orthostatic intolerance due to dysautonomia. This heterogeneous group of syndromes is characterised by rise in heart rate above 30 bpm from base line or to more than 120 bpm within 5-10 min of standing with or without change in blood pressure. This condition present with various disabling symptoms such as light headedness, near syncope, fatigue, nausea, vomiting, tremor, palpitations and mental clouding, *etc*. Various pathophysiological mechanisms have been recognised. It commonly affects younger patients and is rarely reversible. However it has been recognised in older people too. Recognising this condition is important as there are treatment options available to alleviate the disabling symptoms.

CASE REPORT

A 70-year-old woman presented with an 8 mo history of dizziness on standing and unsteadiness on her feet. More recently she experienced a fall and several near falls. She complained of nausea resistant to antiemetics and weight loss. She felt generally weak and had become dependent for all her activities of daily living. She had a brief hospital admission 10 mo prior to the current presentation and was investigated for the persistent nausea and vomiting. Upper gastrointestinal endoscopy, barium swallow and computed tomography scan of abdomen, pelvis and chest showed no identifiable pathology.

She had past medical history of polymyalgia rheumatica, hypertension and anxiety. She was on maintenance dose of prednisolone 1 mg, ramipril 2.5 mg and diazepam at night. She lived with her husband, previously independent for her activities of daily living, was a non smoker and consumed alcohol occasionally.

On assessment she appeared anxious and was lethargic. Her heart rate was 80 bpm regular. Blood pressure was 179/85 mmHg sitting and 119/73 mmHg on standing associated with rise in heart rate to120 bpm. She complained of dizziness on standing. Systemic examination including cardiovascular and neurological examinations was unremarkable.

Routine blood tests including thyroid function tests and random cortisol were normal. Twenty-four hours urine collections on 4 consecutive days for 5-hydroxyindoleacetic acid (5HIAA), cortisol, dopamine, epinephrine, norepinephrine and sodium were sent. 5HIAA excretion was elevated on 2 occasions to 49 and 99 micromol/d (normal 10-42) as was excretion of epinephrine to 190 nmol/d (normal 0-144). Elevation of catecholamines was possibly related to hyperadrenergic condition and significance of 5HIAA elevation was unexplained as it returned to normal in subsequent assays. Twelve lead electrocardiogram (ECG) and 24 h tape showed sinus rhythm. An echocardiogram showed signs of left ventricular hypertrophy. She underwent tilt table test which showed a rise in heart rate above 30 bpm from baseline associated with fall in blood pressure (Figure 1).

She was commenced on propranolol 10 mg tds and fludrocortisone at a starting dose of 50 mcg daily which was increased to 150 mcg. She responded remarkably well; her postural tachycardia resolved with improvement in symptoms of dizziness and nausea. She gradually regained her mobility and was able to resume her personal activities.

All the endocrine tests were repeated after 2 mo of her recovery of symptoms. All her baseline endocrine tests were normal at this point.

On follow up at 4 mo her blood pressure was 150/70 mmHg. She was slowly weaned off fludrocortisone with no recurrence of symptoms. Head up tilt test was repeated at 15 mo (Figure 2) which showed complete recovery and no change in heart rate or blood pressure with postural change.

DISCUSSION

POTS is a relatively rare syndrome recognised since 1940[1,2]. It is most often seen in women of child bearing age (between the ages of 15 and 50), nevertheless it may appear at any age. This is rarely described in older people and pathophysiology can be significantly different in older group of people. The mechanism depends on underlying pathology. It is not always easy to identify the mechanism therefore treatment can be difficult.

Standing results in approximately 0.5 to 1.0 L of blood pooling in the lower extremities and splanchnic circulation. A normal hemodynamic response to postural change requires normal function of the cardiovascular and autonomic nervous systems. An increase in sympathetic outflow, increases peripheral vascular resistance, venous return, and cardiac output, limiting the decrease in blood pressure. Normal compensatory mechanisms result in a decrease in systolic blood pressure (5 to 10 mmHg), an increase in diastolic blood pressure (5 to 10 mmHg), and an increase in pulse rate (10 to 25 beats per minute). Orthostatic hypotension is defined as a decrease in systolic blood pressure of 20 mmHg or a decrease in diastolic blood pressure of 10 mmHg within three minutes of standing compared with blood pressure from the sitting or supine position.

POTS is an orthostatic intolerance due to dysautonomia and is divided into primary and secondary types. It is important to identify the type to facilitate treatment. By definition the primary form occurs in the absence of an underlying condition. In contrast the secondary form of POTS is due to chronic conditions such as diabetes mellitus, sarcoidosis, connective tissue disorders, *etc*[3]. The condition runs a remitting and relapsing course.

This heterogeneous group of syndromes is characterised by rise in heart rate above 30 bpm from base line or to more than 120 bpm within 5-10 min of standing with or without change in blood pressure. In

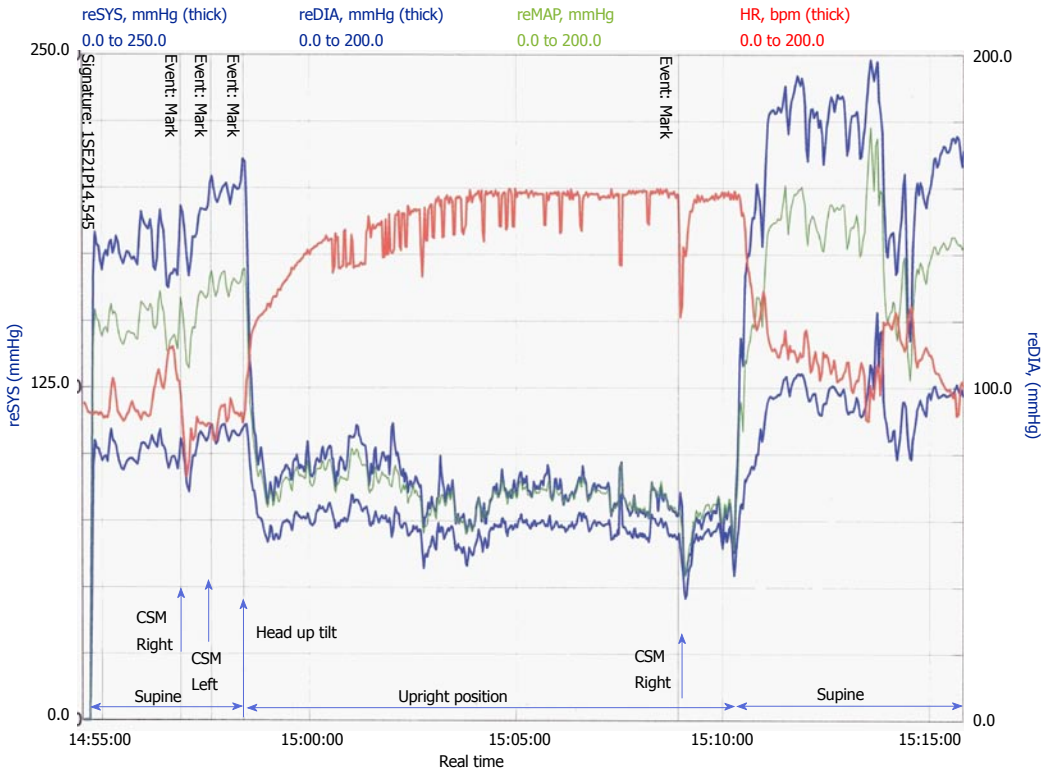

Figure 1 The significant increase in heart rate on head-up tilt (red line) associated with drop in systolic and diastolic blood pressure (in blue). Note the return of both heart rate and blood pressure on returning to supine position. MAP: Mean arterial pressure; reSYS (right Y-axis): Systolic blood pressure; reDIAS (left Y-axis): Diastolic blood pressure; HR: Heart rate; CSM: Carotid sinus massage.

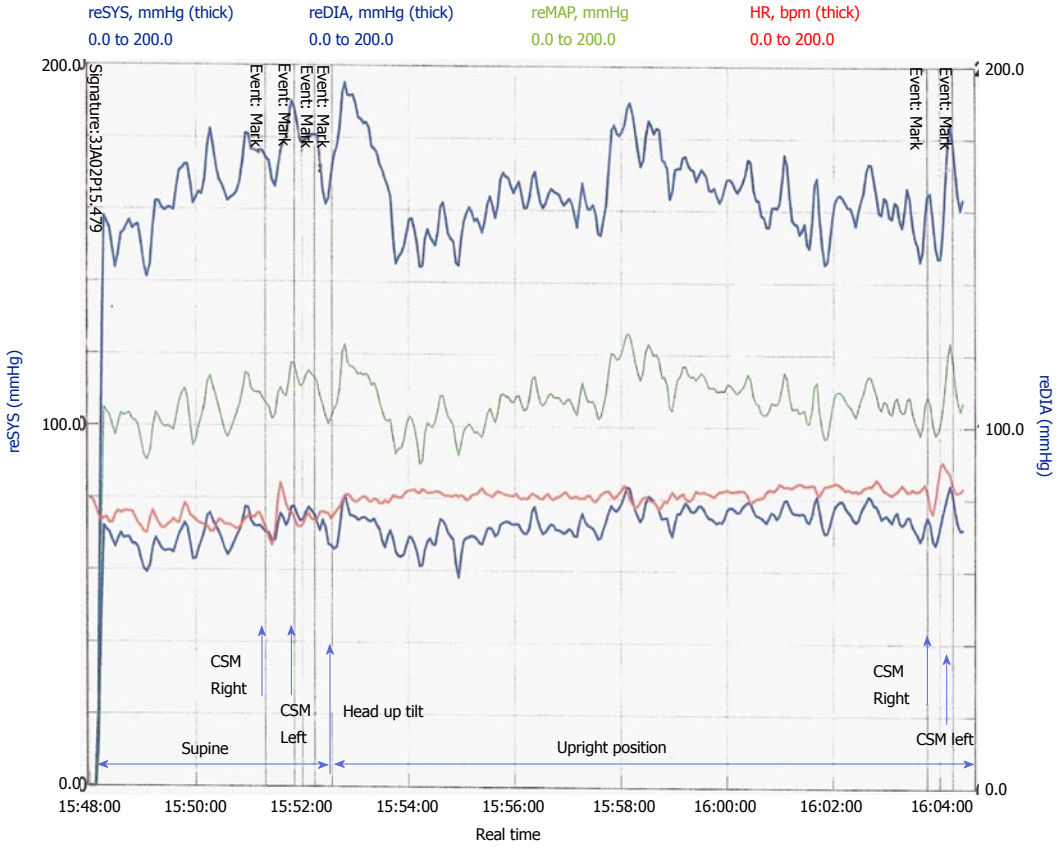

Figure 2 An essentially normal response with minimal change in heart rate on head-up tilt (red line) and non-significant alteration in blood pressure (in blue). CSM: Carotid sinus massage; reSYS (right Y-axis): Systolic blood pressure.

Table 1 Differentiating partial dysautonomic and hyperadrenergic forms

	Partial dysautonomia	Hyperadrenergic form
Frequency	Most common primary form	Less common primary form
Mechanism	Inability of peripheral vessels to constrict	Tachycardia due to elevated catecholamine
Onset	Abrupt	Gradual
Pathophysiology	Autoimmune mediated	Familial–single point mutation
Investigation	Serum acetylcholine receptor antibodies	Standing catecholamine level

fact some authors require no change in blood pressure on standing as a pre-requisite for the diagnosis of POTS but this is controversial[2,4-7]. Many of the mechanisms described in POTS such as vasodilatation, blunted response to angiotensin Ⅱ, low blood volume and red cell volume, abnormal vascular structure and venous capacitance can potentially drop the blood pressure. The drop in blood pressure due to above mechanisms may be compensated to a certain degree in POTS patients by disproportionately elevated heart rate though at times the compensation may be incomplete.

Pathophysiology

The various pathophysiological mechanisms involved in POTS are: (1) high level of standing norepinephrine level (due to reduced norepinephrine transporter expression resulting increased systemic norepinephrine spill over); (2) presence of ganglionic acetylcholine receptor antibodies; (3) alpha 1 adrenergic receptor denervation or hyposensitivity; (4) beta adrenergic super sensitivity; (5) peripheral autonomic denervation with preserved cardiac and cerebral innervations; (6) Partial renal sympathetic denervation leading to reduced renin/Aldosterone[8]; (7) increased angiotensin Ⅱ level with blunted responsiveness of receptors to angiotensin Ⅱ[9]; (8) Low blood volume and Red cell volume; (9) Abnormal vascular structure with impaired venous capacitance; and (10) Increased capillary permeability.

Not all of these mechanisms present in any one patient and treatment should be tailored accordingly. Symptoms are most likely due to cerebral hypoperfusion[10].

Types of POTS

As mentioned earlier POTS patients present with varying clinical features depending on the underlying pathology. Unifying feature is orthostatic intolerance which improves on lying or sitting down. The primary form is not associated with or caused by other chronic disorders. Here the onset is usually abrupt particularly when it occurs following viral illness, immunisation, pregnancy or surgery. An exception is the developmental form which occurs following a period of rapid growth[3]. In this case it runs a slow progress to reach a peak within 2 years.

Two major types of primary forms are identified. They are partial dysautonomic and hyperadrenergic forms (Table 1). Partial dysautonomic form is due to peripheral autonomic neuropathy which results in excessive pooling of blood in blood vessels of lower limbs and mesenteric circulation with the reflex tachycardia. Antibodies to ganglionic acetylcholine receptors are often found in patients with post viral autonomic neuropathy[3,11]. In contrast the hyperadrenergic form is usually a familial condition where there is rise in norepinephrine level on standing which causes the orthostatic tachycardia and orthostatic intolerance[12]. The rise in norepinephrine is due to reduced clearance secondary to poorly functioning reuptake transporter protein[6]. These patients suffer from profuse sweating, anxiety, tremulousness, tachycardia and hypertension[12,13].

Secondary forms are mainly due to chronic disorders such as diabetes mellitus, joint hyper mobility syndrome, sarcoidosis, systemic lupus syndrome, heavy metal poisoning and chemotherapies which affect the nervous system.

Symptoms

Various symptoms are described such as light headedness, near syncope, fatigue, nausea, vomiting, tremor, palpitations, mental clouding, *etc*. Symptoms can be brought on minimal exertion or activities such as eating, showering and walking short distance[2,5,14]. Both symptoms and tachycardia resolve with sitting or lying down. Patients are often diagnosed to have anxiety disorder[1,5].

Investigations

Head up tilt (HUT) is the investigation of choice although some studies suggest that standing haemodynamics is more specific[2,15]. It is important to rule out other conditions which cause tachycardia such as phaeochromocytoma, carcinoid, thyrotoxicosis, cardiac arrhythmia, *etc*. Tachycardia in these conditions is not related to change in posture.

Important investigations are blood tests which should include full blood count, renal function, thyroid function, calcium level, glucose, catecholamines on standing from supine position. Twenty-four hours urine collection for 5HIAA, catecholamines, sodium level are relevant investigations in POTS to rule out other causes of tachycardia and aim treatment options[12]. Routinely an ECG should be performed and further investigations such as 24 h tape and echocardiogram are carried out if indicated. The fact that this syndrome is not often recognised by clinicians, it leads to unnecessary investigations before the diagnosis is made especially in older people.

Management

Conservative: Review of medications which can aggravate POTS and appropriately stopping these medications; these include: (1) drugs that enhance vasodilatation-alpha adrenoreceptor blockers, angiotensin converting enzyme inhibitor (ACEI), calcium channel blockers and nitrates; (2) drugs that enhance tachycardia-beta adrenoreceptor stimulants, tricyclic antidepressants; and (3) drugs that worsens volume depletion-diuretics and ACEI.

Exercise - Aerobic exercise and lower limb resistance training will help pumping the blood. The intensity and duration of exercise should be built up gradually and also depend on patient's age.

Avoid salt and fluid depletion - Increasing salt and fluid take have great impact on reducing severity of symptoms. Fluid intake of 2 L/d and salt intake of 3-5 g/d is recommended. Performing 24 h urinary collection for urinary sodium level would help to identify the patients who would benefit from salt supplements. Studies show that patients with urinary excretion < 124 mmol/d is an indicator of good response to salt treatment[16].

Pharmacological treatment: Vasoconstrictors: Fludrocortisone is the most commonly used drug in orthostatic intolerance. Its action is mediated by improving peripheral sensitivity of alpha adrenoceptors, fluid and salt retention. Midodrine is an alpha-1 adrenoreceptor agonist not only increases the peripheral vascular resistance but also helps orthostatic intolerance by having an effect on heart rate. Other vasoconstrictors used with variable results are: (1) methylphenidate - increases vasoconstriction by increasing catecholamine release and inhibiting monoamine oxidase; (2) erythropoietin: increases the sensitivity of angiotensin II; (3) clonidine is a central sympatholytic and increases peripheral vascular resistance; and (4) octreotide: somatostatin analogue is potent vasoconstrictor.

Heart rate limiting drugs: Beta blockers are the main group of drugs and among them propranolol is favoured by clinicians. There are limited studies with regards to the dosage at which it is effective in treating POTS. Moderate dose of propranolol (20 mg) not only reduces heart rate but also improves symptoms, whereas higher dose (80 mg) is effective in reducing heart rate but does not improve symptoms. In fact it has been reported to worsen symptoms[17]. Other drugs which can reduce heart rate and alleviate symptoms are selective serotonin reuptake inhibitors (SSRI) and selective noradrenalin reuptake inhibitors. SSRI have been used for cardiogenic syncope and orthostatic hypotension. Serotonin plays and important role in central control of heart rate.

Ivabradine has effect on reducing the heart rate and symptom control.

Volume expanders: As mentioned earlier fludrocortisone is a mineralocorticoid and enhances the fluid and salt retention. Erythropoietin stimulates red cell production and increase the red cell mass and blood volume. Treatment with Erythropoietin is reserved for people with refractory symptoms in spite of other medications. Cost and administration by subcutaneous injection are the limiting factors for its use. Desmopressin increases the reabsorption of fluid from kidney, but its use in POTS has not been adequately studied.

Other medications: Pyridostigmine is an acetylcholine esterase inhibitor and is a very promising drug particularly for POTS following viral illness and POTS secondary to autoimmune process and paraneoplastic syndrome.

In conclusion, POTS is a condition characterised by orthostatic intolerance with excessive increase in heart rate due to disturbances in autonomic control. Patients with this condition suffer from numerous disabling symptoms with no specific abnormalities on clinical examination. Head up tilt test is the choice of investigation. Identifying the subtypes is the key to achieve successful management.

Our patient is a rare case of POTS in older people with full recovery.

Her symptoms were severe enough to warrant hospital admission. Medications were commenced once diagnosis was established with HUT and she made good recovery with her mobility and other symptoms.

COMMENTS

Case characteristics

A 70-year-old woman presented with dizziness and unsteadiness on feet.

Clinical diagnosis

Heart rate increased to more than 30 bpm from baseline on standing associated with fall in blood pressure.

Differential diagnosis

Postural hypotension and other conditions which causes tachycardia such as pheochromocytoma, thyrotoxicosis carcinoid syndrome and cardiac arrhythmia.

Laboratory diagnosis

Head up tilt test showed rise in heart rate from 80 to 120 bpm on standing with drop in blood pressure.

Imaging diagnosis

Chest X-ray and computerised tomography of abdomen, pelvis and chest were normal.

Treatment

The patient was treated with fludrocortisone and propranolol.

Related reports

Postural orthostatic tachycardia syndrome (POTS) is described predominantly in young females and to our knowledge this is the first case reported in older person.

Term explanation

Head up tilt test is the tilt-table test involves placing a patient on a flat table with a foot support, then tilting the table upward for a period of time to observe

changes in blood pressure and heart rate.

Experiences and lessons

POTS is a rare disabling condition; but is treatable when diagnosis is established which needs high index of suspicion.

Peer-review

This is an interesting case report.

Abstract

We describe a rare case of an arteriovenous malformation (AVM) embedded in the vestibulocochlear nerve presenting with subarachnoid hemorrhage (SAH) treated by microsurgical elimination of the main feeding artery and partial nidus volume reduction with no permanent deficits. This 70-year-old woman was incidentally diagnosed 4 years previously with two small unruptured tandem aneurysms (ANs) on the right anterior inferior cerebral artery feeding a small right cerebellopontine angle AVM. The patient was followed conservatively until she developed sudden headache, nausea and vomiting and presented to our outpatient clinic after several days. Magnetic resonance imaging demonstrated findings suggestive of early subacute SAH in the quadrigeminal cistern. A microsurgical flow reduction technique *via* clipping between the two ANs and partial electrocoagulation of the nidus buried within the eighth cranial nerve provided radiographical devascularization of the ANs with residual AVM shunt flow and no major deficits during the 2.5 year follow-up. This is only the second report of an auditory nerve AVM. In the event of recurrence, reoperation or application of alternative therapies may be considered.

Key words: Arteriovenous malformation; Flow reduction; Microsurgery; Subarachnoid hemorrhage; Vestibulocochlear nerve

Core tip: Arteriovenous malformations (AVMs) originating within or impinging on cranial nerves are extremely rare, and there is an increased risk of hemorrhage in

AVMs associated with aneurysms. The authors describe the second report of a patient with a vestibulocochlear nerve AVM who presented with subarachnoid hemorrhage. A discussion of the delicate diagnostic and therapeutic implications is presented.

INTRODUCTION

Arteriovenous malformations (AVMs) originating within or impinging on cranial nerves are extremely rare, most of which have been identified in the the optic chiasma[1-6] or trigeminal nerve[7-24]. Posterior fossa AVMs account for only 7%-15% of all intracranial AVMs, however these lesions tend to involve greater morbidity and mortality and recent studies have shown an independent association between infratentorial AVM location and hemorrhagic presentation[25]. Moreover, there is an increased risk of hemorrhage in AVMs accompanied by aneurysms (ANs)[26].

Based on a search of the available literature, the authors found only one report of an intrinsic auditory nerve AVM[27], however the patient suffered a total hearing deficit. Herein we describe a rare case of an AVM embedded in the vestibulocochlear nerve presenting with subarachnoid hemorrhage (SAH) treated initially by microsurgical elimination of the main feeding artery and partial nidus volume reduction with no permanent deficits.

CASE REPORT

This 70-year-old right-handed woman with an unremarkable past medical history was incidentally diagnosed 4 years prior with two small tandem ANs on the right anterior inferior cerebral artery (AICA) feeding a small right cerebellopontine angle AVM. The patient was referred to our hospital for further evaluation and treatment and despite informed consent regarding the potential risks of subsequent hemorrhage and recommendations for microsurgery, Gamma Knife stereotactic radiosurgery, or endovascular embolization, or other interventions, she and her family chose conservative outpatient observation.

Digital subtraction angiography (DSA) was recommended for primary evaluation, however based on the invasiveness, potential complications, and inconvenience, she declined this modality in favor of three-dimensional computed tomography angiography (3D-CTA) and magnetic resonance angiography (MRA) for initial diagnostic evaluation followed by biannual and thereafter annual serial magnetic resonance imaging (MRI) (Figure 1). Dedicated informed consent was routinely offered to the patient and family including an explanation of the cumulative bleeding risks and recommendations for aggressive surgical or alternative treatment options. However the patient declined treatment and was followed on an outpatient basis until she presented to our outpatient clinic with a complaint of severe headache, nausea and vomiting of several days duration. The neurological exam was unremarkable with no apparent cranial nerve deficits. Head computed tomography (CT) did not demonstrate any evidence of bleeding, however, high intensity signals only in the quadrigeminal cistern on T1-weighted MRI were observed, suggesting early subacute SAH (Figure 2). Fluid attenuated inversion recovery imaging was not performed. MRA source imaging and magnetic resonance cisternography demonstrated a small (11.4 mm × 4.2 mm) relatively compact nidus located in the cerebellopontine angle around the cisternal portion of the facial and vestibulocochlear nerves (cranial nerves Ⅶ and Ⅷ, respectively) with extension into the internal auditory canal (Figure 3). On the arterial phase of DSA the right AICA was identified as the predominant feeder with drainage into the right petrosal vein, superior petrosal sinus, and cavernous sinus (Figure 4). Based on the lack of any significant cranial nerve deficits, the occurrence of either minor AVM leakage, hypertensive venous bleeding, or subarachnoid hemorrhage from AN rupture was postulated. Because of the symptomatic nature of this Spetzler-Martin grade Ⅲ AVM (S1V1E1) with two feeding artery aneurysms, and after a comprehensive explanation of the risks and benefits of the various treatment options, including the risks of microsurgical neurological sequelae, the persistent delayed risk of bleeding following radiation therapy, and the possible risk of recurrence or other complications following endovascular embolization, the patient and family agreed to a recommendation of microsurgical treatment.

Surgical procedure

The patient was placed in the right lateral oblique position and a right retrosigmoid craniotomy was performed. After exposing the right lateral cistern and cerebellopontine angle, the right facial and vestibulocochlear nerves (cranial nerves Ⅶ and Ⅷ, respectively) were identified followed by confirmation of the right lower cranial nerves (cranial nerves Ⅸ, Ⅹ, and Ⅺ), the right AICA, proximal basilar-AICA bifurcation, and surrounding trigeminal and abducens nerves (cranial nerves Ⅴ and Ⅵ, respectively). The right AICA was determined to be the predominant feeder supplying a small peripheral nidus buried within the right cranial nerve Ⅷ at the meatus of the internal auditory canal with venous drainage into an engorged red petrosal vein (Figure 5A and B). Close inspection revealed a mid-sized fusiform AN at the proximal AICA

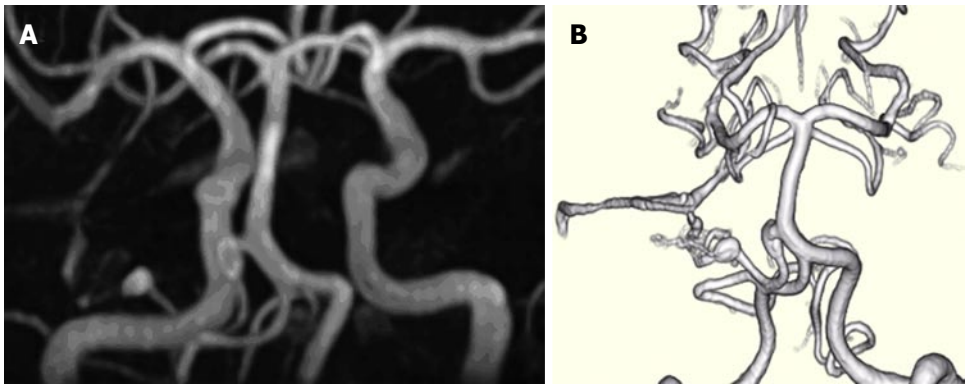

Figure 1 Three-dimensional time-of-flight magnetic resonance angiography. A: Three-dimensional time-of-flight magnetic resonance angiography (3D-TOF-MRA) four years prior to admission; B: Volume rendering 3D-TOF-MRA study 1 year prior to admission, demonstrating two unruptured prenidal feeder artery aneurysms, one 8 mm × 3 mm fusiform proximal anterior inferior cerebral artery (AICA) aneurysm near the takeoff of the basilar artery and one 4.5 mm × 3 mm elliptical distal pedicle AICA aneurysm located at the entrance to the main inflow area of a small inconspicuous vascular nidus.

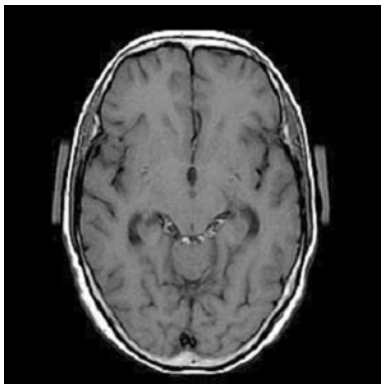

Figure 2 On admission, this 70-year-old woman presented with a severe headache, nausea and vomiting of several days duration. T1-weighted magnetic resonance imaging demonstrated high intensity signals only in the quadrigeminal cistern, suggestive of early subacute subarachnoid hemorrhage.

near the takeoff from the basilar artery and a small distal pedicle feeding artery AN at the inflow area of the nidus. Xanthochromic cerebrospinal fluid was observed with a slight predominance near the proximal AICA AN, however there was no clear evidence of a rupture point from either of the ANs, nidus, or venous drainers. Based on the preoperative imaging studies, the nidus was suspected to extend into the auditory canal, and complete resection was not attempted because of the anticipated high risk of auditory nerve injury. Instead a feeder clip was applied to the AICA which demonstrated normalization of color from red to blue in the right petrosal vein. However, intraoperative microvascular doppler ultrasonography and indocyanine green video angiography confirmed the presence of persistent flow within the AVM despite temporary clipping, suggesting the existence of collateral supply from the external carotid artery system or other sources. Definitive clipping between the proximal and distal AICA ANs followed by partial electrocoagulation of both the nidus and the predominant entry area to the nidus were performed (Figure 5C) with the intention of alleviating hemodynamic stress on the remaining nidus and proximal AN. Figure 6 shows an overall intraoperative schematic illustration. Although auditory brainstem response monitoring remained normal throughout all procedures, preventative intravenous corticosteroids were administered postoperatively.

Postoperative course

The patient had an uneventful postoperative course with follow-up clinical and head CT examinations every 2 to 3 mo for a period of 2.5 years. Biannual follow-up outpatient MRI and MRA source imaging during that period showed clip artifact at the entrance to the internal auditory canal with apparent disappearance of proximal and distal right AICA aneurysms, and a prominent right superior petrosal sinus, indicative of residual shunt flow (Figures 7 and 8 compare preoperative and postoperative changes). The patient experienced a transient right hearing deficit, diplopia, and vertigo which almost completely resolved on discharge. More extensive diagnostic imaging and treatment options including Gamma Knife radiosurgery were under consideration pending the onset of radiological regrowth or symptomatic recurrence.

DISCUSSION

Intrinsic AVMs limited exclusively to the cranial nerves are extremely uncommon although there have been many reports of AVM rupture resulting in damage to nearby cranial nerves or indirect feeder compression of cranial nerves with associated symptoms manifesting in various conditions such as optic nerve apoplexy[1-6], oculomotor nerve ophthalmoplegia[28], trigeminal neuralgia[7,8,10-18,20,21,23,24], hemifacial spasm[29,30], glossopharyngeal neuralgia[31], and hypoglossal nerve paresis[32]. Several rare reports of AVMs originating from within the trochlear nerve[33] and trigeminal nerve[9,19,22] have also been documented. Maher *et al*[19] proposed an embryological basis for explaining the occurrence of AVMs arising in cranial nerves such as the trigeminal nerve, whereby normally migrating fetal axons carry

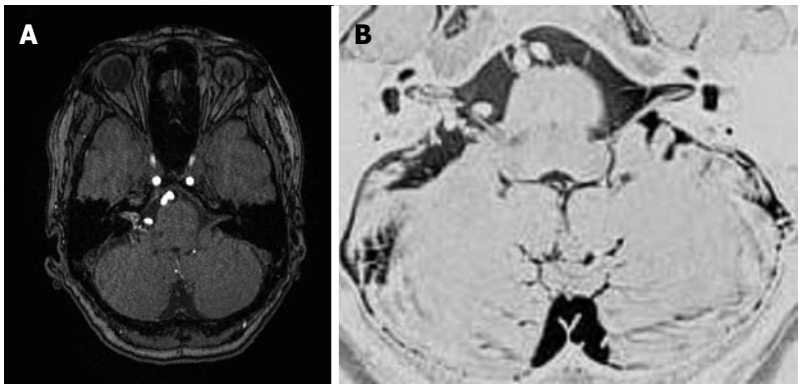

Figure 3 Magnetic resonance angiographic source imaging (A) and magnetic resonance cisternography (B) reveal a small (11.4 mm × 4.2 mm) relatively compact nidus located in the cerebellopontine angle at the cisternal portion of the cranial nerves VII and VIII with extension into the internal auditory canal.

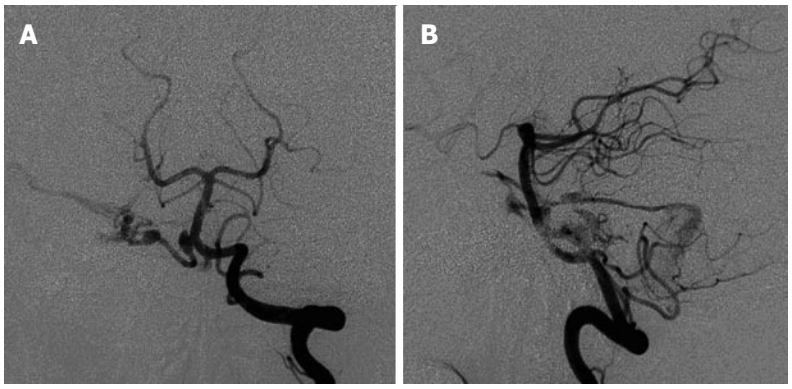

Figure 4 Anterioposterior (A) and lateral (B) views of cerebral angiogram for this patient showing the right anterior inferior cerebral artery as the predominant feeder supplying a small nidus with drainage into the right petrosal vein, superior petrosal sinus, and cavernous sinus [Spetzler-Martin grade III (S1V1E1)].

A: Intraoperative microscopic view showing a right retrosigmoid craniotomy in the a right lateral oblique position which exposed a small nidus buried within the right cranial nerve VIII at the meatus of the internal auditory canal; B: View showing distal right anterior inferior cerebral artery feeding aneurysm, nidus-VIII cranial nerve complex, and draining petrous vein; C: Definitive clip application proximal to the aneurysm and partial electrocoagulation of the nidus and the inflow area just proximal to the nidus was performed.

precursor AVM cells toward an ectopic cranial nuclei location during the 5th to 6th weeks of embryogenesis.

To date, there has been only one case report of an AVM located within the auditory nerve bundle which presented with SAH yet this case involved complete sensorineuronal hearing loss[27]. Because of the severe functional deficit from onset in that patient, total removal of both the nidus and nerve remnant were performed. Interestingly, in many of the cases of intrinsic trigeminal or trochlear AVMs as well as in our case, the patients presented with symptoms unrelated to cranial nerve dysfunction from direct AVM rupture[19,33], or symptoms were not caused by the nidus itself but by neural compression from surrounding vessels such as the feeding superior cerebellar artery[17,18,20,22] or impingement from other vessels at the trigeminal nerve

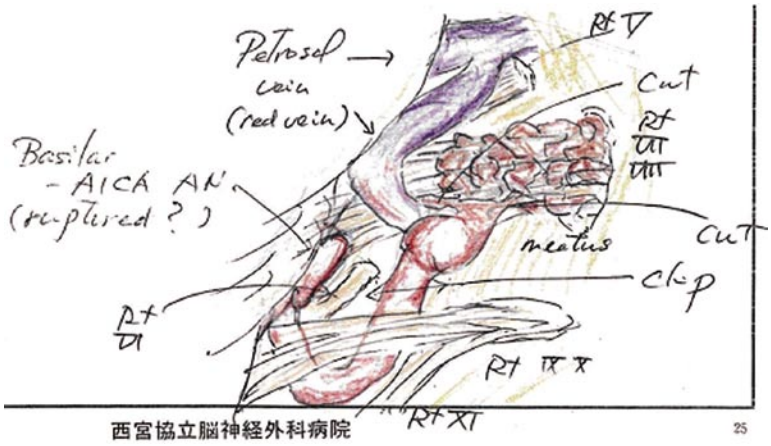

Figure 6 Intraoperative schematic illustration depicting anatomical structures and definitive clipping between the proximal and distal feeding anterior inferior cerebral artery aneurysms and partial electrocoagulation of both the nidus and the main inflow area to the nidus.

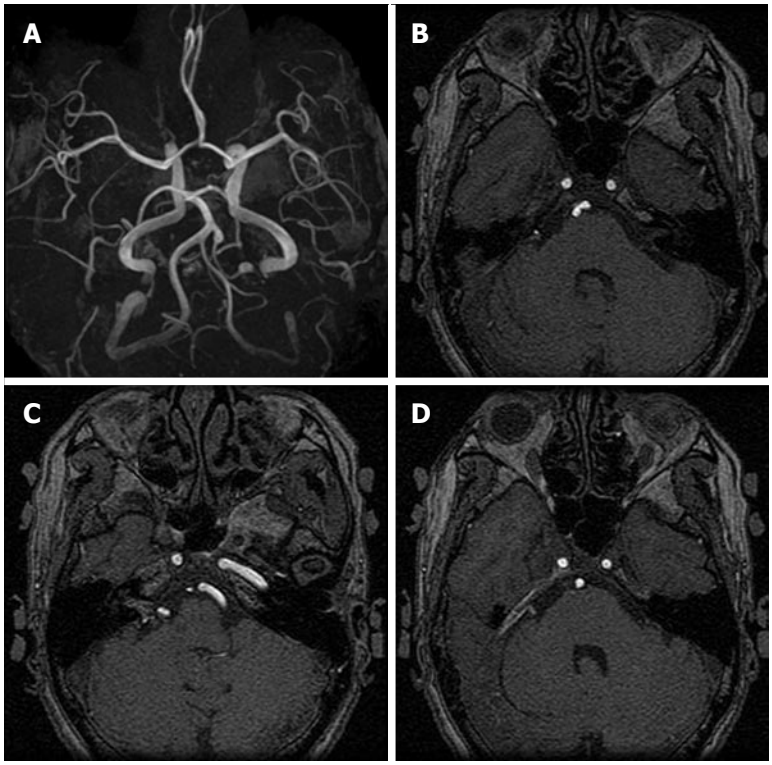

Figure 7 Preoperative three-dimensional time-of-flight magnetic resonance angiography showing proximal and distal right anterior inferior cerebral artery aneurysms (A), and magnetic resonance angiographic source imaging showing proximal right anterior inferior cerebral artery aneurysm (B), distal right anterior inferior cerebral artery aneurysm with relatively strong internal auditory canal nidus signal intensity (C), and right superior petrosal sinus venous shunt (D).

root entry zone[15,16]. In a study by Sumioka *et al*[22] a review of over 600 cases of trigeminal neuralgia were identified to be caused by vascular compression while only a small minority showed no evidence of vascular involvement. In these non-vascular cases, symptoms of trigeminal neuralgia were postulated to be derived from either the twisting or "tilting" by mechanical compressive forces, thickened arachnoid, or the direct effects of embedded AVMs.

In addition, many of the cases of chiasmal or optic nerve apoplexy due to intrinsic AVMs (including cavernous malformations) were typically diagnostically labeled as angiographically occult and only after performing high-resolution MRI were these cryptic micro-AVMs identified[3]. MRI has also been considered to offer a considerable advantage over standard angiography both for reducing complications and procedural related morbidity as well as providing detailed delineation of neurovascular structural relationships crucial for making treatment decisions during the preoperative and postoperative periods[34]. Moreover, in a recent report of the largest surgical series of radiological and clinical follow-up of AVM recurrence after surgery, MRI with and without contrast administration was

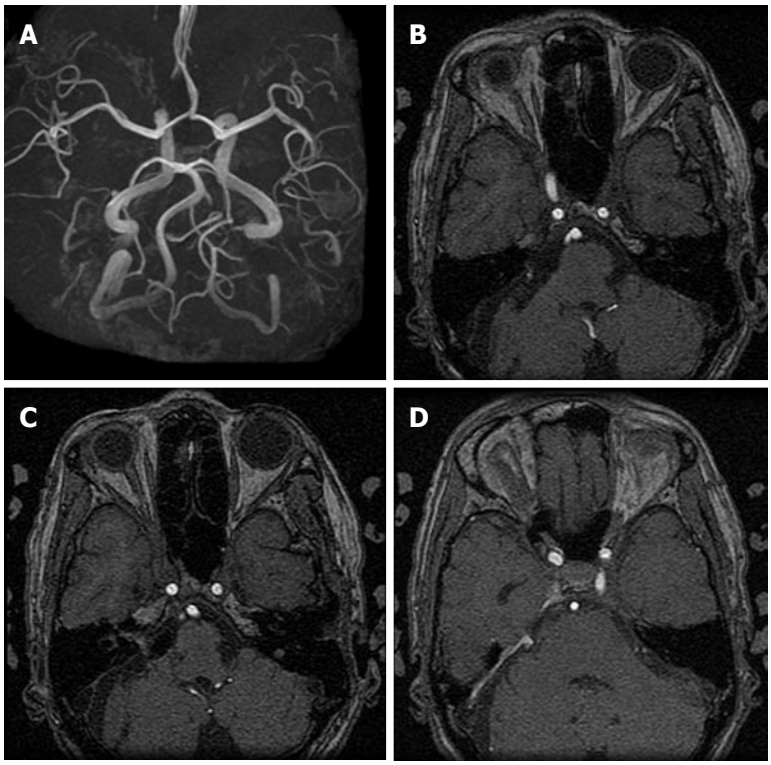

Figure 8 Postoperative three-dimensional time-of-flight magnetic resonance angiography (3D-TOF-MRA) and magnetic resonance angiographic source imaging showing anterior inferior cerebral artery (AICA) stump with disappearance of proximal and distal right AICA aneurysms (A, B), decreased intensity of right AICA and seemingly disappearance of proximal aneurysm, clip artifact at the entrance to the internal auditory canal and decreased intensity of intracanicular nidus (C), and persistence of prominent right superior petrosal sinus venous shunt (D).

recommended as the initial method for monitoring recurrence, with subsequent performance of digital subtraction angiography only in the event of suspected recurrence[35].

Likewise, a review of the recent literature seems to indicate a more palliative, minimally invasive trend for the treatment of cranial nerve AVMs. Sumioka *et al*[22] have suggested that the goal of treating intrinsic AVMs of the trigeminal nerve is generally symptomatic treatment, with prevention of rebleeding and preservation of cranial nerve function. Although treatment of cranial nerve cavernous malformations has been shown to be relatively successful with a lack of major associated complications to the surrounding neurovascular structures, direct microsurgical AVM resection in and around the optic nerve as well as other cranial nerves has typically been associated with significant damage to the nerve itself as well as surrounding microvasculature structures[9,18,22,23]. Indeed Sasagawa *et al*[5] have suggested that curative surgical treatment of optic nerve AVMs is considered nearly impossible, while other reports have shown that microsurgery can be used diagnostically as well as theraputically *via* limited surgical treatment such as optic nerve decompression or by subtotal operation for prevention of AVM growth or rebleeding[1]. As an example, an 8-year-old boy who presented with optic nerve apoplexy was found to have an AVM of the optic nerve and chiasm, but was treated by a diagnostic craniotomy alone without resection[5]. In another case of trigeminal neuralgia caused by an intrinsic trigeminal nerve AVM, complete resection of the AVM was judged to be too risky and only partial microsurgical nidus coagulation, transposition of the offending superior cerebellar artery, and subsequent Gamma Knife radiosurgery was performed for eventual complete radiological obliteration[22].

In our case the choice of treatment took into consideration both the angioarchitectural and clinical features as well as patient preference for a less aggressive option involving minimal risk. Due to the presence of symptomatic SAH presumed to be related to AN rupture and based on the high risk of nerve injury from complete AVM extirpation, a more palliative flow reduction strategy of feeder artery electrocoagulation at the inflow area of the nidus, effective feeder AN trapping, and partial electrocoagulation of the nidus was performed. Although intraoperative findings showed a slight predominance of xanthochromic cerebrospinal fluid near the proximal AICA AN, which was suggestive of having a higher likelihood of being the causative source of bleeding, because of the risk of damaging the abundant small perforators in the basilar-AICA takeoff area, a more distal obliteration point closer to the main inflow region of the AVM was chosen. Despite the seemingly unconventional nature of this method, in principle, we preliminarily followed standard microsurgical AVM

treatment protocol including coagulation of the major superficial feeding artery at a location as close as possible to the point of feeder entry into the nidus[34]. And according to current recommendations for treatment of coexisting intracranial ANs, we attempted to diminish the hemodynamic stress by obliteration of high flow shunting, a variation on a technique which has been shown to result in either regression or disappearance of the prenidal AN[34,36]. However, by placing a clip distal to the proximal AN, there could be a risk of subsequent increased hemodynamic stress and hemorrhage for this aneurysm, especially due to limited distal outflow. Careful follow-up diagnostic studies and consideration of endovascular or other treatment modalities would be recommended. Finally, the observation of a temporary postoperative hearing disturbance may possibly be explained by intraoperative manipulation of the cochlear nerve. However, the possibility of vascular compromise with compensatory extracarotid flow could explain the recovery in hearing, yet this mechanism would be expected to occur over a longer period of time.

Classically there has been caution regarding the potential increased risks of bleeding from incomplete, partial, or subtotal AVM resection[8], as well as recent concerns of bleeding after palliative embolization[34]. In contrast, embolization designed to reduce flow and decrease risk of rupture has been indicated in various conditions, including treatment of associated ANs and large inoperable AVMs, or "inoperable" vascular lesions with recurrent hemorrhage, or locations in eloquent regions, where multimodality approaches of preoperative embolization combined with microsurgical extirpation have been considered. However, there is no evidence in support of such empirical methods and ultimately treatment must be individualized[34,37]. Recently, the Barrow vascular group has found moderate success for treatment of vertebrobasilar aneurysms *via* low-flow bypass and flow reduction *via* complete or partial basilar artery vessel occlusion or distal vertebral artery occlusion[38]. Although our procedure as well as the angioarchitecture of the lesions differed in many ways from the technique used in that study, both lesions resided near critical neurovascular structures and in principle, both involved application to some degree of a procedure designed to reduce flow to the inflow vessel of the aneurysm. Another study from the same institution achieved satisfactory long-term outcome using a technique of subtotal nidus resection for effective devascularization of glomus spinal AVMs (lesions known to have similar angioarchitectural features as found in intracranial AVMs)[39], a technique similar in some ways to our technique of partial nidus electrocoagulation. And a recent pooled analysis of treatment outcomes for spinal glomus AVMs has shown that hemorrhagic risk can be significantly reduced by partial endovascular treatment[40]. In this sense, although the ultimate goal of surgical treatment is AN elimination and AVM extripation, care can be tailored according to the individual lesion, whereby a less invasive, more palliative treatment option can be employed as the initial preemptive strategy.

Radiation therapy as a primary treatment for asymptomatic brain AVMs or as an adjunctive therapy for recurrent AVMs has been advocated for treatment of lesions smaller than 3 cm in diameter and in deep or eloquent brain areas depending on size, angioarchitecture, and other factors, greater than 1- to 3-year obliteration rates range from 60% to 90%[34,41,42]. Moreover, radiosurgery for brainstem AVMs can attain up to 88% complete obliteration[43] and other reports claim complete obliteration rates in approximately two thirds of patients with a 1.7% annual hemorrhage rate for the first 3 years[44]. However, well known drawbacks include a 2.5% to 10% annual hemorrhage risk until complete obliteration, the potential for delayed hemorrhage after angiographically proven obliteration, and depending on location, there is a reported risk of clinically significant complications directly from radiosurgery for AVMs in excess of 3% to 6%, especially in cases of brainstem and other deep seated AVMs[34,43-45]. Radiosurgery for AVMs of the optic nerve and surrounding areas have been reported to cause optic neuropathy and injury to nearby neurovascular structures and consequently recommendations for maximal doses have been limited to less than 8 Gy[46]. And a study of Gamma Knife surgery for pituitary adenomas reported a 4.1% incidence of new visual dysfunction[47]. However, stereotactic radiosurgery for trigeminal neuroma presenting with trigeminal neuralgia has been shown to achieve symptomatic control without additional deficits[48]. Finally, there have been recommendations for other alternative management strategies including endovascular embolization for preoperative reduction of arterial inflow, occlusion of deep feeders, and prenidal aneurysm treatment, however, embolization in general has been associated with relatively high rates of morbidity and mortality (0% to 27%), mostly because of inadvertent embolization of feeding arteries or draining veins in normal surrounding neurovascular structures or post-embolization bleeding due to changes in flow dynamics[34]. Recently, primary embolization treatment with Onyx has shown total AVM obliteration rates of approximately 50%[49].

Major limitations of our study include a relatively brief 2.5 year follow-up in a single case report. Furthermore, we did not perform confirmatory follow-up DSA for verifying persistent patency, degree of alternative feeders, or other evidence of recurrence, however, this was a well informed decision in respect of the patient's ongoing preference for less invasive imaging modalities such as MRI which as mentioned, has been shown to be useful for therapeutic decision making during both the preoperative and postoperative periods as well as for identification of cryptic angiographically occult AVMs. However, as in our case, follow-up MRI showed diminished AICA and nidal flow, with persistence of venous shunt flow. Indeed, mere MRI or MRA confirm-

ation may only show relative flow reduction or stasis in flow and may not accurately represent actual residual or persistent vascular supply. In addition, clip artifact on MRI may prevent accurate assessment, while other testing such as 3D-CTA or DSA, may provide a more definitive understanding of the angioarchitecture. Standard follow-up DSA and application of additional therapy were offered to the patient, but the patient declined and ultimately application of such modalities were considered to be implemented on an as-needed basis in the event of suspected development of recurrence. We surmised that either thrombosis or diminished flow resulted in apparent radiological devascularization of the ANs and no associated clinical recurrence, however, the persistence of AVM shunt flow on follow-up MRI indicates that there is a continued risk of bleeding, although perhaps much less risk than without feeder artery and AN clipping. Furthermore, persistent external carotid artery or other feeding sources, or the potential for added changes in flow dynamics from our treatment could lead to subsequent AVM regrowth or bleeding, bleeding from the proximal basilar-AICA takeoff AN, or other *de novo* AN development. Currently the patient is symptom free and continues to express no interest in invasive testing or further treatment with Gamma Knife radiosurgery or other modalities.

The authors deeply thank Mrs Kumiko Enomoto for providing administrative, technical, and material support.

COMMENTS

Case characteristics

A 70-year-old woman with a history of two incidental aneurysms (ANs) on the right anterior inferior cerebral artery (AICA) feeding a small right cerebellopontine angle arteriovenous malformation (AVM) presented with sudden headache, nausea and vomiting.

Clinical diagnosis

The neurological exam was unremarkable with no apparent cranial nerve deficits.

Differential diagnosis

Although admission head computed tomography did not demonstrate any evidence of bleeding, T1-weighted magnetic resonance imaging showed high intensity signals only in the quadrigeminal cistern, suggesting early subacute subarachnoid hemorrhage, and based on the lack of any significant cranial nerve deficits, the occurrence of either minor AVM leakage, hypertensive venous bleeding, or subarachnoid hemorrhage (SAH) from AN rupture was postulated.

Intraoperative diagnosis

The AICA was determined to be the predominant feeder supplying a small peripheral nidus buried within the right cranial nerve VIII (vestibulocochlear nerve) at the meatus of the internal auditory canal with a mid-sized fusiform AN at the proximal AICA near the takeoff from the basilar artery and a small distal pedicle feeding artery AN at the inflow area of the nidus, and although xanthochromic cerebrospinal fluid was observed, there was no clear evidence of a rupture point from either of the ANs, nidus, or venous drainers.

Treatment

The patient was treated initially by microsurgical elimination of the main feeding artery via clipping between the proximal and distal AICA ANs, followed by partial electrocoagulation of both the nidus and the predominant entry area to the nidus with the intention of alleviating hemodynamic stress on the remaining nidus and proximal AN.

Related reports

The authors describe the second report of a patient with a vestibulocochlear nerve AVM who presented with subarachnoid hemorrhage. Curative treatment of AVMs arising within delicate cranial nerve structures is difficult and fraught with a paucity of surgical evidence.

Term explanation

Flow reduction is an indirect less definitive treatment typically performed by proximal occlusion of the parent artery designed to alleviate hemodynamic stress on distally located ANs or AVMs and other potential hemorrhagic lesions.

Experiences and lessons

After dedicated informed consent, the patient in this case report chose less invasive testing and flow reduction treatment which resulted in no symptoms or permanent deficits throughout the 2.5 year follow-up, however despite radiographical devascularization of the ANs, residual AVM shunt flow and the potential for added changes in flow dynamics could lead to subsequent AVM or AN regrowth or bleeding.

Peer-review

The authors report on a rare case of an arteriovenous malformation of the vestibulocochlear nerve. The case was managed with microsurgery with only transient deficits noted.

Abstract

Gallbladder perforation (GBP) is a rare but serious complication of cholecystitis and needs to be managed promptly. Acalculus cholecystitis leading to GBP is frequently associated with enteric fever and found in critically ill patients, and a surgical approach is not always feasible in such patients. Use of percutaneous tube cholecystostomy (PTC) in such patients is a known entity but it is usually followed by interval cholecystectomy. Here we report a case of perforated gallbladder in a child managed conservatively and successfully with PTC as the definitive treatment wherein cholecystectomy was avoided. The functionality of the gallbladder was confirmed by a Tc99m-HIDA scan.

Key words: Spontaneous; Gallbladder; Perforation; Percutaneous tube cholecystostomy

Core tip: Percutaneous cholecystostomy for selected patients with gallbladder perforation or distended gallbladder with symptoms is a good technique to tide over the acute crisis and may even avert the need for cholecystectomy.

INTRODUCTION

Gallbladder perforation (GBP) is rare in children and is seen as a complication of cholecystitis. Gallbladder stone disease is the most frequent cause of acute cholecystitis and acalculus cholecystitis is seen in only 5%-10% of cases[1]. The majority of the reported cases of GBP are associated with enteric fever. High level of

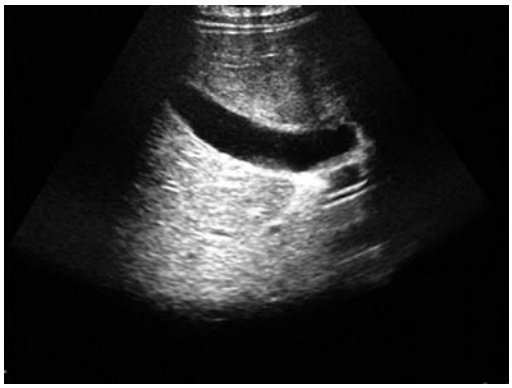

Figure 1 Over-distended gallbladder.

suspicion, early diagnosis and prompt management are of paramount importance in dealing with this entity.

CASE REPORT

A 12-year-old male patient admitted on the medical side was referred to us with complaints of pain in the abdomen for 12 d. The pain was dull aching in nature, more in the right hypochondrium. He had a history of 7-8 episodes of vomiting, gastric in nature with mild fever and headache.

The child was febrile and had tachycardia. There was no icterus or features of liver failure. The abdomen was distended and there was guarding in the right hypochondrium without any rigidity. The liver was palpable 2 cm below the costal margin and the gallbladder was felt as a firm, globular and tender mass.

Complete haemogram, bilirubin, liver enzymes, prothrombin time and renal function tests, were within normal limits. Widal test and blood culture were negative. An erect X-ray of the abdomen was suggestive of gaseous distention of bowel loops. Ultrasonography (USG) on admission was suggestive of a hugely distended gallbladder with echogenic sludge within and mild hepatosplenomegaly. The patient was being treated conservatively and a follow-up USG was done 2 d later for persistence of pain. This time sonography revealed an over-distended (13 cm) gallbladder with perforation at the tip with a narrow tract and small volume of sealed-off collection with duodenal wall thickening and edema (Figure 1).

With these findings the patient was transferred to us and underwent a contrast-enhanced computed tomography (CT) scan of the abdomen which confirmed the USG findings (8.5 mm sized rent seen in the gallbladder wall with mild peri-gallbladder collection 4.2 cm × 2.3 cm × 2.2 cm suspected of sealed-off gallbladder perforation. No free fluid was noted in the abdomen) (Figure 2). USG guided percutaneous cholecystostomy using an 8-Fr pigtail catheter was done and around 150 mL of bile was drained (Figure 3).

Bile culture showed Enterobacter species sensitive to piperacillin and amikacin. The patient received intravenous piperacillin at 250 mg/kg per day for 10 d and amikacin at 15 mg/kg per day for 5 d. Daily bile output through the cholecystostomy tube was around 120 to 140 mL. There was improvement in the patients' general condition with resolution of fever and abdominal pain.

One week after the procedure bile culture showed no growth and liver function tests (LFTs) were normal. Tube cholecystogram showed free passage of contrast into the bowels (Figure 4), hence, intermittent clamping of the pigtail was started with monitoring for fever, pain and change in LFTs. Clamping trial after 4 d was successful and the pigtail was removed on post procedure day 13.

The patient was discharged symptom free and a Tc-99m Mebrofinin (HIDA) scan done 1 mo later showed morphologically normal liver with normal hepatic function and hepatobilliary drainage (Figure 5). At follow-up after 1 year of the episode, the patient remained to be asymptomatic.

DISCUSSION

GBP is a rare complication of acute cholecystitis (2%-11%)[1,2] and is more often seen in patients having critical illness like severe trauma, burns and cardiovascular surgeries. Compared with adult population GBP is even rarer in children and is mainly due to acalculus cholecystitis, trauma, enteric fever, gallbladder wall necrosis due to sepsis or sometimes it may occur spontaneously[3,4].

The most common part of the gallbladder to perforate is the fundus followed by the body, with the reason being attributed to poor blood supply[1]. The majority of the cases of cholecystitis followed by perforation are seen in gallbladder stone disease where the cystic duct often gets occluded, leading to retention of secretions and rise in the intraluminal pressure. Acalculus cholecystitis is seen in 5%-10% of patients with acute cholecystitis[1] and may lead to perforation as seen in our case.

GBP may be traumatic, iatrogenic or idiopathic (spontaneous) and was classified by Niemeier[5] into 3 types. Type 1 (acute) is associated with generalized biliary peritonitis; type 2 (subacute) consists of localized fluid collection at the site of perforation, pericholecystic abscess and localized peritonitis; and type 3 (chronic) has an internal or external fistula formation.

Most recent studies have cited highest rates of type 2 GBP and the same was the case in our patient.

Historically GBP has been associated with a high mortality rate which ranges from 11% to 26%[6] and great care must be taken to diagnose the condition as early as possible. Generally GBP mimics bowel perforation and many cases are diagnosed intraoperatively. Modalities useful for this condition are USG and CT scan, with the latter being more sensitive[1]. Abdominal X-ray may not always show free gas in the

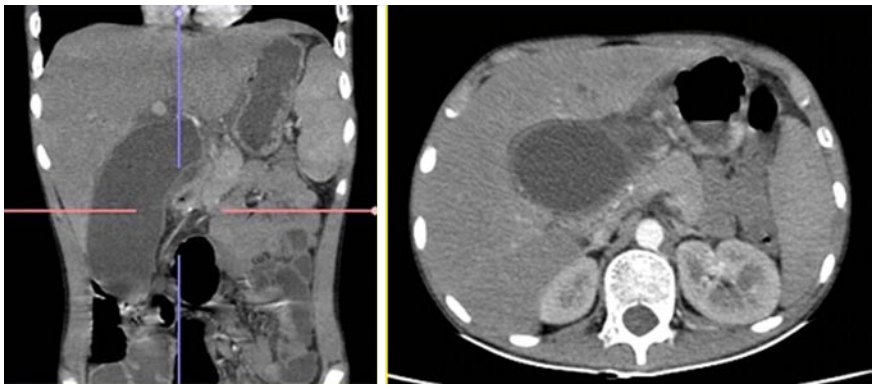

Figure 2 Computed tomography images.

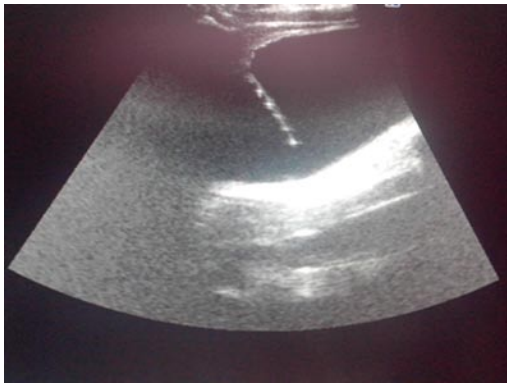

Figure 3 Percutaneous cholecystostomy.

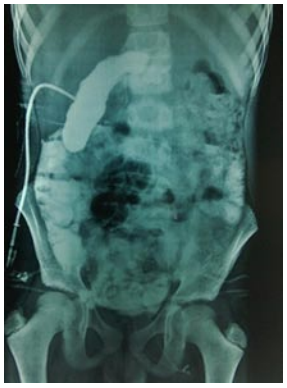

Figure 4 Tube cholecystogram.

peritoneum. HIDA scan, retrograde cholangiography and peritoneal lavage may also be used[7].

Reported complications include bile peritonitis, intrahepatic abscess formation (possible mechanisms include direct extension, subcapsular extension and hematogenous dissemination *via* the portal vein), subhepatic abscess formation, pelvic abscess formation, pneumonia, pancreatitis and acute renal failure[8].

Once diagnosed GBP mandates early intervention, and cholecystectomy with peritoneal lavage is considered sufficient. Laproscopic approach may also be used[2]. In our patient USG and CT scan showed a sealed-off

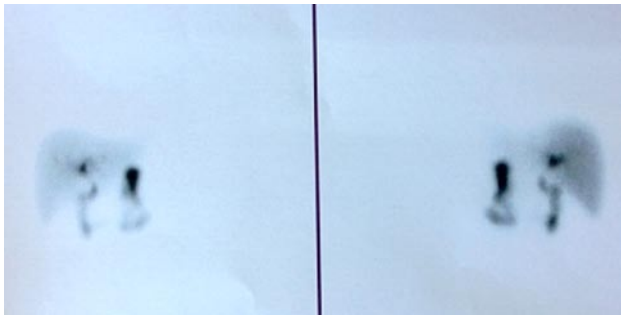

Figure 5 HIDA scan.

perforation without any free fluid in the peritoneum but a distended gallbladder which was persistent even on post prandial scans. Hence, a tube cholecystostomy was done under USG guidance by which the patient improved dramatically and a cholecystectomy was avoided. In many reports tube cholecystostomy is followed by interval cholecystectomy, but in our case we successfully avoided the procedure, thus preserving the gallbladder. Similar management in children has been reported by Mirza B[4] and Alghamdi[9]. The patient also underwent a Tc99m-HIDA scan to confirm the integrity and functionality of the biliary outflow tract, which did well at one-year follow-up.

It should also be mentioned that one must be very vigilant regarding the complications of GBP like persistent bile leak, persistent peritonitis, gallbladder necrosis, *etc.*[4] as they may warrant surgical exploration if not responding to percutaneous cholecystostomy.

In conclusion, we would like to highlight that GBP is a rare condition but demands a high level of suspicion, early diagnosis and prompt management. Using a percutaneous tube cholecystostomy in selected cases may help in avoiding cholecystectomy.

COMMENTS

Case characteristics

The patient was a 12-year-old boy who came with pain in the abdomen, fever and vomiting. He had abdominal distention and guarding in the right hypochondrium.

Clinical diagnosis
The initial suspicion was bowel perforation.

Differential diagnosis
Gallbladder perforation, even though rare, was kept as a differential diagnosis due to guarding localized to right hypochondrium.

Laboratory diagnosis
Complete hemogram, bilirubin, liver enzymes, prothrombin time and renal function tests, were within normal limits. Widal test and blood culture were negative.

Imaging diagnosis
An erect X-ray of the abdomen was unremarkable except gaseous distention of bowel loops. Ultrasonography revealed a perforated gallbladder which was confirmed by a computed tomography scan.

Treatment
As the gallbladder remained persistently over distended and the patient continued to have fever, a tube cholecystostomy was performed which led to resolution of the symptoms. Tube cholecystogram showed free flow of bile into the bowel without any leak.

Related reports
Similar technique of tiding over the acute phase of cholecystitis has been used before but is usually followed by interval cholecystectomy. In the case authors performed a HIDA scan at one month interval to confirm the functionality of the gallbladder and the billiary outflow system and found it satisfactory, thus cholecystectomy was successfully avoided.

Experiences and lessons
Gallbladder perforation is a rare but serious complication of cholecystitis and needs to be managed promptly. Percutaneous cholecystostomy is a good technique to tide over such crisis and can even be used as the definitive treatment, thus avoiding cholecystectomy altogether.

Peer-review
This is an interesting case history.

Abstract

The manuscript describes the efficacy of a new skin closure system (ZipLine™) for wound closure after pacemaker/implantable cardioverter defibrillator surgery. The system is particularly useful when wound healing is difficult with traditional methods and in patients at high risk for surgical site infections (SSIs). This skin closure option is easy and quick to apply and remove, and produces excellent cosmetic results. Although it is associated with a minimal expense upcharge, the benefits, including the potential for decrease in SSI, make it attractive and worth considering for skin closure in device patients, particularly those at increased risk of complications.

Key words: Cardiovascular implantable electronic device infection; Surgical wound; Skin closure system

Core tip: A new skin closure system (ZipLine™) is available for wound closure after pacemaker/implantable cardioverter defibrillator surgery. The system is particularly useful when wound healing is difficult with traditional methods and in patients at high risk for surgical site infections (SSIs). This skin closure option is easy and quick to apply and remove. The benefits, including the potential for decrease in SSI, make it attractive and worth considering for skin closure in device patients, particularly those at increased risk of complications.

De Maria E. New skin closure system facilitates wound healing after cardiovascular implantable electronic device surgery. *World J Clin Cases* 2015; 3(8): 675-677 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/675.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.675

TEXT

Cardiovascular implantable electronic device (CIED) infections are dramatically growing; estimated incidence is between 1% and 2% of all procedures, with a higher

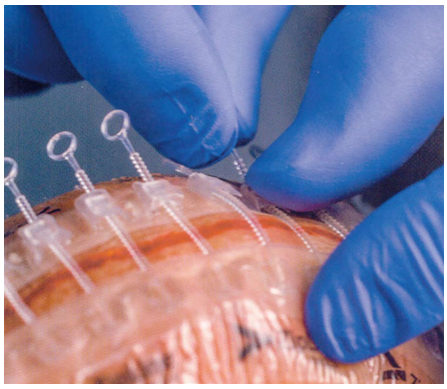

Figure 1 Example of a Zip™ device placement. Reproduced with permission from www.ziplinemedical.com MA00XX REVA.

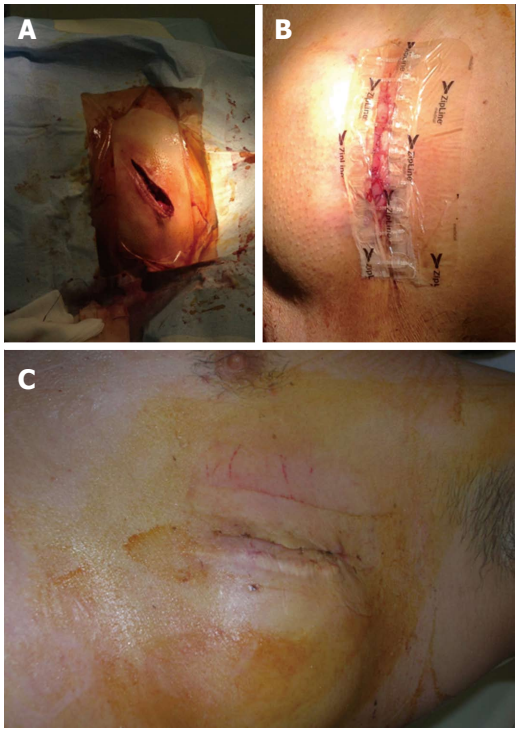

Figure 2 Zip™ applied on the wound after subcutaneous defibrillator replacement in the left anterior axillary area (A and B), wound healing after 14 d (C).

risk for implantable defibrillators and biventricular systems. Prevention is of the utmost importance and should be approached with the same strategy for surgical site infections (SSIs)[1]. The method of skin closure may be a contributing factor toward avoiding such complications; insufficient and/or delayed closure of the wound is a well recognized risk factor for subsequent infections[1]. Options for skin closure include subcuticular reabsorbable suture (braided versus monofilament), surgical "glue", and staples[2]. Closing surgical incisions with traditional sutures and staples increases the risk of SSIs compared to tape-based closure[3,4]. Sutures and staples hold the skin where they pass through it, creating high stress points that can cause ischemia, pain, irritation, edema, slow wound

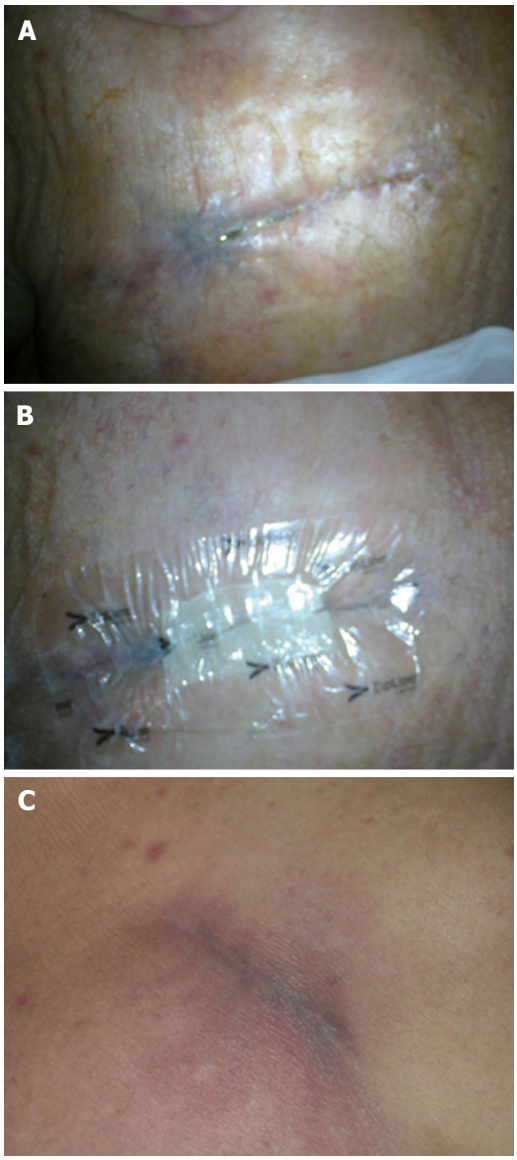

Figure 3 Zip™ applied on a wound with incomplete healing after transvenous implantable cardioverter defibrillator placement in a high risk patient (obese, diabetic, on hemodialysis) (A and B) and wound appearance after removal of the device (C).

healing and promote scar formation.

Recently a new "non invasive" device for skin closure (Zip™ Surgical Skin Closure, ZipLine Medical, Inc., Campbell, CA, United States) was approved for low tension, non-infected, surgical wounds. It is a sterile single-use system with two self-adhesive hydrocolloid pressure-sensitive strips linked with individually adjustable self-locking fasteners (Figure 1). This device increases tensile strength of a wound faster than sutures; the non-uniform distribution of closure forces associated with sutures allows immature collagen fibers to remain in a disorganized arrangement for a longer time, while in a wound closed with an adhesive tape-based closure, stress is uniformly applied to the collagen fibers which cross the wound causing rapid fiber orientation and increased tensile strength[2,3]. In addition, necrosis of tissue, needle puncture marks

and suture scarring are eliminated, leading to better cosmetic results and reduced closure time, potentially reducing SSI risk[5].

Here we present two cases of CIED surgery wounds treated with Zip™ system. In the first case the system was placed as first-line option after the replacement of a subcutaneous defibrillator [S-implantable cardioverter defibrillator (ICD)] due to battery depletion; the pocket was localized near the left anterior axillary line, a zone at risk for suboptimal wound closure (Figure 2). The second patient was an obese diabetic on hemodialysis who had an incomplete wound healing three weeks after a transvenous ICD placement (pocket in the right subclavicular area): the skin remained partially "opened" after having used all "traditional" methods for closure, so a Zip™ device was placed as a "rescue" (Figure 3). In both cases subcutaneous tissues had already been closed with monofilament suture for pocket and subcuticular layer, leaving a < 5 mm incision gap (importantly the device does not replace subcutaneous or other deep, tension-reducing sutures). After 14 d ZipLine was removed obtaining a complete wound healing without further problems in both patients, even at 6 mo follow up.

Although this system is associated with a minimal expense upcharge, the benefits (including the potential for decrease in SSI) make it attractive and worth considering for skin closure in device patients, particularly those at increased risk of complications and delayed healing of the wound: patients with heart failure, diabetes, renal insufficiency, cancer, immunodeficiencies, long-term corticosteroid use, high bleeding risk, longer and more complex procedures. Future studies will be needed to determine if and to what percentage this new device will reduce the incidence of SSI.

Abstract

Flow fractional reserve (FFR) allows to evaluate the functional significance of coronary artery lesions, through the ratio of the mean coronary artery pressure after the stenosis to the mean aortic pressure during maximum hyperemia. The actual widely accepted cut-off value is 0.80. Below this value a coronary lesion is considered significant and therefore it requires invasive revascularization. Several studies [in particular Fractional Flow Reserve *vs* Angiography for Multivessel Evaluation 1 (FAME-1) and FAME-2] have shown the relationship between FFR measurement and hard end-points (death, myocardial infarction, and urgent revascularization). Consequently, FFR evaluation represents the cornerstone in the decision-making in intermediate coronary lesions. Recent studies paved the way for further applications of FFR evaluation in complex and tricky clinical settings. In this paper, we perform an overview of the data regarding contemporary application of FFR. In particular, we review the use of FFR in: left main intermediate stenoses, serial stenoses, evaluation after stenting, guidance in coronary artery bypass surgery, and acute coronary syndrome. All the data presented in our overview confirm the essential role of FFR assessment in the daily clinical practice. The shift from "operator-dependent" to "FFR-dependent" evaluation in intermediate coronary artery stenosis is of paramount importance in order to improve the prognosis of our patients, through the discrimination of the functional role of every single coronary stenosis.

Key words: Intermediate coronary lesion; Fractional flow reserve; Coronary artery bypass surgery; Left main; Acute coronary syndrome; Serial stenoses

Core tip: Fractional flow reserve (FFR) evaluation is well validated in intermediate coronary lesions. Still, there are several clinical settings in which its use is debated. In this paper, we perform an overview on the available data regarding FFR and complex clinical settings, as left main intermediate stenoses, serial stenoses, evaluation after stenting, guidance in coronary artery bypass surgery, and acute coronary syndromes.

Tebaldi M, Campo G, Biscaglia S. Fractional flow reserve: Current applications and overview of the available data. *World J Clin Cases* 2015; 3(8): 678-681 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/678.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.678

INTRODUCTION

Fractional flow reserve (FFR) is an objective method to assess the functional significance of coronary artery lesions. FFR is defined as the ratio of maximal achievable blood flow in coronary artery to the hypothetical maximal achievable blood flow in the same artery in the absence of stenosis. It is derived from the ratio of the mean distal coronary artery pressure to the mean aortic pressure during the period of maximum hyperemia. Initial studies suggested that the cut-off value of 0.75 was reliable in the identification of ischemia-producing lesions. Afterwards, several outcome studies[1,2] validated the cut-off value of 0.80, which is actually widely accepted.

CLINICAL STUDIES

The randomized clinical trial FFR to Determine the Appropriateness of Angioplasty in Moderate Coronary Stenoses (DEFER) first evaluated the clinical benefit of FFR-guided revascularization. This study enrolled 325 patients with intermediate coronary stenosis. Patients with FFR value < 0.75 underwent percutaneous coronary intervention (PCI) (reference group, n = 144), whereas patients with an FFR value $\geqslant$ 0.75 were randomly allocated to PCI (perform group, n = 90) *vs* medical therapy (DEFER group, n = 91). At a median follow-up of 5 years, the prognosis of "non-ischemic" stenosis (FFR $\geqslant$ 0.75) was excellent even without the placement of a stent[3,4]. In the Fractional Flow Reserve *vs* Angiography for Multivessel Evaluation (FAME) study, 1005 patients with multivessel coronary artery disease were randomly assigned to PCI with drug-eluting stents guided by angiography alone or guided by FFR. Patients randomized to receive PCI, underwent stenting of all lesions; whereas those randomized to receive a functional assessment of coronary stenosis by FFR, underwent PCI only if FFR value was $\leqslant$ 0.80. The study showed a statistically significant reduction of the primary end point at 1 year (a composite of death, MI and repeat revascularization) in favor of the procedure guided by FFR (P = 0.02)[5]. In the subsequent FAME-2 trial, patients with stable coronary artery disease and at least one stenosis with FFR $\leqslant$ 0.80, were randomly allocated to medical therapy alone or to medical therapy plus PCI. The trial was stopped prematurely due to a highly significant difference in the incidence of the primary endpoint (a composite of death, myocardial infarction, and urgent revascularization) in favor of FFR-guided PCI, entirely driven by lower incidence of urgent revascularization. There were no statistically significant differences with regard to death or MI between the two groups[2,6]. In summary, FAME-2 showed that FFR-guided angioplasty reduces the incidence of urgent revascularization when compared to medical therapy.

FFR AND LEFT MAIN

In a study published in 2009, Hamilos *et al*[7] randomized 213 patients with angiographically equivocal left main coronary artery stenosis. All patients underwent FFR evaluation on left main. When the value was $\geqslant$ 0.80, patients were treated with medical therapy alone (non surgical group), while when FFR was < 0.80, coronary artery bypass grafting was performed (surgical group). The follow-up performed at 5 years did not demonstrate statistically significant differences between the two groups of patients, with regard to survival and event-free survival. Percent diameter stenosis at quantitative coronary angiography correlated significantly with FFR (r = -0.38, P < 0.001), but a very large scatter was observed. An important evidence emerging from this analysis is that 23% of lesions judged less than 50% at angiographic analysis, resulted critical after FFR evaluation. It follows that in left main intermediate lesions, angiography alone is unable to determine whether a stenosis is critical or not, tending to underestimate its functional significance. In this very important scenario, FFR plays a central role in the decision-making. In a worthy editorial by Kern[8], the author investigated a particularly complicated angiographic scenario, where stenosis in the left main (LM) is associated with a stenosis of the left anterior descending (LAD). In clinical practice, the sum of FFR across both lesions (LM + LAD) determines the need to treat, while the pressure pullback recording determines which lesion needs to be treated. In fact, the lesion with the largest pressure drop (ΔP, not FFR) is treated first. Then, FFR evaluation is repeated across the remaining lesion in order to decide whether even the second lesion needs to be treated. Such a method can be used to assess serial LM - LAD disease, but this approach engenders a downside: acceptance of stenting an unprotected LM after LAD treatment, if FFR remains < 0.80. In this particular case, both anatomical and physiopathological variables can determine a high number of errors. In order to overcome these limitations, intravascular ultrasound is frequently used to assess the minimum luminal area in the LM. Although a minimal luminal area > 6 mm^2 is an oft-quoted threshold, it represents a conservative approximation of true physiology, best indicating a lack of functional significance rather than a minimal luminal area < 6 mm^2 being an indication to treat[8,9].

FFR AND SERIAL STENOSES

Kim *et al*[10] investigated the treatment of intermediate coronary stenoses in series on the same coronary artery

using FFR pullback pressure tracings. If FFR result was < 0.80, the stenosis with the largest pressure step-up was treated with stenting first. Subsequently, the patients were divided into two groups (FFR < 0.8 *vs* FFR > 0.8), according to FFR value after PCI. There were no events related to deferral of lesion treatment. The evaluation by conventional FFR of a single coronary artery stenosis in a vessel where there are several intermediate lesions, is underestimated ("apparent FFR"). Indeed, in this scenario, the assessment with FFR tends to ignore the real contribution of each stenosis to the ischemic burden. The real value of the FFR ("true FFR") can be calculated only after the treatment of the lesion which gave the largest pressure step-up using FFR pullback pressure tracings or by using a more complex method described by De Bruyne *et al*[11] which also considers the coronary wedge pressure[11,12]. In conclusion, FFR-guided revascularization strategy using pullback pressure tracing in serial stenoses is safe and effective[10].

FFR AFTER STENT

In a study published in 2011, Nam *et al*[13] assessed the impact of FFR value after stent on MACE (myocardial infarction, death, ischemia-driven target vessel revascularization) at one year. Patients were divided into two groups according to the value of FFR detected after PCI (FFR < 90: low-FFR group; FFR > 90: high-FFR group). The study showed a statistically significant MACE reduction in the high-FFR group; for that reason the 0.90 value it is considered the cut-off reference to obtain after PCI.

FFR AND CORONARY ARTERY BYPASS SURGERY

Myocardial revascularization is recommended when a large territory of reversible myocardial ischemia is present. Of note, patients undergoing cardiac surgery usually have a very complex coronary anatomy. In such situation, non-invasive functional testing has shown many limitations. On the contrary, as described previously, FFR is safe and accurate even in patients with multivessel disease with multiple stenosis. The usefulness of FFR in patients undergoing coronary artery bypass surgery was confirmed by the results of a registry by Toth *et al*[14]. In this registry, authors evaluated patients with at least one intermediate coronary stenosis. These patients were divided into two groups: the angiography-guided group, in which patients underwent coronary artery bypass graft surgery (CABG) solely on the basis of coronary angiography; and the FFR-guided group, in which patients underwent CABG if FFR was ⩽ 0.80, and were treated conservatively if FFR was > 0.80. The registry showed that FFR-guided coronary artery bypass graft surgery was associated with a lower number of graft anastomoses, a lower rate of on-pump surgery and a lower rate of angina in the absence of an increase of events during follow-up[14].

FFR AND ACUTE CORONARY SYNDROME

During the acute phase of acute coronary syndrome (ACS), we deal with a non-permanent microvascular dysfunction, which both changes during hours and is affected by multiple factors (embolization, changes in filling pressures, duration and intensity of ischaemia, changes in systemic or local vasoconstrictors, *etc.*)[15]. The microvascular dysfunction is a key aspect for the evaluation with FFR: a reduced ability to respond to vasodilation through adenosine by the microcirculation, may cause an underestimation of coronary stenosis. At present, the main study evaluating the relationship between FFR and outcome in ACS patients is the FAMOUS-NSTEMI trial[16]. In this trial, 350 patients with no ST-segment elevation MI were enrolled. The evaluation using FFR resulted in a reduction of patients undergoing PCI without increase of events at 1 year follow-up.

CONCLUSION

All available studies suggest that FFR assessment should be considered an essential tool in daily clinical practice. Therefore, the operator-dependent evaluation of intermediate stenosis should now represent just an old memory in the history of interventional cardiology. FFR value permits to better discriminate the functional role of intermediate stenosis significantly improving the prognosis of our patients.

Abstract

Depressive symptoms are very common in chronic conditions. This is true so for neurodegenerative diseases. A number of patients with cognitive decline and dementia due to Alzheimer's disease and related conditions like Parkinson's disease, Lewy body disease, vascular dementia, frontotemporal degeneration amongst other entities, experience depressive symptoms in greater or lesser grade at some point during the course of the illness. Depressive symptoms have a particular significance in neurological disorders, specially in neurodegenerative diseases, because brain, mind, behavior and mood relationship. A number of patients may develop depressive symptoms in early stages of the neurologic disease, occurring without clear presence of cognitive decline with only mild cognitive deterioration. Classically, depression constitutes a reliable diagnostic challenge in this setting. However, actually we can recognize and evaluate depressive, cognitive or motor symptoms of neurodegenerative disease in order to establish their clinical significance and to plan some therapeutic strategies. Depressive symptoms can appear also lately, when the neurodegenerative disease is fully developed. The presence of depression and other neuropsychiatric symptoms have a negative impact on the quality-of-life of patients and caregivers. Besides, patients with depressive symptoms also tend to further decrease function and reduce cognitive abilities and also uses to present more affected clinical status, compared with patients without depression. Depressive symptoms are treatable. Early detection of depressive symptoms is very important in patients with neurodegenerative disorders, in order to initiate the most adequate treatment. We review in this paper the main neurodegenerative diseases, focusing in depressive symptoms of each other entities and current recommendations of management and treatment.

Key words: Neurodegenerative diseases; Alzheimer; Depressive symptoms; Frontotemporal degeneration; Vascular dementia; Lewy body disease; Depression; Dementia

Core tip: Neurodegenerative diseases commonly associate depressive symptoms. Depressive symptoms of neurodegeneration occur both in the beginning and in the main course of neurodegenerative diseases. They can dominate the clinical picture mostly in the first stage of disease. Besides, depressive symptoms decrease quality of life of patient and relatives in every

stage of disease. This is certainly an usual condition in Alzheimer's disease, by far the main cause of dementia worldwide. Such a situation often happens in neurodegenerative diseases. Depressive symptoms are treatable and its treatment can improve perceived health status and welfare of patients and relatives.

INTRODUCTION

Depressive symptoms are very common in general medical practice and its frequency is remarkable in neurological diseases. Really, depressive symptoms are usual in chronic diseases; every kind of chronic or limiting condition is frequently associated with mood disorders[1]. However, from the very first glance it is apparent that the association between mood disorders and brain disorders is clearly more complex than the association between depressive symptoms and other group of diseases. The mean reason of this complexity is simple: the diseases of the brain have the potential to modify the mood of the affected person as brain is the ultimate controller of the behavior.

In the present paper, we review the relation between depressive symptoms and neurodegenerative disorders from a clinical point of view, focusing on the depressive symptoms described in main neurodegenerative diseases. Specially in neurodegenerative disease, depression may appear as an early symptom and depression may be the main manifestation, more often but no only in the early stages of degenerative brain processes. These depressive symptoms are relevant in medical practice as they can be the more important demand noted by patient or caregivers. Besides, they have an impact on the quality-of-life of patients and have been associated with increased caregiver burden, more rapid progression of disability and functional decline and earlier institutionalization and mortality[2]. However, although the importance of depressive symptoms, they have little or no interest regarding on diagnosis of neurological diseases; so, the features that clearly define the neurodegenerative disease are cognitive or motor symptoms, and not mood disturbances.

DEPRESSION, DEPRESSIVE SYMPTOMS AND COGNITION

Following the DSM-V classification[3] (Table 1) depression is defined as a mood disorder which expresses itself as a combination of symptoms with predominance of affective ones (sadness, desperation, apathy, anhedonia and subjective sensation of discomfort), also associating cognitive and physic phenomenology, causing a marked decreased interest in daily life activities.

In presence of any neurodegenerative disease, the depression diagnosis may be difficult. Frequently, depressive symptoms are masked by cognitive decline. Often cognitive symptoms and mood disorders mix in such a way that it's difficult to determine what group of symptoms are the most relevant to the patient. Neurological patients have difficulty to express typical feelings of sadness and hopelessness. Instead of sadness, prominent symptoms in neurodegenerative diseases may be anhedonia, anxiety, panic, motor disturbances and also lack of concentration. Lack of concentration or indecisiveness is a symptom that can be characteristic of cognitive decline caused by neurodegenerative diseases[4,5] but its specificity is not elevated. Weight loss and sleep disorders, often valuable symptoms of depression, can appear in neurological diseases with or without any associated mood disturbance. On the other hand, patients with neurodegenerative diseases use to manifest apathy[6]. This mood symptom is easily mistaken as anhedonia, that marked decrease in interest or pleasure with different activities to be considered as a main symptom of depression. Also, some particular neurological symptoms complicate the diagnosis because different reasons; as an example, the existence of a language disorder provokes difficulty of patient to express feelings. Another condition like pseudobulbar palsy may be misdiagnosed of depression as result of misunderstanding the significance of pathological crying or emotional lability.

From the clinical point of view, often depression and dementia are combined and their clinical phenomenology can be coincident and considered as strongly linked. From the epidemiological point of view, late-onset depression itself may be considered a risk factor or an early symptom of develop dementia[7]. So, certainly, this risk factor relation as explanation about the epidemiologic link between late-onset depression and dementia is not the only possibility, and other ones will be mentioned soon. It has been proposed that neurodegenerative disease may express as depressive symptoms in the early stages. That explanation is supported amongst other data by neuropathological evidences[8]. Thus, there would be common neuropathological hallmarks found in cognitive impairment that also are associated to depressive symptoms. So, depressive symptoms may be an early manifestation of diseases that later will cause dementia, not really a "risk factor" for dementia. On the other hand, psychopathology experts have argued that the depressive symptoms may be a consequence of self-perception of cognitive deterioration by patient[9].

From the opposite point of view, patients with depression commonly present cognitive disturbances. Cognitive disturbances, specially attention, short term memory, psychomotor speed, and executive function are often reported by depressive patients[10,11]. In fact, it has been observed that functional impairment in depression is closely related to severity of depression and cognitive

Table 1 Criteria for major depressive episode: DSM 5

Five (or more) of the following symptoms have been present during the same 2-wk period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood; or (2) loss of interest or pleasure
Depressed mood most of the day, nearly every day, as indicated by either subjective report (*e.g.*, feels sad or empty) or observation made by others (*e.g.*, appears tearful)
Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
Significant weight loss when not dieting or weight gain (*e.g.*, a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day
Insomnia or hypersomnia nearly every day
Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
Fatigue or loss of energy nearly every day
Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
The symptoms cause clinically significant distress or impairment in social, occupational or other important areas of functioning
The symptoms are not due to the direct physiological effects of a substance (*e.g.*, a drug of abuse, a medication) or a general medical condition (*e.g.*, hypothyroidism)

disturbance[12]. Interestingly, attentional deficits are part of the current diagnostic criteria of major depression and are commonly found in clinical practice[13]. In addition, several studies have shown the improvement of cognitive functions in patients with major depression treated with selective serotonin reuptake inhibitors[14] (SSRI) or dual serotonergic-noradrenergic reuptake inhibitors.

However, cognitive impairment in depression may produce some added difficulties. On one hand assessment of cognitive impairment may be difficult because of severity of depression. On the other hand, cognitive impairment can remain after antidepressant treatment despite of remission of depressive symptoms[15-17]. Thus, it may be recommended to continue the pharmacological and non-pharmacological treatment in presence of cognitive deficits[18], even though neurotransmission and other biological pathways and mechanisms involved in the association of cognitive deficits and major depression remain not clearly understood.

Several risk factors to develop dementia after a depressive episode have been described: mainly, high cultural level, depression severity and failure of treatment with antidepressive drugs[19]. The role of other risk factors, such as stress, depression severity and/or treatment with psychotropic drugs itself continues unclear[20].

So, it is essential to distinguish between depressive symptoms that can be the very first symptom of a neurodegenerative process and those ones what are not linked to this group of brain diseases.

DEPRESSIVE SYMPTOMS IN THE DIFFERENT NEURODEGENERATIVES DISEASES

Alzheimer's disease

Alzheimer's disease is the paradigmatic dementia's cause. As it is, provokes progressive memory and other cognitive functions impairment and causes marked decline in activities of daily living and variable behavioral changes. Neuropathologically it is characterized by neuronal loss with associated accumulation of neurofibrillary tangles and amyloid plaques. Currently, Alzheimer's disease is the most frequent cause of dementia all over the world as a whole and in most, if not all, population subgroups.

Most of the patients suffering from Alzheimer's associate behavioral and psychological symptoms, so called "non cognitive" symptoms, at some point of the evolution of the disease[21,22]. The prevalence of these symptoms is found to oscillate between 60% to 90% of cases, depending on both defined population and methodology of the study[23-26]. These neuropsychiatric symptoms are not included within the diagnostic criteria; in contrast, they contribute to develop a great disability and mortality and represent the main reason for patient institutionalization[27].

Early detection of neuropsychiatric symptoms is very important because they are the main cause of caregiver burden and also they cause acceleration of cognitive decline. In fact, when this symptomatology is observed and correctly identified, it may be treated with pharmacological and non-pharmacological treatment with improvement of the quality of life of patients and caregivers[28]. When these neuropsychiatric symptoms are identified, they can be prevented to recur too. Frequently, neuropsychiatric symptoms may fluctuate during the course of the disease and they disappear when cognition is severely impaired[29,30]. Depressive symptoms are included within this category of neuropsychiatric symptoms and are specially common in early stages of disease when lack of concentration and inattention are commonly found[31].

Depressive symptoms are usual in Alzheimer's disease patients according to different studies[32]. Based on descriptive population studies, about 80% of Alzheimer's patients can develop depressive symptoms to a greater or lesser degree in the whole course of the disease[33]. Depressive symptoms may vary and disappear, in contrast to cognitive symptoms that remain steady and invariably progress with the course of disease. In most cases, depression may be less intense than the depression found in neurologically healthy people or depression in another subtypes of brain diseases like cognitive impairment due to brain vascular disease, so

Table 2 The cornell scale for depression in dementia

Mood-related signs
Anxiety: Anxious expression, rumination, worrying
Sadness: Sad expression, sad voice, tearfulness
Lack of reaction to present events
Irritability: Annoyed, short tempered
Behavioral disturbance
Agitation: Restlessness, hand writing, hair pulling
Retardation: Slow movements, slow speech, slow reactions
Multiple physical complaints (score 0 if gastrointestinal symptoms only)
Loss of interest: Less involved in usual activities (score only if change occurred acutely, *i.e.*, in less than one months)
Physical signs
Appetite loss: Eating less than usual
Weight loss: (score 2 if greater than 5 pounds in one month)
Lack of energy: Fatigues easily, unable to sustain activities
Cyclic function
Diurnal variation of mood: Symptoms worse in the morning
Difficulty falling asleep: Later than usual for this individual
Multiple awakening during sleep
Early morning awakening: Earlier than usual for this individual
Ideational disturbance
Suicidal: Feels like is not worthy living
Poor self-steem: Self-blame, self-depreciation, feelings of failure
Pessimism: Anticipation of the worst
Mood congruent delusions: Delusions of poverty, illness or loss
Scoring system
A= Unable to evaluate; 0 = Absent; 1 = Mild to intermittent; 2 = Severe score greater than; 12 = Probable depression

Table 3 Provisional diagnostic criteria for depression in Alzheimer's disease

Three or more of the following criteria over the same 2-wk period, representing a change from previous functioning:
Depressed mood (sad, hopeless, discouraged, tearful)
Decreased positive affect or pleasure in response to social contacts and activities
Social isolation or withdrawal
Disruption in appetite
Disruption in sleep
Psychomotor agitation or retardation
Irritability
Fatigue or loss of energy
Worthlessness, hopelessness or excessive guilt
Recurrent thoughts of death or suicidal ideation
All criteria are met for dementia of the Alzheimer's type
Symptoms cause distress or disruption in functioning
Symptoms do not occur exclusively during delirium
Symptoms are not due to substances (medications or drugs of abuse)

called, when intense, vascular dementia[34,35].

The recognition of depression in Alzheimer's patients may be a challenge for different reasons: first of all, the absence of a validated questionnaire to detect and quantify the disorder. Second, dementia symptoms themselves like apathy can be confounded with typical features of depression such as sadness or anhedonia, masking the depressive disorder. Finally, the cognitive impairment of these patients supposes difficulties in the expression of sadness, hopelessness and other common affective feelings.

Numerous instruments have been proposed for assessing mood disorders and other neuropsychiatric symptoms in patients suffering from dementia. In 1994 the group of Cummings published the Neuropsychiatric Inventory[36] (NPI). The NPI has been used to characterize neuropsychiatric symptoms in several neurological diseases and is currently the most used scale for this purpose. NPI largely correlates with increasing disability in activities of daily living and increasing cognitive impairment. It has shown to be able to demonstrate the improvement on behavioral symptoms in Alzheimer's disease and other dementias after appropriate treatment[37]. In the initial version of the NPI, this scale evalued ten neuropsychiatric symptoms[38]: delusions, hallucinations, dysphoria, anxiety, agitation, euphoria, apathy, irritability, disinhibition and aberrant motor behaviour. Later, two more items, sleep and eating disorders, were added.

NPI is passed as a structured interview driven by the professional and answered by the caregiver, focusing on the presence or absence of neuropsychiatric symptoms and their intensity. A form to be self-administered by the caregiver[39] (NPI-Q) and another one to be used in nurse home settings[40] (NPI-NH) have been developed later. Different translations of the NPI in its distinct forms are validated in a great number of languages[41-43].

Another more specific instruments to describe and quantify mood disorders in patients with dementia also has been developed: The Dementia Mood Assessment Scale[44] and the Cornell Scale for Depression in Dementia (CSDD)[45]. Particularly, the CSDD is widely used and it allows to differentiate between cognitive and mood symptoms (Table 2). It also may be useful to measure response to treatment and it's commonly used in clinical trials on this purpose.

Finally, specific provisional diagnostic criteria for depression in Alzheimer's disease (PDC-dAD) were proposed in 2002[46] (Table 3). PDC-dAD have shown to provide higher prevalence rates of depression than generic diagnostic criteria[47] such as ICD-10, CAMDEX or DSM-IV. The PDC-dAD are similar to standard depression diagnosis but reduces the importance on verbal expression and in contrast includes irritability and social isolation. Patients must have a diagnosis of Alzheimer's disease and three or more listed symptoms during two weeks. The symptoms must include low mood or decreased pleasure in daily living activities.

Together with depression, apathy is the most common symptom in Alzheimer's disease[48]. Both depression and apathy have a negative impact on evolution of the disease. Frequently, apathy is difficult to separate from depression. In fact, it's often a symptom observed in depression[49]. However, apathy can exist isolated without depression and it is not rare to find isolated apathy. Some paper have addressed the situation that both apathy and depression occur simultaneously in Alzheimer's disease and when both apathy and depression occur it has been shown that they are clinically and anatomically independent[50,51]. In fact, several neurophysiological studies focus on prevalence and clinical features of apathy have been

able to characterize this symptom and formulate some differences in relation to depression[52-54].

Certainly, the significance of depression or the significance of apathy in patients with neurodegenerative disease are different. First, apathy increases the risk of being diagnosed of dementia in patients with mild cognitive impairment and apathy do it more frequently that isolated depression in mild cognitive impairment[55]. Also, apathy tends to be more prevalent as cognitive function declines, in contrast to prevalence of depression that it's reduced in advanced stages of dementia[56]. On the other hand, apathy do not respond to antidepressive treatment, actually, antidepressive treatment have been reported even to increase the intensity of apathy in some cases[57].

As stated, depressive symptoms are important in patients with mild cognitive impairment. Mild cognitive impairment is characterized by cognitive symptoms and demonstrated impairment in neuropsychological testing but no significant functional decline, so patients with MCI do not fulfill dementia diagnostic criteria[58]. Its most common etiology is Alzheimer's disease and constitutes a high risk group to develop dementia at an annual rate of 10% to 15%[59-61].

Behavioral abnormalities are reported in 35%-75% of mild cognitive impairment patients[62]. As in Alzheimer's disease, neuropsychiatric symptoms in mild cognitive impairment are associated with cognitive decline and disability[63]. The most common behavioral symptoms are apathy, anxiety, depression, irritability and agitation[64,65]. Less common symptoms are euphoria, hallucinations, disinhibition and aberrant motor behavior. As previously commented, coexistence of depression and apathy or the presence of isolated apathy have shown to increase the risk of later conversion to Alzheimer's disease[66].

Depressive symptoms have been described up to 30% of the patients with mild cognitive impairment and in most studies depression was the most common neuropsychiatric symptom followed by apathy and irritability[67-69].

Frontotemporal degeneration

Frontotemporal degeneration or frontotemporal dementia (FTD) is clinically characterized by progressive behavioural changes such as disinhibition, compulsion, hyperorality or dietary changes. Patients also show social interpersonal dysfunction. Involvement of memory and other cognitive functions[70,71] is later than behavioural alterations. All these symptoms are due to degeneration of frontal and temporal lobes.

Nowadays, it's commonly accepted that frontotemporal degeneration is expressed with any of three main clinical variants: the more common behavioural variant FTD that have been forementioned and the language variants semantic dementia and progressive non-fluent aphasia[72]. There is also an overlap of FTD with motor neuron disease (FTD-MND or FTD-ALS), as well as another overlap exists with the parkinsonian syndromes progressive supranuclear palsy (PSP) and corticobasal syndrome (CBS)[73]. Characteristicly, a certain grade of parkinsonism tends to be present in all syndromes.

Depression is quite common in FTD (40% of cases in the study by Levy *et al*[74]), although generally with mild or moderate intensity. When depressive symptoms are present, they usually do not manifest as typical features of major depression. Indeed, patients experience mainly apathy and decreased energy, hyperphagia and inappropriately preserved self-esteem, feature that it's extremely uncommon in usual depression.

The diagnostic challenge of FTD is the predominance of clashing behavioral symptoms. Consequently, it's difficult to make an adequate diagnose in initial stages of the process. Often patients may be misdiagnosed with psychiatric disorders conditioning a delay in the diagnosis of neurodegenerative disease. Psychopharmacological treatment with antipsychotics can cause more prominent motor symptoms and thus another confounding factor may contribute to misdiagnosis and failure to provide appropriate treatment.

Lewy body disease

Lewy body disease is another of the most frequent primary causes of degenerative dementia behind Alzheimer's disease. Both Lewy body disease and Parkinson's disease with or without dementia have been proposed to constitute a group of disorders called α-synucleinopathies. This proposal takes the fact that both entities' neuropathological handmark is the presence of Lewy bodies in different regions of the brain, mainly limbic, paralimbic and neocortical regions, and Lewy bodies are constituted mainly by the protein α-synuclein. Lewy body disease is clinically expressed with the presence of dementia associated with visual hallucinations, parkinsonism and a remarkable fluctuation of symptoms. Severe neuroleptic sensitivity is also typical of this disease[75]. Although these evident clinical features would seem to easily distinguish Lewy body dementia from Alzheimer's disease, in the common practice such a distinction is difficult to be made, specially in the early stages. The presence of visual hallucinations becomes relevant in differential diagnosis to Alzheimer's disease[76,77].

Depression in Dementia with Lewy bodies is similar to depression in Alzheimer's disease. Several studies have found higher rate of depression specially in early stages. Also depressive symptoms seems to be more severe[78]. First guidelines for diagnosis of Body Lewy's disease were described in 1996 and laterly in 1999. Current reviewed diagnostic criteria since 2005[75] includes depression as supportive feature of the disease (Table 4).

Corticobasal degeneration

Corticobasal degeneration (CBD) is histopathologically characterized by focal cortical neuronal loss and gliosis. It has been included into the spectrum of frontotemporal lobar degeneration as well as PSP and Pick's disease. All of these entities are biologically included into the group of tauopathies because tau protein is the main

Table 4 Diagnostic criteria for Lewy bodies disease

Central feature
Progressive dementia-deficits in attention and executive function are typical
Prominent memory impairment may not be evident in the early stages
Core features
Fluctuating cognition with pronounced variations in attention and alertness
Recurrent complex visual hallucinations
Spontaneous features of parkinsonism
Suggestive features
REM sleep behavior disorder which can appear years before the onset of dementia and parkinsonism
Severe intensity to neuroleptics occurs in up to 50% of LBD patients who take them
Low dopamine transporter uptake in the brain's basal ganglia as seen on SPECT an PET imaging scans
Supportive features
Repeated falls and syncope (fainting)
Transient, unexplained loss of consciousness
Autonomic dysfunction
Hallucinations of other modalities
Visuospatial abnormalities like depth perception, object orientation, directional sense and illusions
Other psychiatric disturbances like systematized delusions, aggression and depression
A probable LBD diagnosis require either
Dementia plus two or more core features, or
Dementia plus one core features and one or more suggestive features

LBD: Lewy body dementia; PET: Positron emission tomography; SPECT: Single photon emission computed tomography.

component of different microscopic alterations to be found in these diseases. CBD presents in a sporadic pattern without familial aggregation. The common clinical presentation of CBD is the CBS associated to progressive asymmetric rigidity, limb apraxia, alien limb phenomenon, cortical sensory loss, myoclonus and dystonia. However, neither CBS patients have always CBD neuropathology when their brain is studied, nor corticobasal histopathology itself produces always CBS.

In fact, CBS is associated commonly with Alzheimer's disease histopathology. On the other hand, corticobasal histopathology has been associated to different clinical presentations like PSP, FTD or nonfluent/agrammatic primary progressive aphasia.

Depression is common in CBD and it has been described in up to 70% of these patients[79]. Conversely to the findings of similar studies in other neurodegenerative disease, Litvan *et al*[80] found in CBD patients a high prevalence of depression (73%) superior to the prevalence of apathy (40%). As it occurs specially in patients with FTD and another neurodegenerative diseases with prominent neuropsychiatric symptoms, the clinical predominance of depressive symptoms may explain that this entity can be misdiagnosed as a primary psychiatric disorder[81].

Huntington's disease

Huntington's disease is a highly penetrant autosomal dominant disease caused by a mutant protein - huntingtin - that results from an expanded CAG repetition. The progressive neurodegenerative disorder caused by Huntington's disease typically includes chorea and dystonia, incoordination, cognitive decline, and behavioural disturbances.

Classical and recent studies have shown that apathy, aggression and disinhibition are common. Suicide rates in Huntington's disease patients are over four times those of the general population[82,83]. Depression is diagnosed up to 40% of cases[84,85].

Parkinson's disease

Parkinson's disease manifests mainly with motor disturbances. Typically it causes asymmetric bradykinesia, resting tremor, rigidity and in later stages postural instability. Pathologically is characterized by depigmentation of substantia nigra due to loss of melanin-laden dopaminergic neurons containing eosinophilic cytoplasmic inclusions called Lewy bodies and mainly composed of α-synuclein, as previously mentioned.

Apart from motor symptoms that constitute the main clinical features, a wide range of nonmotor symptoms exists since early stages of the disease. These nonmotor symptoms are olfactive disturbances, depression, dementia, sleep disorders, fatigue, apathy and autonomic symptoms. Such a symptoms and other ones like dementia, a late complication of typical Parkinson's disease, are recognized as a major cause of disability and decline of quality of life in patients suffering from Parkinson's disease, especially in the more advanced stages[86]. Characteristically, depressive symptoms may experience fluctuation in the same way as motor symptoms, being often severe in off-periods[87,88]. They may appear in all stages of Parkinson's disease, and also precede motor symptoms[89]. Although sometimes is difficult to identify depressive symptoms in this patients, several risk factors have been described for developing depression: severity of cognitive impairment, female sex, onset of parkinsonian symptoms before age 40 and history of depression prior to diagnosis of Parkinson's disease[90].

Prevalence of depressive symptomatology varies from 20% to 50% in Parkinson's disease. Depressive symptoms are frequently associated with greater disability, rapid progression of motor symptoms and cognitive impairment[91-93]. In fact, depression is the main negative factor that impacts quality of life in Parkinson's disease and it may precede motor symptoms for years[94].

Depression in Parkinson's disease is different in some aspects from major depression: on one hand, guilty or worthlessness and suicidal ideation are not common[95]. Furthermore, only a small percentage of patients have major depression (2%-7%) and most of cases experience minor depression or mild depressive symptoms.

However, despite of frequency and importance of depression in Parkinson's disease, there are not any defined diagnostic criteria for depressive disorder in Parkinson's disease. The current gold standard

for establishing the diagnosis of depression in these patients remains the DSM criteria[96,97].

PSP

PSP is a rare neurodegenerative disorder clinically characterized by symmetrical parkinsonism, postural instability and falls, slowing of vertical saccades and frontal lobe symptoms. It's no so rare degeneration. Although classically grouped into the so-called Parkinson-plus syndromes, nowadays PSP is considered into the Frontotemporal Degeneration Complex. Histopathologically PSP presents cellular inclusions composed by aggregated tau protein that accumulate in prefrontal cortex, globus pallidus, substantia nigra and subthalamic nucleus.

Behavioral abnormalities are often observed in PSP patients, more than half experiencing apathy, depression, and sleeping problems[98]. In fact, the most common feature of mood disorder is apathy, found in more than 90% of PSP patients[99].

Vascular dementia

Cerebrovascular disease is the second most common cause of acquired cognitive impairment. Vascular cognitive impairment and vascular dementia are within the spectrum of cognitive impairment occurring as a result of cerebrovascular disease. The current definition of vascular dementia includes the hereditary vascular dementias, multi-infarct dementia, post-stroke dementia, subcortical ischemic vascular disease and atherosclerotic dementia dementia[100].

Referring to behavioural and psychological symptoms of vascular cognitive impairment, depression and apathy are the commonest symptoms found in most of studies[101-103]. Emotional lability is frequently reported as a classic feature of pseudobulbar palsy[104].

In comparison to Alzheimer's disease, prevalence of depressive symptoms in several studies has shown different results. Some studies showed higher prevalence and severity of depression in vascular dementia[105-107], but other publications has not been found significant differences in the prevalence of neuropsychiatric symptoms between Alzheimer's disease and vascular dementia patients[108-111].

In relation to the affected lobe, patients with posterior circulation lesions have shown a significantly lower rate of depression than patients with middle cerebral artery lesions. Moreover, depression following posterior circulation infarcts was of significantly shorter duration than depression following carotid strokes. Patients develop more severe depressive symptoms according to severity of stroke[112]. In addition, depression may be commoner in subcortical strokes[113] (lacunar state).

THERAPEUTIC APPROACH AND RECOMMENDATIONS

A wide variety of treatments have been used to improve neuropsychiatric symptoms in neurologic diseases including antipsychotics, antidepressive drugs or anti-convulsant ones. Non-pharmacological interventions like supportive psychotherapy or psychological counseling are recommended either complimentary or alternative to drug treatment.

Regarding primary dementias, cholinesterase inhibitors have shown a mild but consistent effect on behavioral symptoms in Alzheimer's disease[114]. They reduce behavioral changes and delay cognitive and functional decline and should be initiated earlier than others pharmacological treatments.

Neuropsychiatric symptoms like apathy, depression, and aberrant motor behavior are the most likely to improve[115,116]. Memantine tends to improve specially agitation and irritability more than mood symptoms, apathy, and aberrant motor behavior. Combination therapy with cholinesterase inhibitors may have advantages in patients with multiple neuropsychiatric symptoms[117]. Current evidence also recommends to use cholinesterase inhibitors in patients with Parkinson's disease with a positive effect on cognitive function and behavioral disturbances. The effect on body Lewy disease remains unclear but usually it's similar at the effect on Alzheimer's disease. Neither cholinesterase inhibitors nor memantine have shown effectiveness in frontotemporal dementias.

Besides cholinesterase inhibitors and memantine, other psychopharmacological treatments should be used individually considering the presence of comorbidities and associated medications. In most of patients, useful treatments are SSRIS, specially sertraline and citalopram[118-123]. Paroxetine has been proposed specifically to fontotemporal dementia[124,125] and Parkinson's disease[126]. However, paroxetine has been associated to further impairment of motor symptoms in some patients[127].

In case of Parkinson's disease patients, is important to determine if depressive symptoms appear in off-periods. In this case, adjustment of antiparkinsonian medication usually allows to obtain an improvement of depression.

Generally, classical drugs as tricyclic antidepressants are poorly tolerated; worsening of mental status is a common secondary effect of its use in this group of patients. By its anticholinergic effect, tricyclic antidepressants tend to worse cognition and also generate orthostatic hypotension, specially in patients with advanced disease[128]. Fluoxetine and fluvoxamine are less used because of potential interactions. Other antidepressive drugs, such as mirtazapine, trazodone, duloxetine and venlafaxine may be used but possibly their use may be restricted to cases of very limited or no response to initial treatment with SSRI[117]. Atypical antipsychotics should be used with extreme caution: their side effects are frequent in dementia patients and easily overcome the possible therapeutic effect. An increase of death rates have been found with the use

of every antipsychotic drug, more marked with typical ones but also present with atypical ones; so these drugs are commonly restricted to old age patients by administrative normatives in most of countries.

The commonly proposed therapeutic strategy to establish the effective dosage of antidepressive and antipsychotic drugs is that of "start low and go slow". That means to start with low doses and progressively increase dosage with caution to minimize side effects. Clinical evolution should be closely observed and clinician must evaluate the possibility of modifying or stopping the pharmacological treatment according to the intensity of symptoms and the potential harm of drug treatment.

Specially in elderly, depressive symptoms may be first manifestation of a neurodegenerative disease. Although clinical patterns of neurodegenerative diseases are different, the presence of depression may be insufficient to distinguish between them. Thus, in most cases it is required to observe closely the clinical evolution to lead the accurate diagnosis. Specific complementary test like neuroimaging or lumbar punction may be useful and can provide data to ascertain a correct diagnosis.

In conclusion, neuropsychiatric symptoms and specially depression are frequent in dementia stages and in most of neurodegenerative diseases. Depressive symptoms contribute significantly to increase disability, morbidity, caregiver burden and illness costs. To limit their extent, adequate identification and evaluation of these symptoms is essential to initiate appropriate early non-pharmacological and pharmacological treatment.

Abstract

Chronic lymphocytic leukemia (CLL) is the most common leukemia in the western world. Despite significant advances in therapy over the last decade CLL remains incurable. Current front-line therapy often consists of chemoimmunotherapy-based regimens, most commonly the fludarabine, cyclophosphamide plus rituximab combination, but rates of relapse and refractory disease are high among these patients. Several key signaling pathways are now known to mediate the survival and proliferation of CLL cells *in vivo*, the most notable of which are the pathways mediated by the B-cell receptor (BCR) and cytokine receptors. A better understanding of the pathogenesis of the disease, the underlying biology of the CLL-cell and the roles of the tumour microenvironment has provided the rationale for trials of a range of novel, more targeted therapeutic agents. In particular, clinical trials of ibrutinib and idelalisib, which target the Brutons tyrosine kinase and the delta isoform of phosphoinositol-3 kinase components of the BCR signaling pathway respectively, have shown extremely promising results. Here we review the current literature on the key signaling pathways and interactions of CLL cells that mediate the survival and proliferation of the leukemic cells. For each we describe the results of the recent clinical trials and *in vitro* studies of novel therapeutic agents.

Key words: Chronic lymphocytic leukemia; Therapy; Microenvironment; Leukemia; Novel

Core tip: The treatment of chronic lymphocytic leukemia (CLL) is in a period of unprecedented revolution. A better understanding of the mechanisms that drive the survival and proliferation of CLL cells has led to the development of novel therapeutic strategies. This review article is a timely summary of the results of many of the recent key clinical and pre-clinical studies of novel therapeutic agents for CLL.

INTRODUCTION

Chronic lymphocytic leukemia (CLL) is characterized by the proliferation and accumulation of CD5/CD19 positive monoclonal B-lymphocytes in the peripheral blood, bone marrow and lymphoid organs. The introduction of the fludarabine (F), cyclophosphamide (C), rituximab (R) regimen[1,2] represented a major advance in the clinical management of the disease with durable remissions beyond 10 years being achievable in a proportion of patients[3]. However, novel treatment strategies are still required for the significant proportion of patients that do not respond to or relapse following FCR treatment.

In recent years it has become increasingly apparent that successful treatment of CLL must target the proliferative compartment of the disease that resides in proliferation centres within the lymph nodes and marrow. Interaction of CLL cells with the tumour microenvironment is believed to be a major contributing factor to resistance and relapse following treatment with the more conventional regimens, including FCR[4]. A better understanding of the role of the microenvironment in CLL-cell survival, proliferation and in drug-resistance has provided the rationale for the clinical trials discussed in this review.

B-CELL RECEPTOR PATHWAY

Given the importance of B-cell receptor (BCR)-mediated signaling in the survival and proliferation of CLL cells[5] much of the recent work on novel therapeutic agents in CLL has focused on inhibitors which target specific components downstream of the receptor. Most notably, clinical trials of ibrutinib and idelalisib, which target the Brutons tyrosine kinase (Btk) and delta isoform of phosphoinositol-3 kinase (PI3-kinase δ respectively, have shown extremely promising results in recent clinical trials.

Ibrutinib

Ibrutinib has been shown to induce apoptosis of CLL cells *in vitro* against both cells in media alone and cells cultured with micro-environmental mimics such as stromal contact or culture with soluble factors such as CD40L, interleukin 4 (IL-4) and BAFF[6]. Ibrutinib interferes with CLL-cell adhesion and migration, which is believed to be important in its mechanism of action[7,8].

RESONATE, a randomized trial comparing ibrutinib to the CD20 monoclonal antibody ofatumumab as single agents in previously treated patients demonstrated significantly better overall response (OR) and survival (OS) rates in the ibrutinib arm of 42.6% *vs* 4.1% and 90% *vs* 81% respectively[9]. The findings of the RESONATE trial have recently been updated showing that these effects are seen regardless of genetic mutation and previous treatment, furthermore an improved haematologic function has also been shown[9,10]. In patients treated with ibrutinib, the phenomenon of treatment-induced lymphocytosis occurs, which is thought to be due to the redistribution of leukemic cells from the tissue microenvironments into the circulation[11], highlights the mechanisms that CLL cells rely on to populate the lymph node and marrow environments. In a phase Ⅱ trial combining ibrutinib with rituximab in 40 high-risk patients (defined as patients with deletion of 17p, mutation of *TP53* or deletions of 11q with disease relapse) the OR rate was 95% of which 8% of patients achieved a complete remission (CR)[12]. It is worth noting that the treatment-induced lymphocytosis in this trial resolved faster than in patients treated with single agent ibrutinib, supporting the rationale for combining inhibitors of Btk with agents that target CLL cells liberated from the lymph nodes and marrow. Investigations into ibrutinib-containing regimens are continuing with a recent dose escalation trial that investigated ibrutinib in combination with lenalidomide. With only 11 patients enrolled and evaluable data on 9 the results of this trial are currently limited, but have shown an OR rate of 100% and do suggest that the combination is well tolerated[13].

Idelalisib

Idelalisib specifically targets the - isoform of PI3-kinase, which in turn decreases phosphorylation of Akt and induces caspase-dependent apoptosis. Idelalisib induces apoptosis of primary CLL cells *in vitro* cultured either in media alone or in combination with factors such as CD40L and tumor necrosis factors (TNF)-α. As well as its cytotoxic effects, idelalisib inhibits the interaction of the leukemic cells with the tumour microenvironment[14,15].

Several phase Ⅰ, Ⅱ and Ⅲ studies of idelalisib as a single agent or in combination with the CD20 antibodies ofatumumab or rituximab and bendamustine have been conducted or are on-going for relapsed/refractory or previously untreated elderly patients. In a phase I trial of idelalisib as a single agent in 54 patients with poor risk characteristics the OR rate was 72%, with 81% of patients demonstrating a nodal response[16].

A phase Ⅰ trial of idelalisib in combination with ofatumumab or rituximab demonstrated that these combinations are well tolerated. Among 40 patients the OR rate was 83% with 3% of patients achieving a CR. Notably, among the 11 patients with deletion or mutation of *TP53* the OR rate was 73%[17]. More recently, the results of a phase Ⅲ trial comparing idelalisib plus rituximab with placebo plus rituximab in 220 relapsed, co-morbid patients demonstrated a significant improvement in OR rate and survival in those patients treated with idelalisib in combination with rituximab; OR

rates were 81% *vs* 13% in the idelalisib and placebo arms respectively with OS rates of 92% *vs* 80%[18]. A phase Ⅱ trial of idelalisib in combination with rituximab in 50 previously untreated elderly (> 65 years) CLL or small lymphocytic leukemia (SLL) patients demonstrated an OR rate of 96% with a progression-free survival at 24 mo of 91%[19], supporting the use of the PI3-kinase inhibitor as potential first-line therapy. An extension to this trial is now underway investigating the use of idelalisib as a mono-therapy in elderly CLL/SLL patients; to date 37 patients have been enrolled and 27 evaluated with an OR rate of 81%[20].

A phase Ⅰ trial of idelalisib in combination with bendamustine and/or rituximab, fludarabine or chlorambucil and/or rituximab in relapsed refractory disease has proven these combinations are also highly active with an OR rate of 82% and a CR rate of 10%[21,22]. Phase Ⅲ trials of idelalisib in combination with rituximab are on-going with promising results[23].

Fostamatanib

The tyrosine kinases SYK and Lyn are also key components of the BCR signaling cascade and as such have been proposed as therapeutic targets. Suljagic *et al*[24] established a rationale for clinical trials of the SYK inhibitor fostamatanib by showing that the drug inhibits signaling downstream of the BCR and increases the survival of Eμ-TCL1 transgenic mice, which represent an *in vivo* model of CLL disease.

A phase Ⅱ trial of fostamatanib (R788) demonstrated activity against relapsed/refractory CLL/SLL disease, with 6 of 11 patients achieving an objective response[25]. Interestingly, 9 of the 11 patients had evidence of treatment-induced lymphocytosis, similar to the effects observed with both ibrutinib and idelalisib. Although there appear to be no plans to pursue clinical trials of fostamatanib for CLL, studies of the next generation of SYK inhibitors, PRT318 and P505-15, have shown that both compounds induce apoptosis under *in vitro* conditions that mimic the microenvironment, inhibit CLL cell migration and chemokine secretion and prevent BCR-induced activity of mitogen activated protein kinase (MAPK)-extracellular regulated kinase (ERK)1/2[26].

Dasatinib

Dasatinib is a broad-spectrum inhibitor of Src-kinases and Abl and in CLL patients appears to function mainly through inhibition of Lyn. Dasatinib has been shown to inhibit the phosphorylation of Akt, ERK1/2 and p38 and induce apoptosis of CLL cells *in vitro*[27].

In a phase Ⅱ trial of dasatinib, among 15 relapsed/refractory CLL patients, 3 (20%) achieved a partial response (PR), 5 a nodal response and 1 had a reduction in node size and lymphocyte count[28]. A similar PR rate (16.7%) was observed in a more recent phase Ⅱ trial of dasatinib in combination with fludarabine[29], suggesting that either as mono-therapy or in combination with fludarabine, dasatinib has, at best, modest effects against relapsed/refractory, fludarabine-resistant CLL disease.

Novel BCR-pathway inhibitors in pre-clinical development

The clinical trial data of idelalisib discussed above highlight the potential of PI3-kinase targeted therapies for CLL and provide the rationale for investigations of novel agents that target multiple isoforms of PI3-kinase. SAR245409 and duvelisib (IPI-145) are inhibitors of the α/δ and δ/γ isoforms of PI3-kinase respectively. Thijssen *et al*[30] have shown that unlike SAR245409 neither BYL719, a specific α isoform inhibitor, nor idelalisib, completely block the phosphorylation of mTOR and that SAR245409 is more cytotoxic *in vitro* than idelalisib. Similarly, Dong *et al*[31] have shown that duvelisib is cytotoxic against CLL-B cells *in vitro* with little effect on normal B cells and that duvelisib prevents the spontaneous development of leukemia and delays leukemic cell engraftment in the Eμ-TCL1 mouse model. Early results of a phase Ⅰ clinical trial of duvelisib for relapsed/refractory CLL disease suggests that the drug is well tolerated with an OR rate of 55% among 54 patients. Pharmacodynamic studies within this trial suggest that duvelisib modulates chemokine and cytokine levels, cell proliferation and the activity of Akt[32]. Direct inhibition of Akt has also been proposed as a therapeutic option for CLL. In a recent study, Ding *et al*[33] demonstrated that the Akt inhibitor MK2006 induces apoptosis of CLL irrespective of poor prognostic characteristics.

MEK1/2 is a key component of the MAPK, ERK pathway, which promotes the survival and proliferation of multiple forms of cancer cell. In B-CLL cells MAPK-ERK signaling is activated in response to BCR ligation and as such is believed to play a role in promoting CLL-cell survival. However, we recently demonstrated that MEK1/2 inhibition by Binimetinib (MEK162, Novartis) has little effect against CLL cells in the absence of factors that mimic the tumor microenvironment[34]. The efficacy of Binimetinib only under *in vitro* conditions that mimic tonic BCR stimulation highlights the importance of considering the interaction of leukemic cells with the tumour microenvironment as part of similar *in vitro* studies[34]. Similar studies have also recently been described for the MEK1/2 inhibitor trametinib. Apollonio *et al*[35] described the efficacy of this MEK1/2 inhibitor against primary CLL cells and in a mouse xenograft model of CLL. In this study trametinib had a marked effect on the viability of primary CLL cells in which ERK1/2 was constitutively phosphorylated, an indication of CLL cell anergy, and inhibited tumour growth and delayed leukemic cell dissemination in the mouse model.

In normal B-cells the Raf-1/MEK/MAPK-ERK1/2 pathway is negatively regulated by the Raf kinase inhibitory protein (RKIP). However, in CLL-cells dysfunction of RKIP may lead to over activity of the Raf-1 and Akt-mediated pathways. Our recent studies suggest that the RKIP inhibitor locostatin induces apoptosis in CLL cells cultured in media and on a CD40L fibroblast layer *via* a

mechanism that involves the down-regulation of both ERK1/2 and Akt, highlighting the potential of RKIP as a therapeutic target in CLL[36].

CC-115 is a novel dual inhibitor of both the mammalian target of rapamycin (mTOR) and DNA protein kinase (DNA-PK). Signals downstream of PI3-kinase and Akt are mediated by a complex consisting of mTOR1 and 2, while DNA repair and genomic stability rely on the function of DNA-PK. DNA repair pathways are of interest in CLL as mutations in the DNA repair machinery, particularly in the *ATM* and *TP53* genes, are associated with poor prognosis. Thijssen *et al*[37] demonstrate that CC-115 is cytotoxic against primary CLL cells irrespective of *ATM* mutational status.

The clinical efficacy of fostamatanib discussed above and several recent *in vitro* studies suggest that CLL cells are sensitive to SYK inhibition. A study by Purroy *et al*[38] suggests CLL cells may be more sensitive to SYK inhibition by TAK-659 than to fostamatanib in a co-culture model of the CLL tumour microenvironment and that this agent may be effective in synergy with fludarabine, ibrutinib and idelalisib. Based on promising results in acute myeloid leukemia, Dielschneider *et al*[39] investigated the efficacy of gefitinib against CLL cells. The drug was effective particularly against CLL cells expressing ZAP-70, which represents a poor prognostic sub-group. Similar studies of the SYK inhibitor GS-9973, also demonstrate cytotoxicity against primary CLL cells *in vitro* and synergy with idelalisib[40].

Finally, the constitutive activity of protein kinase C (PKC) in CLL cells and its role in nuclear factor-kappa B (NF-κB)-mediated cell survival[41] suggest that it may also represent a therapeutic target in CLL[42]. Enzastaurin and sotrastaurin (AEB071) are PKC inhibitors in pre-clinical and early clinical trials for a range of malignancies including CLL. El-Gamal *et al*[43] have shown that sotrastaurin is cytotoxic against CLL cells in both *in vitro* and *in vivo* pre-clinical trials. While the results of trials of enzastaurin (reviewed in[44]) suggest that targeting PKC may well have well have some efficacy in B-cell malignancies, including CLL, as the authors suggest understanding the mechanisms that account for the limited therapeutic actions of enzastaurin may lead to the development of novel PKC-targeted agents or novel combinations.

CELL TO CELL INTERACTIONS WITHIN THE CLL TUMOUR MICROENVIRONMENT

Successful treatment of CLL relies on targeting the proliferative pool of CLL cells that populate the lymph node and bone marrow microenvironments. Pre-clinical models of the tumour microenvironment involving co-culture of primary CLL cells with nurse-like, mesenchymal, stromal or T-cells significantly reduce the spontaneous apoptosis rate of the leukemic cells through mechanisms that likely depend on direct cell to cell contact and the production of cytokines and growth factors. The association between CLL and stromal cells is also likely to facilitate the interaction of CLL cells with T-cells.

It is now widely acknowledged that the proportions and function of each of the T-cell subsets is abnormal in CLL; a high proportion of T-regulatory cells and the limited cytotoxic capacity of $CD8^+$ T-cells may suppress the anti-tumour functions of $CD4^+$ T-cells and allow CLL cell proliferation to proceed unchecked[45]. Recent studies suggest that the formation of the immunological synapse between T-cells and antigen presenting cells is defective in CLL due to dysfunction of the actin cytoskeleton in the T-cells[46]. Data from the same study, involving culture of CLL cells with allogeneic T-cells from healthy individuals, suggested that the CLL cells induce these defects in the cytoskeleton of the T-cells enabling the tumour cells to escape normal immune surveillance.

Lenalidomide

On the strength of trials in other B-cell malignancies lenalidomide was initially trialed in a cohort of CLL patients with relapsed or refractory CLL, with OR and CR rates of 47% and 9% respectively[47]. While the exact mechanisms of action of lenalidomide are not clear a recent study employing lenalidomide to consolidate first line therapy with pentostatin, cyclophosphamide, rituximab (PCR), identified a long-term improvement in anti-tumour T-cell synapse formation and overall response to chemo-immunotherapy[48], suggesting that as well as direct tumor activity through altered activity of an E3 ubiquitin-ligase[49] lenalidomide has immuno-modulatory properties and may at least partially correct the T-cell defect and improve immune surveillance in CLL. Lenalidomide also has marked anti-inflammatory effects that will be discussed in more detail later.

Clinical trials of lenalidomide as a single agent have demonstrated its efficacy against relapsed/refractory disease[50] and in the treatment of elderly patients[51] and more recently as a frontline therapy in combination with rituximab[52,53]. Lenalidomide has also proven effective in combination with rituximab as a salvage therapy for relapsed/refractory disease[54]. Several trials using lenalidomide as maintenance therapy following first and second-line FCR therapy are in progress (CONTINUUM study, clinicaltrials.gov NCT00774345, ALLG Residuum and DCLLSG)[55,56].

CAR-T cells

Studies suggest that the *ex vivo* manipulation of T-cells from CLL patients to produce T-cells with chimeric antigen receptors (CAR T-cells) also represents a method of overcoming the defect in T-cell surveillance of the leukemic clone[57]. In CLL, trials of CAR T-cells expressing a receptor to the CD19 antigen (CTL019) have proven successful in the treatment of relapsed/refractory disease or as consolidation following first-line treatment of high-risk patients (defined as those patients with un-mutated *IgVH* genes, or deletion

of 17p- or 11q-) with PCR. In a trial of 14 relapsed/refractory patients, 4 (29%) achieved a CR and 4 (29%) a PR with an OR rate of 57%[58]. Of the 6 patients enrolled on the phase Ⅰ consolidation trial 2 patients who were in PR after therapy with PCR achieved a CR following the infusion of the CAR-T cells, suggesting that CAR-T cells may be useful in increasing CR rates[59].

The study by Porter *et al*[58] suggests that the advantages of this form of cellular therapy include the provision of ongoing tumor surveillance through the *in vivo* expansion of the CAR T-cells and the specificity of the therapy for B-cells, although the effects on normal B-cells may result in B-cell aplasia. The long-term activity of CAR T-cells is illustrated by the delayed onset of tumour lysis syndrome[60]. Porter *et al*[61] have now commenced a phase Ⅱ trial of CTL019 cells in patients with relapsed or refractory CLL, to 23 patients have been evaluated with a CR rate of 22% and a PR rate of 17%.

Lucatumumab

Targeted blockade of CD40-mediated signaling in CLL cells represents a rational approach to interfering with the interaction between CLL and T cells, since CD40-mediated signaling promotes CLL-cell survival and proliferation[62]. Lucatumumab, a humanized anti-CD40 agonist antibody was shown to inhibit B-cell growth and induce antibody-dependent cellular cytotoxicity *in vitro*[63]. However, the results of a phase Ⅰ trial of lucatumumab (HCD122) were disappointing; of the 26 patients on trial, 17 had stable disease for a mean duration of 76 d but only 1 patient achieved a PR. The authors concluded that further trials of lucatumumab should focus on incorporating the antibody in combination therapies[64].

Bevacizumab

Despite data highlighting the important angiogenic role of vascular endothelial growth factor (VEGF) in CLL proliferation centres within the secondary lymphoid structures[65] and promising pre-clinical data[66,67] the results of a phase Ⅱ trial of the VEGF inhibitor bevacizumab in CLL proved disappointing. No clinical efficacy of bevacizumab was demonstrated among 13 patients with relapsed/refractory disease resulting in early closure of this trial[68].

Novel inhibitors of cell-to-cell interactions in pre-clinical development

CC-122 is a next generation immunomodulatory drug that is believed to have mechanisms of action similar to lenalidomide. Blocksidge *et al*[69] demonstrate that the anti-proliferative effects of CC-122 against primary CLL cells cultured in a CD154/IL-21 tumour model were superior to those of lenalidomide.

C6-ceramide is a nanoliposomal molecule and a member of the ceramide family of lipids. Ceramides are "tumor suppressor" lipids that induce anti-proliferative and anti-apoptotic responses in a variety of malignant cells[70]. Doshi *et al*[71] have shown that C6-ceramide induces tumour regression in an *in vivo* mouse model of CLL and that these effects are likely mediated by its effects on STAT3 phosphorylation and signaling.

BI 836826 is an anti-CD37 monoclonal antibody that mediates its effects on CLL cells through both antigen dependent cell-mediated cytotoxicity and by directly inducing apoptosis[72]. Stephens *et al*[73] investigated the effects of BI 836826 in combination with established BCR pathway inhibitors and suggest that BI 836826 may be effective in combination with idelalisib for CLL, particularly for those patients with *TP53* mutations.

The immunomodulatory drug dimethyl fumarate (DMF) is believed to exert its effects *via* down-regulation of NF-κB activity and TNF signaling. DMF is currently in clinical use for the treatment of psoriasis[74]. In keeping with the role of NF-κB in the survival of CLL cells[75], Wu *et al*[76] demonstrated that DMF is cytotoxic against CLL cells *in vitro* and is synergistic with ibrutinib, *via* a mechanism of action that involves down-regulation of Wnt signaling.

INFLAMMATORY PATHWAYS

Cytokines and chemokines play a significant role in the survival, proliferation and homing of CLL cells to the tumour microenvironment. Studies suggest many of these soluble factors are elevated in the sera of CLL patients compared to normal individuals[77], while *in vitro* studies involving the addition of cytokines to primary CLL cells in culture highlight their role in promoting cell survival, proliferation and migration[78]. Levels of cytokine expression have been linked with the disease course of CLL[77]. However, it remains to be elucidated whether many of these factors are derived from the leukemic cells or accessory cells within the tumour microenvironment.

Targeting the mechanisms that enable CLL cells to home to lymph nodes and to the marrow or interfering with the soluble factors that promote CLL cell survival have been proposed as being effective methods of limiting their longevity and proliferation.

Lenalidomide

In addition to the anti-leukemic effects discussed earlier there is also evidence suggesting lenalidomide, as with its analogue thalidomide, may have potent anti-inflammatory activity through suppression of cytokine and TNF-α production[79].

Plerixafor (AMD3100)

Data from a preclinical study of the CXCR4 inhibitor plerixafor suggests that the agent effectively blocks the capacity of CLL cells to home to the tumour microenvironment, overcomes the protective effect of *in vitro* models of the microenvironment and may represent a means of mobilizing tumor cells to increase the efficacy

of chemotherapies[80]. In a phase Ⅰ dose-escalation trial of 14 patients with previously treated disease plerixafor in combination with rituximab was well tolerated and was associated with a marked increase in lymphocyte count, suggesting successful mobilization of CLL cells from the lymph nodes and marrow[81].

PRO-APOPTOTIC/CELL-CYCLE INHIBITION

CLL-cell survival and proliferation relies on the over-expression of the anti-apoptotic protein B-cell lymphoma 2 (Bcl-2)[82] and the activity of cyclin-dependent kinases (CDKs)[83]. Redressing the balance of expression of the Bcl-2 family proteins towards a pro-apoptotic profile and inhibition of CDKs has been a focus of several recent clinical trials in CLL.

ABT-199

ABT-199 is the most clinically advanced compound among several developed known as BH3 mimetics, so-called after the binding domain that is common to the BH3-family of proteins, which includes Bcl-2. Tumour lysis syndrome appears to be a complication associated with treatment with ABT-199, particularly in the earlier trial cohorts; Souers *et al*[84] reported tumour lysis in three of their relapsed/refractory CLL patients on trial. In a recent phase Ⅰ clinical trial, ABT-199 was highly active against relapsed/refractory, FCR-refractory or 17p-deleted disease; in 56 relapsed/refractory CLL or SLL patients the OR rate was 84%, of which 20% achieved a CR[85]. Within this same trial those patients with deletion of 17p or fludarabine-refractory disease displayed similar OR rates of 82% and 78% respectively. Phase Ⅱ trials of ABT-199 as a single agent or in combination with rituximab (ClinicalTrials.gov NCT01682616) or obinutuzumab (ClinicalTrials.gov NCT01685892) for 17p-deleted or relapsed/refractory CLL patients are ongoing. To date, 49 patients have been enrolled in a trial combining ABT-199 and rituximab, which has had an OR rate of 86% and CR rate of 31%[86]. A trial of ABT-199 and obinutuzumab has recruited 9 participants to date but has yet to report any response or remission rates. Findings of these latter trials suggest the adjusted regimens and novel combinations of ABT-199 are well tolerated with tumour lysis syndrome having only been observed in 1 study participant[87].

Dinaciclib

Pre-clinical studies of flavopiridol provide a strong rationale for CDK inhibition as a therapeutic option in CLL, with a mechanism of action that includes both cytostatic and pro-apoptotic effects. While flavopiridol is undoubtedly the most thoroughly studied CDK inhibitor in CLL, its narrow therapeutic window and toxicity has prompted development of newer, more specific inhibitors, including dinaciclib. While *in vitro* studies suggest that dinaciclib induces apoptosis in CLL cells irrespective of poor-risk indications, including 17p deletion, it fails to overcome the protective effects of CLL-cell co-culture with a stromal layer[88]. These data suggest that the clinical efficacy of dinaciclib may require its incorporation into combination therapies. The results of a phase Ⅲ trial of dinaciclib are yet to be presented but recent data from an update on a phase Ⅰ dose escalation trial of 52 relapsed/refractory patients suggests that dinaciclib is clinically active and well tolerated in this setting. Of the 48 patients assessed, the overall response rate was 58%. Importantly, 57% of the patients with deletion of 17p13 and 63% with deletion of 11q23 achieved at least a PR[89]. A phase 1b/2 study of dinaciclib and ofatumumab has also recently commenced and to date 36 patients have been enrolled with a PR rate of 33% and stable disease in 56% of patients[90].

Novel pro-apoptotic/cell cycle inhibitors in pre-clinical development

MLN4924 is an inhibitor of the NEDD8-activating enzyme. It is believed that MLN4924 induces DNA damage and cell cycle arrest through its effects on Cdt1[91]. MLN4924 has been shown to induce apoptosis in primary CLL cells stimulated with CD40L and IL-21 and, although the exact mechanisms of action remain unclear, Cdt1 accumulation was also demonstrated in two further studies[92,93].

It is well established that mutations of *TP53* and *ATM* are associated with unchecked DNA repair in cancer and poor risk disease in CLL[94]. Inhibition of DNA repair which triggers accumulation of DNA damage has been proposed as a method for overcoming resistance to genotoxic agents. AZD6738 is one such drug which targets the Ataxia Telangiectasia and Rad3 related (ATR) protein and inhibits ATR-mediated DNA repair. Stankovic *et al*[95] and Kwok *et al*[96] have shown that AZD6738 is cytotoxic against CLL cells *via* a mechanism of action that involves the accumulation of DNA damage. Furthermore, studies suggest AZD6738 is synergistic with the DNA-damaging agents chlorambucil, fludarabine, bendamustine and cyclophosphamide and the PARP inhibitor, olaparib.

TARGETED THERAPY RESISTANCE MECHANISMS AND COMBINATION THERAPIES

There is emerging evidence that a subset of patients develop resistance to BCR-pathway targeted therapy. In data presented at the recent European Haematology Association meeting late disease progression while on ibrutinib was found to be associated with the acquisition of mutations in *BTK* and *PLCγ2*[97].

In a recent report that utilised an *in vitro* model of the CLL tumour microenvironment, prolonged CD40

stimulation resulted in resistance to ABT-199, due to induction of Bcl-XL, Mcl-1 and Bfl-1. Interestingly, these CD40-mediated effects could be blocked by the broad-spectrum kinase inhibitor dasatinib[98]. Using interaction proteomics, Abl and Btk were identified as dominant targets of dasatinib in primary CLL cells. Like dasatinib, the Abl inhibitor imatinib, but not ibrutinib, can overcome resistance to the BH3-mimetics. Conversely, BCR and chemokine-mediated adhesion can be abolished by dasatinib and ibrutinib, but not by imatinib[98]. These reports highlight the complexity of potential resistance mechanisms and the potential of drug combinations for overcoming resistance to these agents. They also highlight the need for ongoing research into signal pathways, their interactions and the relationship between CLL cells and the microenvironment.

CONCLUSION

The treatment of CLL is in a period of extraordinary revolution with the advent of multiple novel, targeted therapies. Unprecedented response rates among relapsed/refractory, high-risk and elderly patients suggest that there may very soon be more effective treatment options available for these patients. While the trials of treatment naïve patients support the use of the novel agents in the frontline setting, this would currently be difficult to justify in patients other than the 17p-deleted subgroup, given the high response rates to FCR. Extended follow-up data from on-going and future trials will provide the key to determining the response duration or curative potential of the novel agents reviewed here.

Abstract

Malignant cardiac arrhythmias which result in sudden cardiac death may be present in individuals apparently healthy or be associated with other medical conditions. The way to predict their appearance represents a challenge for the medical community due to the tragic outcomes in most cases. In the last two decades some ventricular repolarization (VR) markers have been found to be useful to predict malignant cardiac arrhythmias in several clinical conditions. The corrected QT, QT dispersion, Tpeak-Tend, Tpeak-Tend dispersion and Tp-e/QT have been studied and implemented in clinical practice for this purpose. These markers are obtained from 12 lead surface electrocardiogram. In this review we discuss how these markers have demonstrated to be effective to predict malignant arrhythmias in medical conditions such as long and short QT syndromes, Brugada syndrome, early repolarization syndrome, acute myocardial ischemia, heart failure, hypertension, diabetes mellitus, obesity and highly trained athletes. Also the main pathophysiological mechanisms that explain the arrhythmogenic predisposition in these diseases and the basis for the VR markers are discussed. However, the same results have not been found in all conditions. Further studies are needed to reach a global consensus in order to incorporate these VR parameters in risk stratification of these patients.

Key words: Electrocardiographic predictor; Ventricular repolarization markers; Ventricular fibrillation; Sudden cardiac death; QT interval; Corrected QT interval; QT dispersion; Tpeak-Tend interval; Tpeak-Tend QT ratio

Core tip: Malignant ventricular arrhythmias are a common cause of sudden cardiac death in clinical

practice. They may present in individuals apparently healthy or be associated with other medical conditions. It is possible to predict the appearances of ventricular arrhythmias by analysing ventricular repolarization markers through surface 12 leads electrocardiogram. It may represent a tool to evaluate the risk stratification and for achieving a better medical management of our patients.

Ventricular repolarization markers for predicting malignant arrhythmias in clinical practice. *World J Clin Cases* 2015; 3(8): 705-720 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/705.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.705

INTRODUCTION

An electrocardiogram (ECG) represents one of the most common medical tools used by physicians in clinical practice. Its adequate interpretation gives the possibility for diagnosing and predicting multiple cardiac diseases. These features accompanied by its relative low cost allow that ECG interpretation needs to be known by medical doctors of several specialities including internists, cardiologists, anaesthesiologists, family physicians, and all that have a direct contact with patients.

Sudden cardiac death (SCD) causes approximately 800000 deaths each year in the world[1]. It is often produced by malignant ventricular arrhythmias (MVA). In most cases it is derived from ventricular fibrillation, or less frequently, by monomorphic or polymorphic ventricular tachycardia and Torsades de Pointes[2]. MVA which may result in SCD frequently occur in sick hearts but around 15%-20% occur in healthy hearts[3].

Many people that develop MVA have a previous disease that may be the cause of this condition. By ECG analysis it is often possible to predict the development of ventricular cardiac arrhythmias in these patients. That is feasible by analysing several ventricular repolarization (VR) markers. Some of the most explored predictors in clinical practice are: QT interval and its correction by heart rate (QTc)[4], QT interval dispersion (QTd)[5] and other recently published markers like Tpeak-Tend (Tp-e)[6], Tp-e dispersion (Tp-ed)[7] and Tp-e/QT ratio[8]. These markers have demonstrated a high usefulness to indicate patients with a high risk to develop cardiac arrhythmias in multiple clinical conditions (Table 1).

The methods to measure these VR markers are not difficult. These VR markers are useful tools for evaluation of patients' risk to develop MVA. They help us make better medical decisions in the management of patients with various medical conditions.

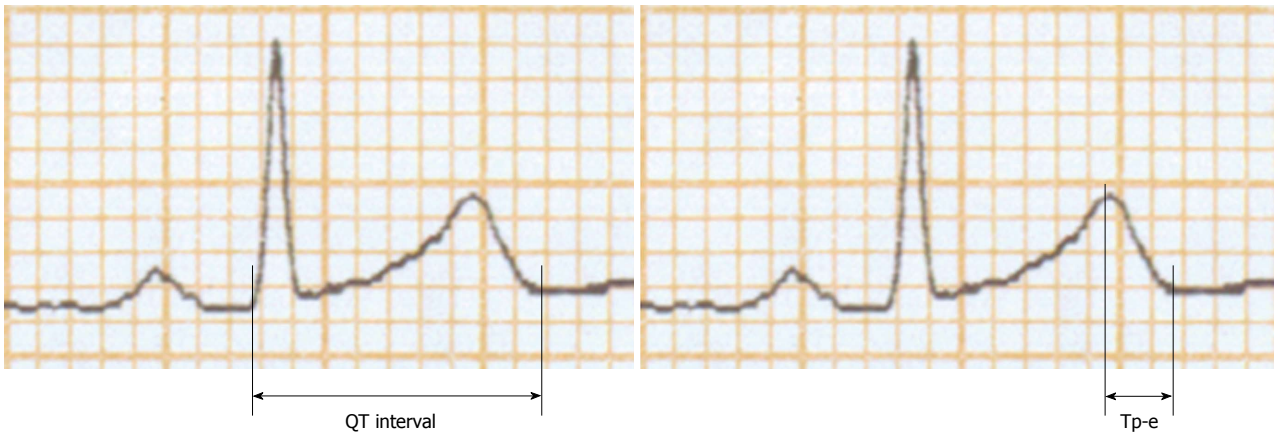
The aim of this manuscript is to review the usefulness of electrocardiographic VR markers to predict SCD in several conditions such as long and short QT syndromes, Brugada syndrome, early repolarization syndrome, acute myocardial ischemia, heart failure, hypertension, diabetes mellitus, obesity and high trained athletes and the possible mechanisms involved in order to encourage their clinical use to improve patients' risk evaluation.

QT, QTc and QTd

Measurement of the QT interval from surface 12 lead ECG was proposed at the beginning of last century[9]. It was primarily used to identify patients with arrhythmogenic syndromes which are common causes of SCD. These syndromes are long and short QT syndromes. However, its usefulness has been extended in multiple clinical conditions.

The QT interval is measured from the onset of the QRS complex to the end of the T wave (Figure 1). It should be recorded in Ⅱ or V5 leads where it has demonstrated the most predictive capacity. The QT interval may be modified by heart rate. Because of this, formulas have been proposed with the aim to reduce the heart rate influence. QT interval corrected by heart rate is known as QTc. Around 20 formulas to measure the QTc have been suggested. However, the most commonly used in clinical practice are the QTc by Bazzet's method [QTc = QT/(R-R)$^{1/2}$] and by Fridericia's method [QTc = QT/(R-R)$^{1/2}$] both expressed in seconds (Table 2)[10]. Also it is recommended to consider gender in QRS prolongation. Abnormal proposed values of QTcfor adults are $\geqslant$ 450 ms in men and $\geqslant$ 460 ms in women, while a QTc $\leqslant$ 390 ms is considered short[11]. Proposed normal values of QTcin children between 1 and 15 years are < 440 ms, with a range between 440 to 460 ms and abnormal values > 460 ms[12]. However, other authors have established that the 98th percentile limit for rate-adjusted QT is approximately 450 ms in children younger than 12 years of age[11].

Although QT interval and its correction (QTc) have been satisfactorily used to predict cardiac arrhythmias, another marker which evaluates its dispersion has been created and implemented in clinical practice. This marker is the QTd, which is defined as the difference between the maximum and minimum QT interval in surface 12 lead ECG[13]. QTd represents the heterogeneity state of VR. An increase in ventricular heterogeneity augments the vulnerable period time in the heart and predisposes to ventricular arrhythmias[14]. It was implemented in clinical practice by Day *et al*[15], and currently has been suitably evaluated as a marker to predict MVA. The values of QTd in normal subjects and general population are controversial. Reports from several studies reveal values of 33.4 ± 20.0 ms, with a range from 10.5 ± 10.0 ms to 71 ± 7.0 ms and a median in 37 ms. There are not statically significant differences between the genders while by other studies were found age-related differences < 10 ms[5]. Recently published data show that in healthy individuals a QTd > 58 ms increase 3.2-fold the risk of cardiovascular mortality[16] and those with a QTd $\geqslant$ 80 ms have 4-fold risk for cardiac death compared to patients with QTd



QTc = See different formulas to measure QTc
QTd = Maximun QT interval-Minimun QT interval on 12 leads ECG

Tp-ed = Maximun Tp-e-Minimun Tp-e on precordial leads ECG
Tp-e/QT ratio = Values of these markers on the specific lead

Figure 1 Methods to measure the different markers on electrocardiogram.

Table 1 Medical condition where have been investigated the ventricular repolarization markers

Long QT syndrome	Heart failure
Short QT syndrome	Hypertension
Brugada syndrome	Diabetes mellitus
Early repolarization syndrome	Overweight/obesity
Acute myocardial ischemia	Highly trained athletes
Kawasaki disease	Duchenne muscular dystrophy
Systemic lupus erythematosus	Liver transplantiation
Rheumatoid arthritis	Rheumatoid arthritis
Chronic renal failure	Rheumatic fever
Scleroderma	Chagas disease
Ankylosing spondylitis	Chronic hepatitis B
Obstructive sleep apnea	β-thalassemia
Spinal injury	Polycythemia vera

values < 30 ms[4].

Tp-e and Tp-ed

An increase in dispersion of repolarization and modifications in normal pattern of ventricular recovery are mechanisms associated with predisposition to develop cardiac arrhythmias[17]. Tp-e is the interval between the peak of the T wave and the end of the T wave (Figure 1). Commonly it is considered a reflection of the transmural cardiac repolarization expressed through surface 12 lead ECG. It has been proposed to indicate patients at an increased risk for ventricular arrhythmias[18,19]. Recent investigation examined Tp-e interval using a computer model of the rabbit heart ventricles. The authors concluded that Tp-e corresponds with global dispersion of repolarization[20].

Tp-e should be measured in precordial leads where it has been demonstrated to be more specific[21]. It has been found that in healthy men subjects Tp-e has a mean value in V5 lead of 94 ± 10 ms in men and 92 ± 11 ms in women[22]. However, there is not a consensus about Tp-e normal values and further investigations are needed to define them. Tp-e has been evaluated in several clinical conditions. It has been considered more useful to predict cardiac arrhythmias than QTc and its dispersion in some clinical conditions[23].

Table 2 Formulas to calculate the QTc

Name	Formula
Bazzet modificated by Taran and Szilagyi	$QTc = QT/(R\text{-}R)^{1/2}$
Fridericia	$QTc = QT/(R\text{-}R)^{1/3}$
Framingham	$QTc = QT + 0.154 \times (1 - RR)$
Hodges	$QTc = QT + 1.75 \times (HR - 60)$
Sarma	$QTc = QT - B1\ Exp(-k1 \times RR)$
	$QTc = QT\ [1 - Exp(-k2 \times RR)]$
	$QTc = QT\ (RR)^{1/2} + B3$
	$QTc = QT\ (RR)^{1/2}$
Ecuación de fuerza	$QTc = 453.65 \times RR1/3.02\ (R2 = 0.41)$
Van de Water	$QTc = QT - 0.087\ (RR - 1000)$
Matsunaga	$QTc = \log(600)\ QT/(\log RR)$
Kawataki	$QTc = QT/RR \times 0.25$
Mayeda	$QTc = QT/RR \times 0.604$
Larsen y Skulason	$QTc = QT + 0.125 \times (1 - RR)$
Schlamowitz	$QTc = QT + 0.205 \times (1 - RR)$
Wohlfart	$QTc = QT + 1.23 \times (HR - 60)$
Boudolas	$QTc = QT + 2.0 \times (HR - 60)$
Sagie	$QTc = QT + 0.154 \times (1 - RR)$
Malik	$QTc = QT/RR \times 0.371$
Lecocq	$QTc = QT/RR\ (0.314)$

This table was taken and adapted with permisson of Editor in Chief from Chávez González[10]. B and K are regression parameters. Exp: Exponential function with base e = 2.718; HR: Heart rate; RR: RR distance; QT: QT interval; QTc: Corrected QT interval.

Tp-ed was proposed by Castro Hevia *et al*[7]. Using this marker, they found an increased risk for ventricular arrhythmias in patients with Brugada syndrome than healthy controls. It has been examined in other diseases demonstrating its usefulness to predict malignant arrhythmias and SCD. However, limited information has been published about it and it should be studied in further investigations.

Tp-e/QT ratio

Tp-e/QT ratio is a novel index to predict cardiac arrhythmias[8]. It includes the values of transmural dispersion

(Tp-e) and spatial dispersion (QT) of VR (Figure 1). It has a substantial advantage than other markers because does not need to be corrected by heart rate. Tp-e/QT ratio almost has no variations between 60-100 beats/min. Tp-e/QT measured in healthy populations in precordial lead V6 which best reflects the trasmural axis of left ventricle has a mean value of 0.21 ± 0.03 and a range of value from 0.15 to 0.25[24].

Brief electrophysiological considerations

Heterogeneity of VR is associated with MVA[25]. QT interval is an index of VR and its variations represents its heterogeneity, commonly measured by QTd. An increase in VR dispersion increased the vulnerable period in the heart and predisposes to MVA. Regional differences in the potential action (inhomogeneity) may be found in several heart parts, but the transmural (ventricular wall) is the most important[14]. Ventricular myocardium is comprised by endocardial, epicardial and myocardial (M) cells. These cells are structurally similar, but have different electrophysiological properties. M cells have a longer action potential than cells located in epicardium and endocardium[26,27]. This property is noted in response to slowing of heart rate or agents than prolong the action potential. The prolonged action potential of M cells is due to a delay or blockage of K^+ and a rise in Na^+ currents[14]. In normal conditions, the physiological differences among these cells are minimized by electronic influences from well coupled myocytes[28]. The interplay between these opposing transmural forces among these cells determines the height and width of the T wave[29]. A rise in transmural repolarization determines a prolongation of T wave and subsequently the Tp-e. Multiple conditions determine pathophysiological changes with alteration in normal pattern of repolarization, increasing heart heterogeneity and the risk of MVA.

Application of QT, Tp-e, its dispersions and Tp-e/QT ratio to predict MVA in some diseases is discussed below.

Long QT syndrome

Long QT syndrome is an arrhythmogenic channelopathy characterized by severe alterations in VR. Long QT syndrome can be congenital or acquired.

The congenital long QT syndrome is caused by hereditary defects of molecular structure in ion channel proteins. Mutations in genes that codify to sodium and potassium channels cause a prolongation of VR. These alterations predispose to the development of Torsade de Pointes. This arrhythmia can result in ventricular fibrillation and SCD[30,31]. Long QT syndrome is often an autosomal dominant disease. It has been found mutations in 13 genes in long QT syndrome, determining 13 different types of this condition. However, the most known are long QT syndrome 1, long QT syndrome 2 and long QT syndrome 3, which are related with *KCNQ1*, *KCNH2* and *SCN5A* genes respectively[32].

The acquired form of long QT syndrome is a prolongation of QT interval that also predisposes to the patient to develop Torsade de Point and SCD. It may be caused by drugs[33], electrolyte abnormalities[34], hypothermia[35], toxic substances[36] and central nervous system injury[37].

Patients with QTc $\geqslant$ 500 ms have a high risk for developing MVA. Sauer *et al*[38] studied patients with long QT syndrome and the utility of QTc to predict SCD in these cases. Those with QTc duration between 500 and 549 ms were associated with a greater risk. In this same work, a QTc $\geqslant$ 550 ms was related with a 6.3-fold increase in the risk. Another investigation showed that patients with QTc duration $\geqslant$ 530 ms had a higher predisposition to develop cardiac arrest and SCD than those with shorter QTc values[39]. Recently, the risk for life-threating cardiac events was evaluated in 403 patients with long QT syndrome. Patients with multiple gene mutations had longer QTc than those with a single mutation (506 ± 72 ms *vs* 480 ± 56 ms respectively; $P = 0.003$) and a higher rate of life-threating cardiac events[40]. This study demonstrates the complexity of this syndrome, and how the gene mutations may modify the values of QTc and maybe other markers. The phenotypes derived from the gene mutations may express several clinical forms of this condition and make the interpretation of the results difficult.

In these studies, higher QTc values were associated with SCD. However, it has been demonstrated that the risk stratification in patients with congenital long QT syndrome is beyond QTc values. Also, it has been demonstrated that it is necessary to evaluate other variables as the gender, specific gene mutation/s and family history[41].

QTd is another marker evaluated in these cases. It has been found prolonged in patients with idiopathic long QT syndrome and represents a marker for therapeutic efficacy[42]. Yamaguchi *et al*[43] evaluated 27 patients with long QT syndrome. These patients were divided into two groups. The group A ($n = 27$) were patients with Torsades de Pointes and group B ($n = 15$) without this. The measurement of QTd in the first group was 112 ± 64 ms and in the second 70 ± 40 ms; $P = 0.0456$. These authors also evaluated the Tp-e. Values of Tp-e in V5 were 185 ± 46 ms in group A and 84 ± 18 ms in group B; $P < 0.0001$. Tp-e showed more significant differences than QTd between patients with and without Torsades de Pointes. Moreover, Tp-e has been found to be prolonged and to be an arrhythmogenic index in patients with long QT syndrome in other studies[44,45]. In this same investigation by Yamaguchi *et al*[43], Tp-e/QT ratio in V5exceeding 0.28 was also associated with the risk to develop Torsades de Pointes.

Short QT syndrome

Congenital short QT syndrome is a rare chanelopathy which increases the incidence of paroxysmal atrial fibrillation, ventricular tachycardia and/or fibrillation[46-48]. The diagnostic criteria are in debate and not yet been established. Most investigators use a grey area for the

QTc between 370 and 330 ms[49]. Recently data have been published which reveal an estimated prevalence of 0.7 per 100000 persons using a QTc ⩽ 300 ms as diagnostic criteria[50]. It has been proposed values of QTc values of 350 ms for men and 360 ms for women derived considering a cutoff values of ⩽ 2 SD from the mean value of general population[51]. Currently a QTc < 320 ms is accepted as an abnormal QTc value[52]. However, the risk to develop MVA in patients with abnormal short QTc values is undetermined. In patients with a prior history of atrial or ventricular fibrillation a QT interval less than 340 ms or a QTc less than 345 ms is usually sufficient[53]. Due to the non-existence of an international consensus of QT values for the diagnosis of short QT syndrome it has been proposed diagnostic criteria. These include the values of QTc, personal clinical history, family history and genotype[49].

Several mutations in potassium channels (KCNH2, KCNQ1 and KCNJ2) and calcium channels (CACNA1C, CACNB2B, CACNA2D1) have been identified in these patients[54].

Anttonen *et al*[55] studied patients with symptomatic short QT syndrome and evaluated some VR markers. They found that in the group of patients with short QT syndrome values of Tp-e/QT ratio were more prolonged than in the control group (0.30 ± 0.04 *vs* 0.24 ± 0.04, $P = 0.001$). Tp-e/QT ratio in the normal population is around 0.21. In this case both patients' groups had values over this point, but it seems that there is a cut off value which increases the risk of malignant arrhythmias which is unknown and should be explored by researchers and physicians. Similar results were found in another study. In this case after a follow-up with a 24-h ECG recording patients with short QT syndrome the Tp-e/QT ratio was 0.28 ± 0.03 and 0.21 ± 0.02 in control subjects, $P = 0.01$[56]. Also Tp-e has been demonstrated to be prolonged and correlated with transmural dispersion repolarization in an experimental model of short QT syndrome[57].

Short QT syndrome should be studied further like other conditions which are associated with genetic mutations and several clinical presentation forms. There are limited studies to conclude about the usefulness of VR markers to evaluate the risk of patients with short QT syndrome to develop MVA. There are points which should be analysed such as the absence of a consensus about diagnostic criteria, the low prevalence of this condition, the genetic heterogeneity and possible differences among age, gender and races. An advance in this field has been with the exploration of Tp-e/QT ratio with encouraging results.

Brugada syndrome

An alteration of VR markers has been observed in other clinical conditions. Brugada syndrome was established in 1992. It is defined by a J point and ST-segment elevation 2 mm or greater followed by a negative T wave in the ECG right precordial leads[58]. Recently, a consensus report from the International Society for Holter and Noninvasive Electrophysiology has established 2 Brugada patterns[59]. They combined the type 2 and 3 patterns outlined in a previous report[60]. This syndrome has been linked to *SCN5A* gene mutations which affect sodium channel function[61,62]. Its prevalence is around 1 in 2000 people[63] and may explain 20% of SCD in patients without structural cardiac disease[60]. Patients with Brugada syndrome have an increased risk to develop malignant cardiac arrhythmias. They have a high incidence of ventricular tachycardia and/or ventricular fibrillation in structurally normal hearts[64-67] and are asymptomatic in most cases[68].

A prolongation of QTc in right precordial lead has been found in patients with Brugada syndrome[69]. A mechanism to explain QTc prolongation in patients with Brugada syndrome may be by the rise of the action potential notch in the right than in the left ventricular epicardium observed in these subjects.

Castro Hevia *et al*[7] studied 29 patients with Brugada syndrome and 29 healthy controls. Patients were followed by a mean of 42.65 ± 24.42 mo. QTc > 460 ms in V2 lead was a risk factor for arrhythmias recurrence. Maximum Tp-e (measured in precordial leads) and Tp-ed were associated with more recurrence of life-threatening cardiac events in Brugada syndrome patients compared with controls. Also, all Brugada syndrome patients with Tp-e values ⩾ 100 ms or Tp-ed values > 20 ms had events during 60 mo of follow-up. As was established by the authors, this work gives a novel way to analyze the risk stratification in Brugada syndrome.

Recently 23 individuals (spontaneous $n = 10$ or drug-induced $n = 13$) with type 1 ECG pattern of Brugada syndrome received a programmed ventricular stimulation. Tp-e in leads V2 and Tp-e/QT ratio in leads V6 were significantly increased in patients who developed ventricular tachycardia/ventricular fibrillation. However, QTc (by Bazzet's method) and QTd did not show significant differences[70].

Several mechanisms have been formulated to explain arrhythmogenic risk in patients with Brugada syndrome. One of the most accepted establishes that the decrease of the depolarizing in sodium channels presented in this condition leads to a functional predominance of the repolarizing Ito current. These differences result in an increase in epicardial action potential notch. These changes produce an increase in the transmural heterogeneity of repolarization and a predisposition to MVA[71-73]. It has been proved that phase 2 reentry might appear under these conditions[74]. Another theory is based on depolarization abnormalities. It has been observed that there are regional differences between activation of the cells located in right ventricular tract outflow myocardium and the rest of right ventricle. These alterations modify cell interactions and increase the risk of reentry arrhythmias[72,73,75]. Also it has been proposed discontinuous conduction and malfunctioning channels as hypotheses to explain arrhythmogenic risk in these patients[72].

Brugada syndrome is a very complex condition with several genetic subtypes, arrhythmic pathophysiological mechanisms, electrocardiographic patterns and clinical presentations. Thus, it is possible to understand the multiple variants described in clinical practice. These characteristics also may influence the ability of VR markers to detect patients at high risk of malignant cardiac arrhythmias in this condition. In order to elevate clinical sensitivity of these markers in these cases investigators should be take into account these factors and to design clinical trials to achieve better conclusions.

Early repolarization syndrome

Early repolarization pattern consists in a J wave or J point elevation, a notch or slur of the terminal part of the QRS and an ST-segment elevation on surface 12 lead ECG[76-78]. It has prevalence from 6% to 24% in the general population[79] and is higher in trained athletes[80]. Early repolarization pattern was primarily considered a benign electrocardiographic finding[81,82]. However, recent studies have demonstrated an increased risk for malignant cardiac arrhythmias in these patients[83-85]. Early repolarization pattern adopts the name early repolarization syndrome when it is associated with cardiac arrhythmias and SCD[86]. Current studies have determinated three patterns of early repolarization and the risk to develop arrhythmic events of each of them[87].

The predisposition to have malignant ventricular arrhythmia in these patients was evaluated by Letsas *et al*[88]. They found increased values of Tp-e in leads V2, Tp-ed in precordial leads and Tp-e/QT ratio in leads V2 in patients with early repolarization pattern compared with those without it. There were not significant differences regarding markers studied in localization of early repolarization pattern (lateral *vs* infero-lateral). Previously, another investigation demonstrated that QTc was useful to predict primary end points in these individuals[89]. The use of these markers to indicate patients at risk to suffer SCD by MVA in this setting should be explored further.

The arrhythmogenic substrate of early repolarization syndrome has been proposed to be the outward current of Ito. Ito current is more prominent in epicardium than endocardium. This gradient voltage has been associated with the beginning of cardiac arrhythmias[90,91]. Furthermore, an investigational group demonstrated that there are abnormal large spatial repolarizations gradients in early repolarization that predispose to reentry cardiac arrhythmias[77]. Previous investigations demonstrated a high incidence of malignant arrhythmias in patients with early repolarization pattern in inferior/inferiolateral leads or in inferior, lateral and right precordial leads than patients with only in the lateral precordial leads[87]. These differences provide additional data and increase the complexity of this condition. As the arrhythmogenic index may be variable depending of ECG topography, VR markers should be explored independently to reach trusty results.

Acute myocardial ischemia

Cardiovascular diseases are the most common cause of mortality in developed countries[92]. Acute coronary syndrome is often associated with SCD[93]. In patients with acute coronary syndrome an increased risk for MVA with a worse prognosis has been observed[94]. QT interval has been used to estimate the arrhythmogenic risk after an acute coronary syndrome. Schwartz *et al*[95] demonstrated the clinical value of QT interval many years ago. They showed that patients with Q wave acute myocardial infarction and prolonged values of QT interval had a high probability to develop SCD. Another study documented that exercise after an acute myocardial infarction may induce changes in QTc. In this case, the prolongation of QTc interval predisposes to develop SCD and was useful to differentiate patients at high risk for SCD and those at low risk for it[96]. These results show the benefit of using the QTc for identifying patients with exercise-induced ischemia who are at risk of SCD. In addition, a correlation between QTc prolongation and SCD in patients with non-ST elevation acute coronary syndrome has been observed[97,98]. These studies support previous results about the utility of QTc in acute coronary syndrome and additionally provide new elements from QTc applicability in risk stratification for SCD.

Other VR markers have been explored with the purpose to increase the sensibility to predict SCD in patients with acute myocardial ischemia. Ciolli *et al*[99] studied 101 patients with acute myocardial infarction and a control group of 97 healthy patients. After 10 d follow-up, QTd was significantly more prolonged in subjects who developed severe ventricular arrhythmias than control (125.8 ± 68.5 *vs* 80.8 ± 38.9, $P < 0.0005$). Similar results were found by other researchers. In this case, QTd was found to be increased in patients with ventricular tachycardia or ventricular fibrillation compared those with only ventricular premature beats (96.25 ± 15.97 ms *vs* 80 ± 15.04 ms, $P < 0.01$)[100]. Moreover, QTd represented a predictor to death by ventricular arrhythmias. It was a very interesting work about QTd utility in patients with acute myocardial infarction. As can been seen, it was not only prolonged in patients with ventricular arrhythmias but was a predictor of death. This study provides relevant data to continue our investigation about QTd importance in this field.

Tp-e also has been found to be useful to predict cardiac arrhythmias in patients after myocardial infarction. Seventy-six patients with previous myocardial infarction were followed during 23 ± 19 mo. Tp-e was longer in patients who developed ventricular arrhythmias than those without (116 ± 26 ms *vs* 102 ± 20 ms, $P = 0.01$). Additionally, Tp-e was found to be an independent predictor of ventricular arrhythmias when adjusted for age, ejection fraction and QRS duration[101]. Also, QTc has been found to be prolonged in patients with unstable angina with an increased risk for cardiac arrhythmias[102].

Underlying mechanisms to explain modification of these indicators in acute myocardial ischemia include

an expression of M cells properties. Activation of M cells determines an increase in the action potential in the heart and subsequently a QT interval and Tp-eprolongation[14,26-29]. Other proposed mechanisms are the reduction in epicardium temperature[103], acidosis[104] and changes in sodium and potassium currents[105]. These processes increase myocardium heterogeneity and predispose to malignant cardiac arrhythmias.

Reperfusion therapies (fibrinolysis and primary percutaneous coronary intervention) are the primary goal in ST-elevation myocardial infarction for improving clinical outcomes. They have demonstrated to be useful reducing the incidence of cardiac arrhythmias, including ventricular tachycardia and/or ventricular fibrillation[106,107]. There are studies demonstrating the usefulness of VR markers to predict malignant cardiac arrhythmias in this setting. QTc[108], QTd[109-111], Tp-e[112,113] and Tp-e/QT[114] have been found to be useful to indicate effectiveness of thrombolytic therapy and primary percutaneous coronary intervention in patients with acute ST-elevation myocardial infarction. These results indicate patients with reduced risk to develop MVA giving the physician another tool to evaluate the patients' risk in this setting. However, these markers need further study in other situation commonly present in patients treated with reperfusion methods. Patients with ST-elevation acute myocardial infarction develop with relative frequency a transient ST-elevation on ECG when undergoing treatment with fibrinolysis or primary percutaneous coronary intervention. This phenomenon is named "reperfusion peak" and it is followed by a complete ST-resolution[115]. The real significance of this event is not clear. In some studies it has been related with negative cardiac outcomes[116,117]. Application of VR markers in this setting may be important to detect patients at an increased risk for malignant arrhythmias and SCD when presenting with this phenomenon.

Heart failure

Patients with heart failure frequently have ventricular arrhythmias. Ventricular tachycardia and premature ventricular beats are seen with increased incidence in individuals with a dilated left ventricle and reduced ejection fraction[118]. Taking this into account, several studies have been designed to explore arrhythmia markers and to determine the arrhythmogenic risk in these patients.

Davey *et al*[119] found that QTc was significantly longer in heart failure patients than in controls or in subjects with left ventricular hypertrophy (471 ± 10 ms, 421 ± 6 ms, 420 ± 6 ms, $P < 0.05$ respectively). Tp-e also has been found to be useful in this setting. Its prolongation in V1 lead has correlated with increased incidence of SCD in chronic heart failure patients[120]. Tp-e has been evaluated in patients with left ventricular ejection fraction $\leqslant$ 35% and therapy with implantable cardioverter-defibrillator. It demonstrated to be effective predicting ventricular tachycardia and overall mortality[121]. Heart failure is defined as a syndrome derived from multiple cardiac and non-cardiac conditions. It has a complex pathophysiology and mechanisms proposed for the development of MVA are diverse and include: ischaemia, infarction, cardiomyopathy, myocarditis, hypokalaemia, hypomagnesaemia and digitalis overdose[118]. All of these processes may increase the ventricular heterogeneity and predispose to MVA. Some factors which could be associated are age, aetiology, drugs and comorbidities. As heart failure may be caused by multiple conditions, to analyse the risk for MVA can be very difficult.

Hypertension

Hypertension is a very common condition worldwide. Its prevalence is around 30%-45% in the general population[122]. Hypertensive patients have an increased risk for cardiac arrhythmias due to an increase in VR dispersion[123]. Left ventricular hypertrophy often develops in hypertension and it increases the risk of developing cardiac arrhythmias[124,125]. Carmona Puerta *et al*[126] observed that QTd and Tp-e were more prolonged in patients with left ventricular hypertrophy than those without it. Also, a linear correlation among QTd, Tp-e and duration of hypertension was observed ($r = 0.453$, $P = 0.001$ and $r = 0.306$, $P = 0.034$ respectively). Mozos *et al*[127] support these findings with similar results. In another investigation, QTc and Tp-e were associated with systolic blood pressure, body mass index, and left ventricular mass in resistant hypertensive patients[128]. The prognosis of patients with resistant hypertension is probably worse compared with those that have easily controlled hypertension. However, it has not been specifically evaluated. It may be influenced by some risk factors or associated conditions[129]. This investigation may give us a new alternative to evaluate the prognoses of resistant hypertensive patients by the analyses of VR markers. However, prospective studies would be required to achieve definite conclusions.

Recently, an investigational group demonstrated that in hypertensive patients without ischemic heart disease the global cardiovascular risk is related to some electrocardiographic markers for cardiac arrhythmias. QTc and Tp-e showed the most significant correlation ($P = 0.010$ and $P = 0.000$ respectively)[130]. Global cardiovascular risk may be examined by several methods. In this study the risk score proposed in the 2007 European Guidelines for the Management of Hypertension was used. The use of global cardiovascular risk scores associated with VR markers could help to identify patients at high risk of malignant cardiac arrhythmias. It could represent a novel tool for physicians in the future for better patients' management.

Further studies should be conducted to explore other arrhythmias markers and global cardiovascular risk scores.

There are several pathophysiological mechanisms to explain the predisposition to develop MVA in hypertensive patients. Left ventricular hypertrophy is found often in these cases and is recognized as the most important factor. It correlates with malignant arrhythmias and

SCD[131]. Left ventricular hypertrophy causes early after-depolarization and favors the occurrence of ventricular arrhythmias[132]. It may also cause myocardial ischemia by an unbalance between blood supply to the myocardium and oxygen consumption. Moreover, in this condition it may cause an increase in subendocardial ischemia due to a reduction in diastolic blood flow to this region[133]. These processes may be more intense in long-term hypertensive patients' in which left ventricular hypertrophy is more frequent. In fact, QTd has been found to be increased in elderly hypertensive individuals with the presence of left ventricular hypertrophy and myocardial ischaemia on ECG[134]. Myocardial ischemia increases cardiac heterogeneity and the predisposition to SCD.

Other changes in the heart of hypertensive patients include arise of collagen deposits as part of ventricular remodeling. Ventricular remodeling favors ventricular heterogeneity and ventricular re-entry arrhythmias[135]. In hypertensive patients there is often an increase in sympathetic nervous system activity, and activation of this system has been associated with increased cardiac arrhythmias[136]. Additionally, alterations in gap-junctions in myocardial cells and an elevated risk to develop ventricular arrhythmias in hypertensive animal models with hypokalaemia has been observed[137].

Diabetes mellitus

Diabetes mellitus had a prevalence of 360 million people worldwide in 2011. This prevalence will increase to 552 million people with diabetes by 2030[138]. SCD is often observed in diabetic patients and may be associated with ventricular arrhythmias[139,140]. Ventricular arrhythmias predictors in these patients have been evaluated in several studies.

Patients with type 1 diabetes mellitus and autonomic dysfunction have shown significantly higher values of QTd than patients without autonomic dysfunction and controls. After a follow-up by 24 h holter monitoring, individuals with autonomic dysfunction and a prolonged QTd had a higher incidence of ventricular arrhythmias[141].

Clemente *et al*[142] designed an investigation with the aim to study the effects of diabetes mellitus on VR markers. A group of 110 diabetic patients and a group of 110 controls were selected. Maximum QTc was significantly greater in diabetic patients than in controls (413.70 ± 28.10 ms *vs* 395.31 ± 16.28 ms, $P < 0.001$). Diabetics had a significantly higher mean QTd than controls (27.49 ± 10.10 ms *vs* 15.73 ± 4.18 ms, $P < 0.001$). Similar results were found with the measurement of QTd corrected by heart rate (29.92 ± 10.57 ms *vs* 16.68 ± 4.48 ms, $P < 0.001$).

More recently an investigational group found that QTc and QTd are prolonged in newborns of diabetic mothers. QTd prolongation was associated with inter-ventricular septal thickness at end diastole ($r = 0.514$, $P = 0.042$). The authors concluded that elevated values of these markers represent risk factors for the development of arrhythmias in these patients[143].

The results of these studies are encouraging, but further studies are needed to know with more precision the risk of diabetic patients to develop malignant cardiac arrhythmias. It should be important to evaluate other markers to know whether they may be added to the risk estimation in these patients.

The proposed mechanisms explain predisposition to develop cardiac arrhythmias in diabetic patients are diverse. They have a high incidence of coronary atherosclerosis, microvascular disease and autonomic neuropathy. The arrhythmogenic substrate, may be in part, due to compensatory hypertrophy in non-infarcted myocardium, progressive ventricular remodeling and neurohormonal abnormalities[144,145]. These processes increase VR heterogeneity and elevate the risk of re-entry arrhythmias.

Obesity

Obesity is a common condition worldwide. It is present in developed and non-developed countries and affects peoples of all ages. People with obesity have an increased risk to develop several diseases which worsens significantly their prognosis[146,147]. Several studies have demonstrated alterations in VR markers in overweight or obese people which appear to increase risk for MVA in these cases. Mshui *et al*[148] evaluated maximum and minimum QTc in obese patients before and after therapeutic weight reduction. Both QTc values were significantly longer in obese patients than controls before weight reduction. With weight reduction these markers were reduced significantly in the obese group. The authors concluded that obesity is a cause of prolongation of this marker and that it may be modified by weight reduction. Positive effects on reduction in QTc values with a low calorie diet followed by a weight reduction were observed in a previous study[149] supporting the benefits of weight loss to improve the QTc. Continuing on this topic, Seyfeli *et al*[150] studied both QTc and QTd in obese women and controls with m (B) index = 40 ± 3 kg/m^2 *vs* 22 ± 1 kg/m^2, $P < 0.001$ respectively. A significant correlation was found with m (B) index, maximum QTc and QTd ($r = 0.410$, $P < 0.001$ and $r = 0.429$, $P < 0.001$ respectively). Another work, found similar outcomes, but failed to find a statistically significant association among uncomplicated obesity and overweight with QTd, Tp-e, Tp-ed and Tp-e/QT[151].

Minimal myocardial dysfunction may be detected in obese patients even in the absence of any apparent symptoms[152]. These primary heart changes may increase the cardiac heterogeneity and could explain prolongation of these markers observed in uncomplicated obesity. For other hand, some conditions such as hyperinsulinemia, glucose intolerance and autonomic dysfunction may affect the values of these markers increasing the risk of ventricular arrhythmias[150]. Heterogeneity of samples involved in these studies and possible association of obesity/overweight with other comorbidities are factors which may modify and explain these results. These investigations show that QTc

appears to be the most useful marker in these patients, but to achieve definite conclusions further studies should be performed.

Highly trained athletes

SCD has been observed with higher incidence in athletes than the general population[153]. It is the main cause of death during exercise. MVA may play an important role in these cases. Several studies have examined the arrhythmogenic risk in these patients. QTc has been found more prolonged in athletes than non-athletes. It was observed by Lengyel *et al*[154]. They studied 76 professional soccer players and 76 controls with age mean 22.0 ± 0.61 and 22.0 ± 0.54 respectively. The maximum QTc by Fridericia and Hodges formulas were significantly longer in athletes than controls. Lawan *et al*[155] studied variations of QTd in 100 dynamic athletes, 50 static athletes and 100-matched controls. Results showed that both groups of athletes had an increased prolongation of QTd and that it significantly related to duration of physical activity. In other investigations it was found that maximum QTc, QTd and Tp-e were more prolonged inelite female water polo players than controls[156].

Currently the results derived from application of these markers to predict malignant cardiac arrhythmias in elite athletes are inconsistent. Maximum QTc has demonstrated to be shorter in professional soccer player than controls 413.9 ms *vs* 445.3 ms, $P < 0.001$ respectively)[157]. Similar results have been obtained by other researchers[158-160]. There are some points which should be analyzed in future studies and could represent possible explanations to contradictory outcomes after application of these markers in several setting of high trained physical activity: (1) Lack of identification of associated comorbidities; (2) Cardiac modifications presented in these cases (*e.g.,* left ventricular hypertrophy; (3) Exercise type depending on each sport characteristics; (4) Duration and intensity of physical activity; and (5) Recovery after highly trained activity.

These elements may act alone or combined to explain why VR markers are prolonged in athletes in some studies but not in others. The development of left ventricular hypertrophy has been widely studied and commonly associated with no prolongation of these parameters. In this case it could be a shield factor against the appearance of malignant cardiac arrhythmias and for that these markers are reduced compared with non-athletes. It has been observed that patients with left ventricular hypertrophy induced by physical training activity have shorter values of QTd than those with pathological left ventricular hypertrophy by hypertension[159].

As was discussed above, SCD occurs with increased incidence in athletes. Many of these cases are secondary to conditions which predispose to malignant cardiac arrhythmias. For that reason and due to the usefulness of these markers in other clinical conditions there should be continued investigation in this field. Other more expensive tests could be avoided in these patients if ECG through the analysis of these markers demonstrates to be effective in these cases.

Perspectives

The prevalence of malignant cardiac arrhythmias and their association with SCD is relatively frequent. They may occur in healthy individuals without structural cardiac abnormalities or be found in other medical conditions. There is the potential to predict their development and subsequently design strategies to avoid adverse outcomes in our patients through the analysis and interpretation of VR markers. So far, the predictive capacities of VR markers have demonstrated to be useful in some clinical situations but not completely in others. Some of these predictors should be explored further, such as Tp-ed and Tp-e/QT which are relatively new in clinical practice. In order to increase their value, they need to be studied in healthy patients to know normal values of markers by sex, age and maybe among races. For achieve this aim it will be important to design studies with long-term follow up and many patients. However, this approach will be difficult in some conditions which have low incidence in the general population such as long and short QT syndromes and Brugada syndrome. A way to increase the sensitivity of these markers could be to combine several of them during studies in order to reduce the margin of error.

There are other medical conditions not discussed in this manuscript in which markers have demonstrated positive results[161-177] such as Kawasaki disease, systemic lupus eythematosus, rheumatoid arthritis, chronic renal failure, scleroderma, Duchenne muscular dystrophy, liver transplantation, HIV-infected patients, rheumatic fever and Chagas disease among others (Table 1). The interest in these ventricular repolarization markers has grown and has been introduced novel predictors with good results[120,178-181]. The QT variability index has been associated with SCD. A study by Piccirillo *et al*[120] demonstrated that patients with chronic heart failure with left ventricular ejection fraction $\leqslant$ 35% and SCD have higher values of QT variability index than in the group of left ventricular ejection fraction > 35%. The QT/RR and Tp-e/RR slopes have demonstrated to be useful to show loss of rate-dependent property in patients with Brugada syndrome with history of ventricular fibrillation[178]. Another marker commonly studied in patients with ventricular tachycardia is JT interval and its correction by heart rate. A study population of 20 patients with idiopathic ventricular tachycardia and 30 controls demonstrated that JT interval and its correction by heart rate were higher in patients with previous history of malignant arrhythmias JT (272 ± 36 ms *vs* 265 ± 25 ms, $P = 0.01$), JTc (336 ± 28 ms *vs* 318 ± 18 ms, $P=0.01$)[179]. T wave alternant have been proposed has a marker for heart heterogeneity and lead to electrical instability. These phenomenon have often found in patients with long QT syndrome that develop

MVA[180]. Also, it has been assessed the value of T wave alternant in predicting SCD in patients after an acute myocardial infarction[181].

Currently there is a growing evidence to support the use of these markers to evaluate the risk of ventricular arrhythmias. However, it should be necessary to discuss some possible limitations on their use: (1) The manual determination of T wave offset is unreliable, principally when there is a low T wave amplitude and merges of T waves with U and/or P waves. In order to reduce the margin of error it has been developed automatic methods[5]. A precise calculation of some markers as Tp-e could be difficult in clinical practice and a computer method may represent a better choice; (2) For an accurate assessment of QTd is necessary all 12 leads of the ECG to be recorded simultaneously in order to avoid the effect of QT dynamicity[5]. However, not always is possible to achieve this aim due to mainly to technological deficit in non-developed countries; and (3) Although the utility of these markers for predicting malignant arrhythmias has been recognized, there are some conditions such as long and short QT syndromes, Brugada syndrome and early repolarization pattern when the patients' risk stratification must be evaluated taking into account another variables such as gender, age, family history and gene mutations.

These markers extend our alternative for arrhythmias' prediction. It is necessary to continue medical studies in this field with the aim to clarify some aspects discussed above and to achieve a global consensus which would result in better management of our patients.

CONCLUSION

The QTc, QTd, Tp-e, Tp-ed and Tp-e/QT have been found to be useful in predicting malignant cardiac arrhythmias in multiple medical conditions, but further long-term studies are needed. The aim should be to include them as tools to evaluate arrhythmogenic risk and as a way to improve clinical management of patients.

Abstract

The term bezoar refers to an intraluminal mass in the gastrointestinal system caused by the accumulation of indigestible ingested materials, such as vegetables, fruits, and hair. Bezoars are responsible for 0.4%-4% of cases of mechanical intestinal obstruction. The clinical findings of bezoar-induced ileus do not differ from those of mechanical intestinal obstruction due to other causes. The appearance and localization of bezoars can be established with various imaging methods. Treatment of choice depends on the localization of the bezoar which makes the clinical findings.

Key words: Phytobezoar; Intestinal obstruction; Ileus

Core tip: Bezoars are conglomerates of indigested foreign material that accumulate in the gastrointestinal tract. They are responsible for 0.4%-4% of cases of mechanical intestinal obstruction although the true incidence is not known. Recent advances in imaging methods have facilitated the diagnosis of intestinal obstruction due to phytobezoars. The most valuable method for determining the location and etiology of intestinal obstructions is contrast-enhanced computed tomography. This review aims to summarize the definition and history, causes of bezoar formation, clinical findings, diagnostic methods, treatment of these rare intestinal obstructions caused by phytobezoars.

DEFINITION AND HISTORY

The term bezoar refers to an intraluminal mass in the gastrointestinal system caused by the accumulation of indigestible ingested materials, such as vegetables, fruits, and hair[1,2]. Called "panzehr" in Arabic and "padzhar" in Persian, the term means antidote[3]. Although there is written evidence of bezoars identified in animal and human gastrointestinal systems in the 10th century AD, the first scientific definition was made by Baudmant[1,2] with the publication of a case of trichobezoar in 1779. In 1854, Quain named the mass of intragastric food residue found at autopsy a "bezoar". The first preoperative trichobezoar case was reported by Stelzner[4] in 1894.

Bezoars are named according to the material they are made of: a trichobezoar consists of hair; a phytobezoar of vegetable and fruit residues; a lactobezoar is formed from dairy products; a pharmacobezoar is caused by medications; and a polybezoar is caused by ingested foreign bodies[3,4]. In addition, Chintamani *et al*[5] identified biliary bezoars caused by bile stasis following hepatobiliary or gastric diversion surgery. The most common type of bezoar is the phytobezoar, which consists of indigestible food residue, such as cellulose and hemicellulose.

Trichobezoars are generally seen in individuals with trichophagia, a psychiatric disorder that usually occurs during childhood and in young adults. Trichobezoars are generally located in the stomach. However, if trichophagia is not noticed by the parents and if it becomes prolonged, then a condition called Rapunzel Syndrome can develop; it starts with hair in the stomach and the bezoar extends into the small intestine[3,4]. Since a psychiatric disorder underlies trichobezoar, recurrence is inevitable if insufficient psychiatric support is provided after surgical treatment[6]. Pharmacobezoars are usually caused by Kayexalate (sodium polystyrene sulfonate), cholestyramine, and antacid medications[7]. Lactobezoars generally occur in low-birth-weight newborns as a result of concentrated baby formulas[4].

CAUSES OF BEZOAR FORMATION

Bezoars are responsible for 0.4%-4% of cases of mechanical intestinal obstruction, although the true incidence is not known[8-10].

Previous gastric surgery

Gastric motility disorders and hypoacidity after gastric surgery are the basis of bezoar formation. Bezoars located in the stomach can pass through the small intestines easily and cause symptoms of intestinal obstruction, especially in patients with pyloric dysfunction after a pyloroplasty or wide gastrojejunostomy, resulting in a wide gastric outlet[3,11-13]. In a study of 42 diseases, Kement *et al*[14] reported that previous gastric surgery was the most important factor predisposing to bezoar formation, with a rate of 48%. In their series, Krausz *et al*[15] and Bowden *et al*[16] reported rates of 20% to 93%. Bezoar-associated ileus is more common in cases undergoing surgery for ulcer treatment, although this has become more rare with the introduction of proton pump inhibitors[16].

In patients who have had surgery for ulcer treatment, a vagotomy accompanied by a partial gastrectomy is the most important factor predisposing to bezoar formation[9-17]. A vagotomy and partial gastrectomy reduce gastric acidity, negatively affecting peptic activity. Furthermore, the antrum has an important role in the mechanical digestion of ingested food. The pylorus also prevents ingested food from passing through the small intestine as bolus, contributing to digestion. In this regard, the risk of bezoar formation was higher in patients who had a pyloroplasty and antrectomy[14,15]. The time taken for a bezoar to form after gastric surgery ranges from 9 mo to 30 years[15].

Bezoars can also form primarily in the small intestine when a mechanical factor alters the small intestinal passage, such as a diverticulum, stricture, or tumor[14,17]. Primary bezoars of the small intestine almost always cause intestinal obstruction. The most common location of obstruction is the terminal ileum[18].

High-fiber diet

High-fiber foods such as celery, pumpkins, grape skins, prunes, and especially persimmons are a risk factor for bezoar formation[14,15]. Persimmons, which means the "God of fruits" in Greek, are the fruit of plants in the genus *Diospyros*. Immature persimmons contain tannins, which form an adhesive-like substance when they encounter acids and hold other food residues, causing bezoar formation[14]. Krausz *et al*[15] and Erzurumlu *et al*[9] reported that 17% to 91% of bezoars in their series were caused by persimmons.

Other factors

Other factors predisposing to bezoar formation include systemic diseases such as hypothyroidism causing impaired gastrointestinal motility, postoperative adhesions, diabetes mellitus, Guillain-*Barré* syndrome, and myotonic dystrophy. Personal factors such as swallowing a large amount of food without sufficient chewing due to dental problems, especially in the elderly, the use of medications slowing gastrointestinal motility, and renal failure are also predisposing factors[4,19-21]. Erzurumlu *et al*[9] suggested that bezoar formation could occur without any predisposing factors.

CLINICAL FINDINGS

The clinical findings of bezoar-induced ileus do not differ

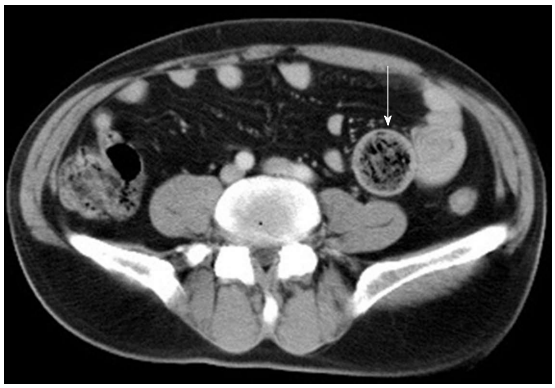

Figure 1 Intraluminal round bezoar and mottled gas pattern were seen in the jejenum segment. Wall thickening due to inflammation were seen at the obstruction site (arrow).

from those of mechanical intestinal obstruction due to other causes. Almost all patients have poorly localized abdominal pain that is similar to ischemic pain. Other symptoms include abdominal distention, vomiting, nausea, a sense of satiety, dysphagia, anorexia, weight loss, gastrointestinal hemorrhage, and constipation[22,23].

It is generally difficult to determine whether bezoars are the clinical cause of ileus. The great majority of patients have a history of abdominal surgery, and adhesions following previous surgery are often responsible for ileus[24,25]. To reduce mortality and morbidity, it is important to consider bezoars in patients with a history of gastric surgery because the treatment of intestinal obstruction suspected of being induced by bezoars is mostly surgical. Prompt treatment can minimize the complications that might develop during medical follow-up.

DIAGNOSTIC METHODS

Recent advances in imaging methods have facilitated the diagnosis of ileus[24-27]. The air-fluid levels associated with mechanical intestinal obstruction can be seen on plain X-rays in most patients, but plain radiographs are not useful for differentiating other causes of ileus[27].

The appearance and localization of bezoars can be established with barium studies, which are effective for differentiating diverticular disease, intraluminal adenomas, primary malignancies of the small intestine causing mechanical obstruction, and bezoars[27,28]. However, these studies are not applicability in an emergency setting, can exacerbate peritonitis in the presence of perforation, and increase symptoms in complete obstruction[28].

Ultrasonography can detect the cause in 88%-93% of bezoar-induced ileus[28,29]. Typically, bezoars create hyperechoic acoustic shading on ultrasonography. However, the place of ultrasonography is controversial, since the examination is operator-dependent and requires experience. Furthermore, the air-fluid levels in the obstructed intestines block the view and ultrasonography has low sensitivity when there are multiple bezoars[30].

The most valuable method for determining the location and etiology of intestinal obstructions is contrast-enhanced computed tomography (CT) (Figure 1). The sensitivity and specificity of abdominal CT for bezoar-induced ileus are 90% and 57%, respectively[29,31]. Abdominal CT is effective for excluding other causes of intestinal obstruction. The advantages of CT are its ability to detect dilatation and edema in the intestinal loops, the presence of intra-abdominal free fluid, and the level of obstruction and development of strangulation[31]. Zissin *et al*[32] reported that a round, mottled intraluminal mass in the area of obstruction with dilated intestinal loops proximally and collapse distally was a pathognomonic CT finding for a bezoar resulting in ileus. Air bubbles might be seen within bezoars. When there are multiple bezoars, intraluminal bezoars distant from the area of obstruction area might go unnoticed if not sought carefully[28,31,32].

Feces in the small bowel can appear similar to a bezoar radiologically and are seen in about 8% of the patients treated for intestinal obstruction[32]. Their radiological differentiation from bezoars is important because the treatment is generally medical. Small bowel feces generally appear in a longer segment than the bezoar and cause sharp-margin dilatation. Zissin *et al*[32] reported that the most evident radiological feature for differentiating a bezoar and small bowel feces was the longer transition zone of the feces-like view in the dilated segments proximal to the obstruction in small bowel feces compared to bezoar.

Preoperative CT assessment in patients with suspected intestinal obstruction induced by bezoars is helpful for determining the timing of surgery. When a bezoar is detected on CT, the surgery is generally performed within 48 h[31]. For small intestinal obstructions thought to result from non-bezoar causes, such as previous surgery, most patients can be treated medically, instead of surgically. A preoperative CT assessment allows the diagnosis of complications, such as perforation, necrosis, and ischemia secondary to bezoar-induced obstruction, and facilitates the planning of the timing of the surgical intervention[32].

TREATMENT

The initial treatment of bezoars causing obstruction is no different from that for obstructions of other etiologies. With intestinal obstruction, fluid deficiency and electrolyte imbalances result from vomiting and fluid accumulation within the intestinal segment. Therefore, the first step in treatment is intestinal decompression and fluid-electrolyte replacement[33].

The most common location of bezoars in the gastrointestinal system is the stomach, although gastric bezoars usually do not cause obstruction. Therefore, endoscopic methods have become the main treatment. Mechanical disintegration (mechanical lithotripter, large polypectomy snare, electrosurgical knife, drilling, laser destruction, and a Dormia basket for extraction) and chemical dissolution (saline solution, hydrochloric acid,

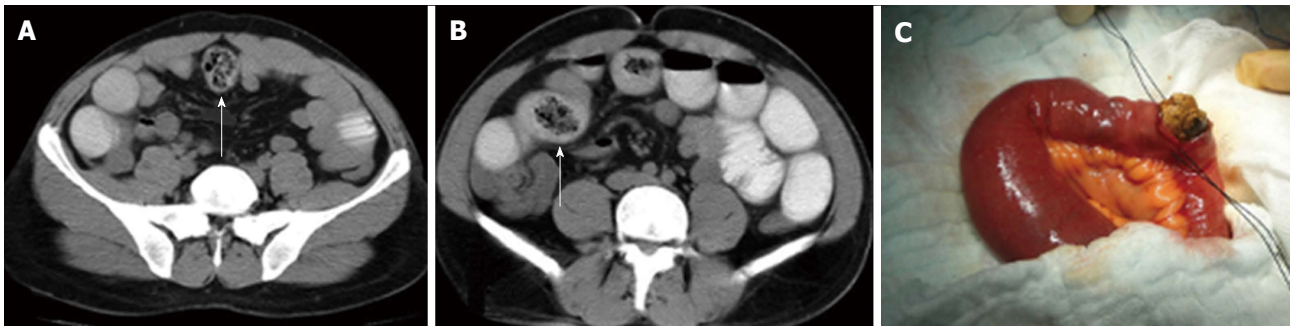

Figure 2 A 62-year-old male patient. Multiple small bowel bezoars which have round or irregular shape and mottled gas pattern were detected on abdominal computed tomography (A and B; arrows). Intraoperative finding (C); an irregular shaped bezoar which caused intestinal obstruction was removed *via* enterotomy, dilated proximal segments and non-dilated distal segments are visible.

sodium bicarbonate, and Coca-Cola lavage) methods have been described[33,34] Ladas *et al*[35] reported a very high success rate (90%) in gastric bezoars using a combination of mechanical and chemical methods. The treatment of choice is surgical for gastric bezoars in which endoscopic treatment failed.

Bezoar-induced intestinal obstructions occur mostly in the distal small intestine[35,36]. The greater width of the colon lumen reduces the possibility of colonic mechanical obstruction due to bezoars, although a few rare cases of colon obstruction have been reported in children[37,38].

Bezoar-induced intestinal obstructions usually occur 50-70 cm proximal to the ileocecal valve[9], because of the reduced lumen diameter towards the distal end, the lower motility in the distal small intestine, and the decreased motility of bezoars due to the increased water absorption at the distal end[36].

When surgical treatment is chosen, open or laparoscopic abdominal exploration may be performed[39]. Laparoscopic exploration is currently used more frequently; however, it requires technical experience because of the presence of dilated intestinal segments. It also requires a good preoperative radiological study to localize the bezoar because there can be multiple bezoars and there are reports of cases requiring surgery for an unnoticed bezoar[40]. The factors to be considered when selecting the laparoscopic method include the size and number of bezoars, the presence of complications (such as perforation and peritonitis), and previous abdominal operations[39,41]. In a study of 24 diseases, Yau *et al*[42] reported that the laparoscopic method had more advantageous outcomes when used in selected patients compared to the open method in terms of operating time, complication rates, and duration of hospital stay. Nirasawa *et al*[43] reported treatment outcomes with the laparoscopic method in patients with gastric bezoars and Son *et al*[44] reported such outcomes in patients with gastric bezoars that could not be treated endoscopically. Fraser and Song emphasized that the laparoscopic technique might be used safely in selected patients with giant gastric bezoars[45,46]. Son *et al*[44] discussed the risk of intra-abdominal contamination and the location of the gastric incision as the points to be considered for laparoscopic gastric bezoar surgery.

Laparoscopic interventions are being performed increasingly; however, open surgery is still the most common method used for the surgical treatment of bezoar-induced intestinal obstructions. The review by Gorter *et al*[47] reported that laparotomy intestinal bezoar treatment was successful in more than 100 studies.

After determining the need for surgical intervention, the issue of what kind of intervention should be performed arises. The decision to perform an enterotomy to remove bezoars varies with experience[9]. Surgeons often use the milking technique, which is used to advance the intestinal contents manually either proximally or distally. However, a laceration in the intestinal serosa or mesentery can occur during this procedure[36,39]. Aysan *et al*[48] reported that rats undergoing milking developed significantly more peritoneal adhesions compared to the control group and that the peritoneal cultures were positive.

The bezoar location in the gastrointestinal system (duodenum, jejunum, or ileum) plays an important role in selecting the surgical method (Figure 2). Oh *et al*[49] reported that an enterotomy was more successful for bezoars located in the proximal small intestine. For the patients with ischemia and perforation caused by bezoars, anastomosis or stoma procedures should be performed with segmental small bowel resection[49-52].

In conclusion, the possibility of bezoars must be considered in patients with mechanical intestinal obstruction, although they are rare. This possibility must be considered especially in regions where there is excess consumption of high-fiber food, which causes bezoar formation, in patients with intestinal obstruction, and in patients who have a history of abdominal surgery for a peptic ulcer. Early preoperative contrast-enhanced CT assessment aids both the diagnosis and decision for early surgical treatment. Surgery is usually chosen for bezoars causing intestinal obstruction. In addition to the physical characteristics of the bezoar, its location should be considered when selecting the surgical procedure.

Abstract

To study dermatological manifestation of T-lymphoblastic lymphoma and to help clinicians in the diagnosis, we report here the case of a 75-year-old patient who presented with violaceous nodules acquired during the last 4 wk and affecting the scalp and right arm. The diagnosis of systemic lymphoma was suggested upon the appearance of cutaneous tumors, palpable lymph nodes and general symptoms including asthenia and weight-loss. The pathology features: positive immunostaining for CD3 and terminal deoxynucleotidyl transferase (TdT) and staging, led us to the final diagnosis of T-lymphoblastic lymphoma (T-LBL) with cutaneous involvement. He received a CHOP regimen as first-line treatment. Unfortunately, the patient relapsed and died 8 mo after the treatment initiation. T-LBL may be diagnosed by skin lesions. Additional immunostaining including TdT and experienced histopathologists are needed to correctly classify this aggressive disease and discuss the correct management including bone-marrow transplantation where appropriate.

Key words: Cutaneous lymphoma; Lymphoblastic lymphoma; Skin

Core tip: The clinical presentation of our patient with disseminated erythematic patches and infiltrated nodules suggested a diagnosis of cutaneous involvement of T-lymphoblastic lymphoma (T-LBL). Finally, histopathological examination of a skin biopsy with immunohistochemical study established the diagnosis of T-LBL. For accurate diagnosis, experienced histopathologists are needed. We wish to add this case to the current literature of T-LBL with cutaneous involvement,

emphasizing the importance of a correct diagnosis and aggressive treatment.

Ginoux E, Julia F, Balme B, Thomas L, Dalle S. T-lymphoblastic lymphoma with cutaneous involvement. *World J Clin Cases* 2015; 3(8): 727-731 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/727.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.727

INTRODUCTION

T-lymphoblastic lymphoma (T-LBL) is a rare subtype of adult non-Hodgkin lymphoma (NHL) which represents almost 2% of lymphoid leukemias. This disease arises from precursor T lymphocytes and is associated with a very poor prognosis. Although skin involvement occurs in less than 20% cases it is often the first observable manifestation of the disease and leads to the correct diagnosis. By adding this case, we hope to help clinicians in this diagnosis which needs to be made fast as possible.

CASE REPORT

A 75-year-old patient was referred to our out-patient unit following the rapid onset of several reddish nodules associated with loss of weight and fatigue. His past medical history was marked by type 2 diabetes, sarcoidosis, hypertension, and prostatectomy for prostate cancer 5 years previously.

On physical examination, we observed 2 large cutaneous nodules: the first was located on his right arm (Figure 1) while the second was on the occipital area (Figure 2). The skin lesion on the arm was purplish asymptomatic and measured 10 cm on the larger diameter. The second one was a large purple painful nodule located on the occipital part of the scalp. They were both deeply infiltrated into the sub-cutaneous fat, non-pruriginous and rapidly growing. He also presented several red patches on trunk and back. On general examination we noticed bilateral palpable superficial lymph nodes on the axillary, cervical, and inguinal areas. He complained about extreme fatigue and up to 10% weight loss during the last 2 mo. Additional B-symptoms such as fever and nightly sweats were absent.

Blood samples analysis showed a lymphocytosis at 4.14 G/L, including 20% of atypical lymphocytes with irregular chromatin and a high nucleo-cytoplasmic ratio. By flux cytometry, 93% of the atypical population was CD4 positive, 50% was also CD3 positive while, of the tumoral cells, 17% aberrantly expressed CD4 and CD8.

Histological examination of skin biopsy specimens from the arm lesion revealed that the dermis was infiltrated by monomorphic medium size lymphoid cells. This infiltrate was dense and diffuse infiltrating collagen bundles. The tumoral cells showed a scant cytoplasm, and an irregular prominent nucleus with dispersed chromatin and inconspicuous nucleoli. The epidermis was spared. The high number of mitotic figures rate suggested an aggressive process (Figure 3). Few mitotic figures were seen.

Immunostaining was performed on skin samples. The tumoral infiltrate was positive for CD3, CD5, CD4 (Figure 4), ki67 + (Figure 5) and negative for EMA (Epithelial Membrane Antigen), CD34, CD68, CD10, CD30, CD20, CD79, CD23, CD56, CD8, and myeloperoxidase. Terminal deoxynucleotidyl transferase (TdT) marker, a specialized DNA polymerase expressed in immature, pre-B, pre-T lymphoid cells, and acute lymphoblastic leukemia/lymphoma cells, was found positive on paraffin embedded biopsy (Figure 6). Bone marrow aspiration showed an identical intramedullar lymphocytic T-cell proliferation, thus resulting in a diagnosis of lymphoblastic lymphoma. A total body computed tomography-scan showed multiple tumoral lymph nodes on cervical, axillar, inguinal and deeper areas.

The diagnosis of T-LBL $CD4^+$, $CD56^-$ with cutaneous involvement and leukemic involvement was made. The Ann Arbor stage was Ⅳ B and E.

The patient was then referred to the haematology department. This patient was not eligible for bone marrow transplantation. Because of the aggressiveness of the disease, a CHOP regimen (cyclophosphamide, doxorubicin, vincristin, prednisone) was immediately started as first-line treatment. Despite a short-term partial response, the patient relapsed after the fourth cycle of chemotherapy and was subsequently included in a Holoxan (ifosfamide) Vepeside (etoposide) therapeutic protocol. After 3 cycles of this chemotherapy a clinical remission occurred and because of poor hematologic tolerance (grade 4 leucopenia and thrombopenia) the treatment was discontinued. The patient relapsed and was admitted into a palliative care strategy. He eventually died 8 mo after the initial diagnosis.

DISCUSSION

T-LBL is a rare subtype of adult non-Hodgkin lymphoma with an incidence representing approximately 2% of NHL cases[1]. Lymphoblastic lymphoma predominates in young adults and teenagers with a median age at diagnosis of 20 years. It has a poorer prognosis compared to B-LBL. In adults the overall survival rate at 5 years is 26%[2-6]. Prognostic factors for adult T–LBL have not so far been determined.

This disease is the malignant counterpart of the precursor T-cell lymphocytes. The lymphoblasts infiltrate lymph nodes or extranodal structures, especially the bone marrow, spleen, and central nervous system[3]. It is characterized by male predominance, high rate of lactate dehydrogenase, Ⅲ or Ⅳ Ann Arbor staging and mediastinal involvement[2] (Table 1). Typically, patients with lymphoblastic lymphoma are diagnosed with painless lymphadenopathy, splenomegaly, neurologic deficits or testicular masses[2].

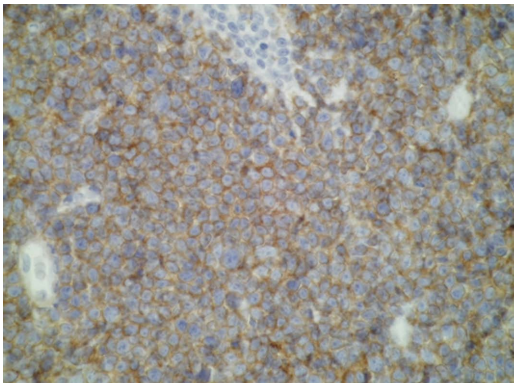

Figure 4 Tumour cells positive for CD4.

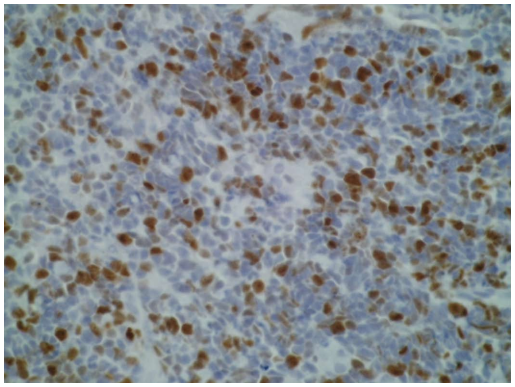

Figure 5 Tumour cells positive for ki67.

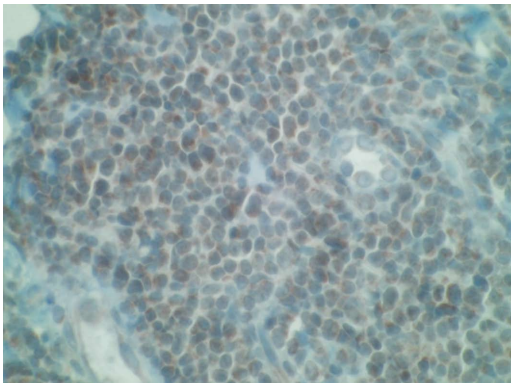

Figure 6 Positive terminal deoxynucleotidyl transferase marker.

Involvement of the skin in T-LBL is rare, although the exact frequency at which this occurs has not been calculated[4]. In the majority of reported cases, the cutaneous involvement is secondary or concomitant to bone marrow or lymph node spreading[6]. Skin involvement is more common in association with B-LBL.

Diagnosis is commonly made thanks to an excisional node biopsy or exploration of extranodal sites. Typically, histology with hematoxylin-eosin coloration shows a monomorphous dermis-infiltrate of small to medium-sized lymphoid cells with scant cytoplasm, moderately condensed to dispersed chromatin and prominent nucleus with inconspicuous nucleoli[5]. Epidermotropism is not present and the grenz zone is located beneath the epidermis. In some areas, the tumor cells can be arranged in a mosaic-like pattern[4]. However, diagnosis is not made by Hematoxylin-Eosin sections alone; immunohistochemical studies are also needed to diagnose T-LBL. T-LBL is confirmed when lineage markers for B-cells (CD20) and NK cells (CD56) are negative, and those for precursor T cells (CD3 and CD5) are positive, whilst expression of ki67 proves malignancy. TdT expression is seen only in lymphoblastic lymphoma (B-LBL and T-LBL) contrary to the mature lymphoma[5]. A recent study based on cytogenetic analysis and gene expression profiling

Table 1 Clinical presentation of the patients with cutaneous T-lymphoblastic lymphoma, cases from the review of literature

Patient	Sex/age	Staging	Cutaneous involvement	Extracutaneous lesions
1[2]	M/16	Stage 4	Subcutaneous nodule on the left side of neck	BM involvement, lymph nodes
2[2]	M/20	Stage 4	Multiple scalps nodules	Prostate involvement
3[2]	M/25	Stage 4	Multiple subcutaneous nodules on left side of face, scalp, and chest wall	BM involvement, lymph nodes, scrotal involvement
4[2]	M/17	Stage 4	Subcutaneous nodules on left side of neck and abdomen	Mediastinal mass, BM involvement, lymph nodes
5[2]	F/25	Stage 4	Multiple subcutaneous nodules on right breast, right side of neck, chest wall, and both legs	BM involvement, lymph nodes
6[2]	M/39	Stage 4	Multiple nodule on scalp	Mediastinal mass, lymph nodes, BM, bone, left kidney, left pleura involvement
7[2]	M/22	Stage 4	Multiple subcutaneous nodules on back	Mediastinal mass, lymph nodes, tonsil, nasopharyngeal involvement
8[7]	F/24	Stage 4	Multiples nodules on malar regions of face, breast, trunk	Lymph nodes, conjunctiva
9[7]	M/25	Stage 4	Nodule on scalp	Mediastinal mass
10[8]	M/8	Stage 1	Nodule on abdominal wall	None
11[4]	M/65	Stage 4	Multiples nodules on lower extremities and abdomen	Mediastinal mass, lymph nodes and BM
12[9]	F/29	Stage 4	Multiples nodule face, breast, thoraco - mammary region, abdomen, tights	Lymph nodes, BM
13 case reported	M/75	Stage 4	Nodules on scalp and right arm and multiples patches on trunk	Lymph nodes, BM

BM: Bone marrow; F: Female; M: Male.

proved that primary cutaneous T-LBL is characterized by a gain of 1p36.33-p22.1 in the early stages and a large number of chromosome losses/gain in the later stage. The gain of 1p36.33-p22.1 could be an interesting marker to perform an earlier diagnosis of primary cutaneous T-LBL[9].

Diagnosis is also made on bone marrow biopsy, with lymphoblasts which may comprise up to 25% of marrow elements. If lymphoblasts involve more than 25% of the marrow, patients are arbitrarily diagnosed with acute lymphoblastic leukemia (ALL).

Indeed, conversely to cutaneous B-LBL which typically presents as a unique lesion located in neck or head area, T-LBL develop multiple skin lesions on back, chest, legs and breasts to the same extent as the head and neck areas[2]. This clinical presentation must be differentiated from the blastic plasmacytoid dendritic cell neoplasm presentation which can be quite similar. It is a disease with frequent skin involvement appearing as widespread, purplish, dermal nodules localized on the trunk, limbs or head. Usually, as in T-LBL, patients progress rapidly with involvement of bone marrow, peripheral blood, lymph nodes and extranodal sites. Diagnosis can be made from the immunohistochemical analysis of tumor cells when TdT and T-cell markers (CD3) are negative and CD4 and CD56 positive[10].

Various treatments have been applied to LBL in adult: protocols for high-grade NHL such as CHOP, CHOEP, or treatments according to a regimen for ALL, and autologous stem cell transplantation (SCT)[1]. The major challenge of local disease control is the effective treatment of mediastinal tumors. It is now believed that ALL chemotherapy regimens are more appropriate for LBL[11]. It has been shown that a hybrid NHL/ALL chemotherapy protocol followed by consolidation with SCT appears superior to the use of chemotherapy alone[11].

The clinical presentation of our patient with disseminated erythematic patches and infiltrated nodules suggested a diagnosis of cutaneous involvement of T-LBL. Finally, histopathological examination of a skin biopsy with immunohistochemical study established the diagnosis of T-LBL. For accurate diagnosis, experienced histopathologists are needed.

We wish to add this case to the current literature of T-LBL with cutaneous involvement, emphasizing the importance of a correct diagnosis and aggressive treatment.

We thank Sarah Kabani for editorial assistance.

COMMENTS

Case characteristics

The disease arises from precursor T lymphocytes and has a poor prognosis.

Clinical diagnosis

The clinical presentation of the skin involvement is large purplish skin nodules.

Differential diagnosis

The blastic plasmacytoid dendritic cell neoplasm but the Cd4 and CD56 are positive.

Laboratory diagnosis

Positive terminal deoxynucleotidyl transferase (TdT) marker, positive precursors T cell markers (CD3 and CD5) and histology make the diagnosis.

Pathological diagnosis

The pathological diagnosis of skin involvment of T-lymphoblastic lymphoma (T-LBL) is made by histology with hematoxylin-eosin coloration which commonly shows a monomorphous dermis-infiltrate of small to medium-sized lymphoid cells with scant cytoplasm, moderately condensed to dispersed chromatin and prominent nucleus with inconspicuous nucleoli.

Treatment
Protocols for high-grade non-Hodgkin lymphoma (NHL) like CHOP CHOEP or stem cells transplantation.

Related reports
Some related case has been reported by Lee *et al*[2] (Precursor B- or T-LBL presenting with cutaneous involvement: a series of 13 cases including 7 cases of cutaneous T-LBL).

Term explanation
Tdt marker is a specialized DNA polymerase expressed in immature pre-B, pre-T lymphoid cells and acute lymphoblastic leukemia.

Experiences and lessons
Importance of a correct diagnosis for a fast treatment.

Peer-review
The authors have performed a good study, the manuscript is interesting.

Abstract

Meckel's diverticula incarcerated in a hernia were first described anecdotally by Littré, a French surgeon, in 1700. Meckel, a German anatomist and surgeon, explained the pathophysiology of this disease 100 years later. In addition, a congenital paraduodenal mesocolic hernia, known as a Treitz hernia, is a rare cause of small bowel obstruction. These hernias are caused by an abnormal rotation of the primitive midgut, resulting in a right or left paraduodenal hernia. We treated a patient presenting with pain and diagnosed extraluminal air in the abdomen after a computed tomography examination. We performed a laparotomy and found a combination of these two seldomly occurring congenital diseases, incarceration and perforation of Meckel's diverticulum in a left paraduodenal hernia. We performed a thorough review of the literature, and this report is the first to describe a patient with a combination of these two rare conditions. We considered the case regarding the variety of terminology as well as the treatment options of these conditions.

Key words: Incarceration; Meckel's diverticulum; Perforation; Left paraduodenal hernia; Treitz' hernia; Littré's hernia

Core tip: Meckel's diverticula incarcerated in a hernia were first described anecdotally by Littré, a French surgeon, in 1700. Meckel, a German anatomist and surgeon, explained the pathophysiology of this disease 100 years later. INTRODUCTION

Internal hernias are the protrusion of viscus through an opening in the peritoneal or mesenteric fold[1]; they account for 0.2% to 0.9% of small bowel obstructions[2] and are classified as acquired or congenital. Littré's hernia is a very rare type of hernia. In 1700, a French surgeon, Alexandre de Littré, first described a type of inguinal hernia that was different from known hernias[3]. An antimesenteric sacculation, not the whole bowel's circumference, protruded through a defect in the abdominal wall, which explains why Littré's patient did not die from a bowel obstruction. Littré could not discover a reason for the bowel eversion; however, 100 years later (1809), Meckel, an anatomist and surgeon, theorized that the persistence of the omphalomesenteric duct could be causative[3]. The omphalomesenteric duct, also known as the Ductus vitellinus, joins the midgut to the yolk sac. If the duct does not obliterate, a Meckel's diverticulum remains, which is the most common congenital anomaly of the gastrointestinal tract. Only 4% to 16% of the patients with this true diverticulum experience complications[2] such as bleeding from ectopic gastric mucosa or obstruction caused by intussusceptions or adhesion bands[4].

For several decades, studies have described cases presenting with incarceration of Meckel's diverticulum in different types of hernias, including inguinal, femoral or umbilical hernias[5], as well as in incarcerations in incisional hernias[6].

Another type of hernia, congenital paraduodenal mesocolic hernias, represents 53% of internal hernias[7]. Paraduodenal hernias, known as Treitz hernias, had been described by others before being defined for the first time by Treitz in 1857[1]. The two types of paraduodenal hernias are left and right, and left paraduodenal hernias occur more frequently than right ones[7]. Left paraduodenal hernias are caused by an abnormal rotation of the primitive midgut[8] when the small bowel invaginates into an avascular segment of the left mesocolon[9]. The bowel prolapses through the Landzert's fossa behind the fourth segment, the ascending duodenum. It locates behind the inferior mesenteric vein and left colic artery[10] and becomes trapped between the mesocolon and the posterior abdominal wall in a hernial sac within the leaflets of the left colon mesentery[7]. Bowel loops are present between the stomach and pancreas. Recent studies have reported laparoscopic management of this condition[11].

We performed surgery on a patient with an incarceration of Meckel's diverticulum in a left paraduodenal internal hernia.

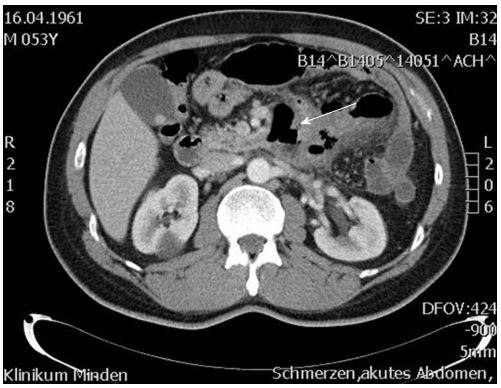

Figure 1 Extraluminal air was detected beside the duodenojejunal flexure (arrow) caused by perforated Meckel's diverticulum.

CASE REPORT

A 53-year-old man reported having unspecific moderate pressure for two weeks before presenting with sudden acute and severe pain in his upper abdomen. The patient consulted the emergency department of our hospital. During the clinical examination, we found moderate abdominal epigastric tenderness. The white blood cell count (16.9 g/L) and C-reactive protein were elevated (203.5 mg/L), and the patient underwent a computed tomography examination of the abdomen (Figure 1). Extraluminal air was detected beside the duodenojejunal flexure. Therefore, we performed surgery. During the laparotomy, we found that the small bowel was fixed adjacent to the duodenojejunal flexure, with the abdomen appearing to be "empty". Small bowel was herniating through a tight, well-formed, fibrous ring. After having mobilized the non-ischemic bowel, we identified a Meckel's diverticulum showing a fibrous ring at the base and perforation at the tip (Figure 2). The small bowel, including a 5-cm Meckel's diverticulum that was located 60 cm oral of the ileocecal valve, was slipped through the hernial orifice of a left paraduodenal hernia. We repositioned the bowel and resected the diverticulum. Histologically, we found venous congestion of the diverticulum with a perforation at the tip and signs of peritonitis. After having opened the bursa omentalis by dividing the gastrocolic ligament, we opened the hernial sac and lavaged and drained the bursa. In the hernial sac, we found local fibrinous peritonitis. We closed the hernial orifice with an omental flap. The postoperative course of the patient was uneventful despite infection with clostridium difficile, which was treated with metronidazole.

DISCUSSION

The terminology in this medical field is highly variable.

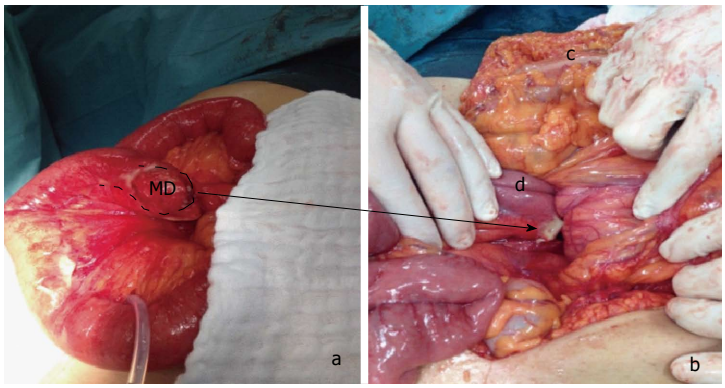

Figure 2 Intraoperative situs. a: Meckel's diverticulum shows a well-formed, fibrous ring where it was assumably incarcerated; b: Hernial orifice (arrow's tip); c: Colon; d: Duodenum. MD: Meckel's diverticulum.

In a scientific paper in 1785, Gottlieb Richter, a professor of medicine in Göttingen, described the diversity of hernias. He counted intestinal wall hernias and Littré's hernias among the small hernias that include all the hernias in which only one side of the bowel is incarcerated[3]. His descriptions are probably the reason that the clinical terminology of these hernias is confusing. All intestinal wall hernias are frequently referred to as Richter-Littré hernias or Littré's hernias, particularly by German speakers. In 1888, Frederic Treves differentiated Littré's hernias from Richter's hernias[3]. A Littré's hernia is present if the content of the hernia exists in a Meckel's diverticulum whereas Richter's hernia applies to all intestinal wall hernias.

Paraduodenal hernias as well as Meckel's diverticula are rare, and their discovery is frequently delayed because they induce diffuse symptoms. The symptoms of Meckel's diverticula could be similar to those of appendicitis. The diagnosis of paraduodenal hernias is challenging because of the lack of explicit symptoms. Paraduodenal hernias are rare causes of bowel obstruction, and if strangulation is present, the mortality rate could approach 50%[12]. There is a discussion of left paraduodenal hernias being identified as congenital mesocolic hernias[13].

To treat our patient, we considered the basic principles of hernia surgery by reduction and assessment of the hernial contents and correction of the defect. First, we repositioned the sac contents, which frequently consist of the majority of the small bowel, so that following the laparotomy, the surgeon accomplishes a lack of small bowel in the abdominal cavity[14], as in our case. After the reduction, we unexpectedly found the perforated Meckel's diverticulum with a fibrous ring at its base. We suspected that the Meckel's diverticulum was incarcerated in an additional pouch of the large hernial sac and that the fibrous ring had to be interpreted as an incarceration ring. This finding was confirmed histologically. We resected the Meckel's diverticulum with a stapler. To prevent a postoperative abscess in the preformed hernial sac caused by contamination resulting from perforation of the Meckel's diverticulum, we opened the bursa omentalis by transection of the gastrocolic ligament, resected the hernial sac and lavaged it. We performed a tension-free closure of the paraduodenal hernial orifice with the use of an omental flap to prevent recurrence of the hernia. To achieve that surgical goal, we used an absorbable running suture, taking care to avoid injury to the nearby mesenteric vessels. Our finding was an incarcerated and perforated Meckel's diverticulum in a Treitz hernia.

In a thorough search of the literature, we could not find a similar case. Developing a hernia induced by a combination of these two seldomly seen congenital defects is a rare coincidence. There were several case reports of patients with a Littré's hernia during the 20th century, as well as other rare conditions including Meckel's diverticulum in an obturator hernia[5]. A recently published case described a patient with a congenital defect of the mesocolon in which an ileal loop with a Meckel's diverticulum was prolapsed[4]. In that case, there was a defect in the right transverse mesocolon; however, the patient presented without a hernial sac, and thus there was no true internal hernia. To the best of our knowledge, this paper is the first report of an incarcerated and perforated Meckel's diverticulum in a confirmed internal paraduodenal hernia.

COMMENTS

Case characteristics

Acute abdominal pain.

Clinical diagnosis

Temperate abdominal epigastric tenderness.

Differential diagnosis

Diseases causing hollow organ perforation in the upper abdomen.

Laboratory diagnosis

White blood cell count: 16.9 g/L; C-reactive protein: 203.5 mg/L.

Imaging diagnosis

Extraluminal air was found in the computed tomography-scan near the ascending duodenum.

Pathological diagnosis
Perforated Meckel's diverticulum with venous congestion and peritonitis in a left paraduodenal hernia.

Treatment
Reduction of the bowel, resection of the Meckel's diverticulum and the hernia sac and closure of the hernial orifice with an omental flap.

Experiences and lessons
This case report presents the clinical characteristics of a perforated Meckel's diverticulum in a Treitz' hernia. This new clinical situation has to be considered in differential diagnosis of acute abdomen.

Peer-review
The authors have described an interesting case.

Abstract

The evidence in the medical literature on the efficacy and safety of rituximab therapy for primary glomerulonephritis is limited and controversial. We describe two male Caucasian patients with rapidly progressive kidney failure due to primary proliferative glomerulonephritis. Both of them received high-dose intravenous corticosteroids and oral cyclophosphamide with limited benefit. The first patient (hepatitis C virus-negative mixed cryoglobulinemia) underwent plasma-exchange with intravenous immunoglobulins; he showed significant benefit on kidney function (he became dialysis independent with serum creatinine going back to 1.6 mg/dL) after one rituximab pulse even if urinary abnormalities were still present. No improvement in renal function or urinary changes occurred in the second patient. Both these individuals developed sepsis over the follow-up, the first patient died two months after rituximab therapy. This report is in keeping with the occurrence of severe infections after rituximab therapy in patients with renal impairment at baseline and concomitant high-dose steroids.

Key words: Chronic kidney disease; Cryoglobulinemic vasculitis; Membranoproliferative glomerulonephritis; Rituximab

Core tip: A small but growing body of evidence is emerging on the efficacy and safety of rituximab therapy for primary glomerulonephritis. Various authors have claimed that rituximab for glomerular diseases is effective and has minimal adverse effects. We report on two male Caucasian patients who were refractory to conventional immunosuppressive therapy; each of them received one rituximab pulse and developed sepsis over the follow-up, the first patient died two months after rituximab therapy. The risks (and the predictive

factors) of severe infections in kidney patients on rituximab therapy are unclear and appear an area of active research.

Fabrizi F, Cresseri D, Fogazzi GB, Moroni G, Passerini P, Martin P, Messa P. Rituximab therapy for primary glomerulonephritis: Report on two cases. *World J Clin Cases* 2015; 3(8): 736-742 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/736.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.736

INTRODUCTION

Primary glomerulonephritis (GN) remains an important cause of end-stage kidney disease. Preliminary trials have recently shown the efficacy of rituximab for adult-onset primary GN[1]; rituximab being a genetically chimeric monoclonal antibody directed to CD20 antigen, a B-cell-specific transmembrane found on immature and mature cells, as well as on malignant B cells. Following treatment with rituximab (RTX), B-cells are prevented from proliferating, and undergo apoptosis and lysis through complement-dependent and - independent mechanisms. B-cell depletion usually persists for 6-9 mo in around 80% of patients, but the degree of depletion is greatly variable. Rituximab is currently approved for treating various malignancies including B cell non-Hodgkin's lymphoma and chronic lymphocytic leukemia; also, it has been licensed for refractory rheumatoid arthritis, granulomatosis with polyangiitis (Wegener's granulomatosis) and microscopic polyangiitis. Rituximab was expected to inhibit the production of autoantibodies involved in the pathogenesis of the disease without the toxicity of nonspecific immunosuppression. It has been the first monoclonal employed for the treatment of glomerular diseases and has been initially used for patients with membranous nephropathy but its use has rapidly spread to other glomerular diseases[1]. Membranous nephropathy and membranoproliferative GN are characterized by glomerular deposition of immune complexes; a crucial role of B cells in membranous (MN) and membranoproliferative glomerulonephritis pathogenesis through autoantibody production and antigen presentation has been mentioned. A small but growing body of literature is emerging on the benefits of rituximab in MN and membranoproliferative glomerulonephritis as primary treatment or as treatment of lesions refractory to other immunomodulatory regimens. In this setting, the drug appears to be well tolerated with small adverse events (Table 1)[2-8].

We report here our experience on rituximab use in two patients with progressive kidney failure due to primary proliferative GN. Both of them received conventional immunosuppressive therapy with limited benefit on urinary and biochemical abnormalities; then, they underwent one RTX pulse but developed sepsis over the follow-up. A brief review on the safety and efficacy of rituximab for primary GN has been also added.

CASE REPORT

Patient 1

A 51-year-old Caucasian male patient was admitted to hospital for two-week's duration of abdominal pain with vomiting and diarrhoea. His medical history included arterial hypertension and symptomatic hepatitis C virus (HCV)-negative mixed cryoglobulinemia (since three years) with recurrent purpura and peripheral neuropathy at the lower extremities. Skin biopsy had shown leukocytoclastic vasculitis whereas neurological evaluation had revealed mono-neuritis at the left foot with axonal ischemic damage, probably related to cryoprecipitable immune complexes in the vasa nervorum. He had received low dose oral corticosteroids and azathioprine with partial control of cutaneous and neurological abnormalities. A bone marrow biopsy had reported no evidence of malignant lymphoma, and a small expansion of B lymphocytes (10%-15%).

A physical examination showed bilateral edema and hypertension (180/100 mmHg), purpuric rash with ulcers at the legs (Figure 1); no bowel movements were apparent from the clinical standpoint, this being confirmed by an abdomen X-ray. An ultrasound scan of the abdomen showed normal sized kidneys bilaterally, with normal echotexture. At presentation (Table 1), abnormal laboratory results included serum creatinine level of 2.5 mg/dL, proteinuria, 3.6 g/24 h, and hypoalbuminemia (2 g/L). Other pertinent chemistries were: positive cryoglobulins, with a cryocrit of 3% (polyclonal IgG and monoclonal IgM*k*), elevated rheumatoid factor (148 IU/mL) and hypocomplementemia. Serology was negative for hepatitis B virus (HBV), HCV and human immuno-deficiency virus (HIV) markers, polymerase chain reaction tested negative for HCV RNA. Repeat urine sediment, analyzed by phase-contrast microscopy, showed severe microscopic hematuria (> 50 erythrocytes/microscopic field), many dysmorphic erythrocytes and casts (ialine, granular and red cell casts). Bence Jones proteinuria (kappa type) was positive. The search for anti-neutrophil cytoplasmic antibody (proteinase 3 and myeloperoxidase), anti-glomerular basement membrane antibody, extractable nuclear antigen antibody, antinuclear and anti-double stranded DNA tested negative.

Renal biopsy was not performed due to anatomic reasons, and a diagnosis of essential MC with rapidly progressive renal failure due to nephritic/nephrotic syndrome was made. Treatment was initiated with intravenous methylprednisolone (600 mg/d for three days), oral prednisone (50 mg/d on taper), and oral cyclophosphamide (100 mg daily). The progressive deterioration of kidney function (serum creatinine raised to 6.3 mg/dL, blood urea nitrogen to 279 mg/L) led us to make sequential plasma-exchange (nine sessions) and high-dose intravenous immunoglobulins (five procedures); in addition, hemodialysis was started. We

Figure 1 Purpuric rash with ulcers at the leg (patient 1).

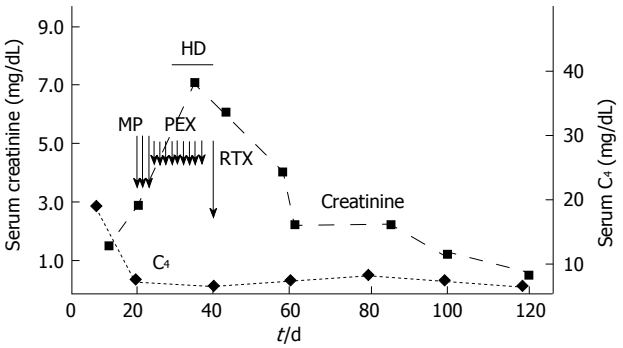

Figure 2 Biochemical/serological response to therapy (patient 1). HD: Haemodialysis; MP: High-dose methylprednisolone; PEX: Plasma-exchange; RTX: Rituximab.

observed healing of skin ulcers and improvement of neuropathic pain; GI disorders disappeared but immunosuppressive therapy was complicated by *Clostridium Difficile*-positive diarrhea, which was successfully treated with oral vancocine. Due to the persistence of severe renal failure (serum creatinine of 4.2 mg/dL), he received one infusion of RTX (375 mg/m^2) off-label (Figure 2); by day 6 of the RTX dose, an improvement of urine output occurred. Since then, serum creatinine went back to 1.6 mg/dL, and blood urea nitrogen to 104 mg/dL. At discharge from the hospital, his medications included oral steroids, rabeprazole, amlodipine, furosemide, calcium carbonate, gabapentine, and darboepoetin.

Two weeks after hospital discharge, serum creatinine was 1.76 mg/dL, blood urea nitrogen, 86 mg/dL, serum albumin 2.5 g/dL; severe and dysmorphic hematuria and non-nephrotic proteinuria (1.43 g/L) being still present. Low white blood cell count after RTX administration (3.4 × 10^3/mmc) occurred. According to flow cytometry, CD20$^+$ B cells were 19% of total peripheral blood lymphocytes (before RTX) and fell to 1% (after RTX, since day 6) with no increase over the following weeks.

One month later, he became pyrexial with a temperature around 38 ℃ and was admitted again to the hospital. Pertinent biochemistry included serum creatinine (0.8 mg/dL), cryoglobulins and rheumatoid factor tested positive. Complete blood count gave the following features: white blood cells 2.67 × 10^3/mmc, erythrocytes 3.57 × 10^6/mmc, platelets 209 × 10^3/mmc. Flow cytometry: lymphocytes 169/mm^3, CD3$^+$ cells 142 (83.9%), CD19$^+$ 0 (0%), natural killer cells 25 (14.9%). Gamma globulins were 0.16 g/dL (3.9%, 11%-18.8%). IgA < 4 mg/dL (70-400), IgG 84 mg/dL (700-1600), IgM 108 mg/dL (40-230). Monoclonal component by serum electrophoresis (IgMk + oligoclonal Ig) was again detected. An active urinary sediment with non-nephrotic proteinuria (1.21 g/d) was still present. Sepsis from *Enterococcus Spp.* was identified whereas the chest radiograph reported multiple pneumoniae. The culture of the broncho-alveolare lavage fluid was positive for *Candida albicans*, thus, we initiated intravenous imipenem and antifungal

medications. Medical and supportive therapy was unsuccessful and the patient ultimately expired due to septic shock (two months after RTX pulse).

Patient 2

A 49-year-old Caucasian male underwent kidney biopsy for evaluation of serum creatinine 1.35 mg/dL [estimated glomerular filtration rate (eGFR) 56 mL/min per 1.73 m^2 by MDRD equation], 3.2 g of proteinuria on 24-h urine collection and active urinary sediment (severe microscopic hematuria with red blood cell casts). Renal biopsy showed global ialinosis in some glomeruli (5 out of 14); the others had intense glomerular hypercellularity (mainly due to mesangial proliferation), a limited number of mesangial immune deposits and segmental thickening of glomerular basement membrane were also present. Final diagnosis was mesangial proliferative GN with immune deposits of unclear significance. Other pertinent chemistries were: negative cryoglobulins, normal rheumatoid factor and complement fractions; serum protein electrophoresis in the normal range. Serology tested negative for HBV, HCV and HIV markers, polymerase chain reaction was negative for HCV RNA. The search for anti-neutrophil cytoplasmic antibody (proteinase 3 and myeloperoxidase), anti-glomerular basement membrane antibody, extractable nuclear antigen antibody, antinuclear and anti-double stranded DNA tested negative. At discharge from the hospital, his medications included oral steroids, rabeprazole, amlodipine, doxazosine, furosemide, calcium carbonate, and darboepoetin. Partial remission of nephritic/nephrotic syndrome with improvement of kidney function (serum creatinine going back to 1.1 mg/dL) was obtained with intravenous methylprednisolone pulses, oral cyclophosphamide, azathioprine, and mycophenolate mofetil in variable associations. Eight years later, he was again admitted to our unit, showing bilateral lower-extremity edema, arterial hypertension and serum creatinine of 2.9 mg/dL (eGFR 23 mL/min per 1.73 m^2 by MDRD equation). Nephrotic proteinuria was demonstrated (proteinuria of 9.2 g/d) with active urinary sediment. A repeat kidney biopsy revealed intracapillary/extracapillary glomerular proliferation with several crescents and fibrinoid necrosis, diffuse arteriolosclerosis, in addition to uniform and diffuse thickening of the glomerular basement membrane. Immunofluorescence demonstrated sporadic and granular deposition of C1q/C3 in the mesangium and capillary walls; fibrinogen in the Bowman space. Renal biopsy was complicated by perirenal hematoma and a few units of red packed cells were given. He received high-dose intravenous diuretic therapy with edema resolution and body weight loss, and intravenous methylprednisolone pulse therapy (500 mg daily intravenous for three alternate days) with low-dose oral steroids was not effective. Thus, one infusion of RTX (375 mg/m^2) off-label was administered. One month after rituximab administration he was again hospitalized (acute pulmonary insufficiency with septic shock); serum creatinine of 4.56 mg/dL (eGFR, 11 mL/min per 1.73 m^2). Active urinary sediment and nephrotic proteinuria persisted. Pulmonary aspergillosis was documented- medical plus supportive therapy was initiated and the patient recovered in a few weeks; however, he developed irreversible kidney failure and initiated dialysis acutely. He is currently doing well on maintenance hemodialysis (thrice weekly) treatment.

DISCUSSION

We report here on two patients with rapidly progressive renal failure due to idiopathic proliferative GN who were resistant to conventional immunosuppressive therapy. Both the patients underwent rituximab treatment in off-label condition, RTX infusion was well tolerated by both the patients but sepsis developed over the follow-up, fatal course occurring in patient 1. Numerous case reports and case series have suggested that the addition of rituximab to standard chemotherapy for malignant lymphoma increases the risk of viral infections such as varicella zoster[9], cytomegalovirus[10], HBV[11], parvovirus[12], and enteroviral encephalitis[13]. The risk of HBV reactivation has been added to the existing Boxed Warning of the rituximab label by the Food and Drug Administration in 2013[14]. Impaired immunity against non-viral pathogen agents such as Pneumocystis jirovecii[15] or cryptococcus[16] after rituximab therapy has been also noted.

A recent systematic review and meta-analysis has shown that rituximab plus standard chemotherapy for malignant lymphoma increases the incidence of severe leucopenia (RR = 1.24; 95%CI: 1.12-1.37) and granulocytopenia (RR = 1.07; 95%CI: 1.02-1.12) even if the overall risk of severe infections has not been increased (RR = 1.0; 95%CI: 0.87-1.14)[17]. We have already reported on a case of cholestatic hepatitis C after rituximab therapy for gastric cancer in a renal transplant recipient[18]. On the other hand, various authors have claimed that rituximab use for glomerular diseases is effective and has minimal adverse effects (Table 2)[1,19,20].

Our first patient presented idiopathic cryoglobulinemic vasculitis which has undefined therapeutic management[21]. There is some evidence on the efficacy and tolerance of RTX in patients with HCV-associated mixed cryoglobulinemia vasculitis who were naïve, resistant or intolerant to antiviral therapy[22-25]. Two randomized controlled trials have compared RTX with conventional immunosuppressive therapy for HCV-related mixed cryoglobulinemia vasculitis[26,27]. As listed in Table 3, evidence in the medical literature on RTX use among patients with non-infectious cryoglobulinemia vasculitis targeting kidneys is extremely limited, and a total of 16 cases were retrieved[28-37]. Patient 1 gives emphasis on the efficacy of RTX, as one RTX pulse made possible the control of renal disease: kidney function normalized, nephrotic syndrome disappeared and only nephritic urinary changes persisted. However, RTX use was complicated by sepsis a few weeks after

RTX pulse. On the basis of the evidence reported in Table 3, severe infections after RTX treatment are not uncommon [35% (6/17)].

RTX therapy in patients with nonviral cryoglobulinemia vasculitis or membranoproliferative GN raises various questions such as the role of RTX as first-line or rescue therapy, the efficacy/safety of maintenance therapy with RTX, and the tolerance to RTX. In the absence of randomized controlled trials, such questions remain unanswered; as an example, the poor tolerance of our patients after RTX administration remains unclear. The French multicenter CryoVas survey retrospectively evaluated 242 patients with non-infectious mixed cryoglobulinemia vasculitis, RTX plus corticosteroids had greater therapeutic efficacy compared with corticosteroids alone and corticosteroids plus alkylating agents[38]. However, RTX plus corticosteroids was associated with more frequent infections than corticosteroids alone (HR = 9; 95%CI: 3.1-20, $P < 0.001$). Prospective data from the AIR (AutoImmunity and Rituximab) registry, which includes data on patients treated with rituximab off-label, have shown that among patients (*n* = 23) with nonviral cryoglobulinemia vasculitis on RTX, side-effects occurred in almost half of the patients (*n* = 11), including severe infections[34]. Infectious episodes were mostly reported in a patient subgroup (age > 70 years, essential type Ⅱ MC, GFR < 60 mL/min, and high-dose steroids) and were fatal in many (*n* = 3)[34]. Both our patients had important kidney impairment at baseline and concomitant therapy with intravenous high-dose corticosteroids, among other immunosuppressive agents.

The current study calls for further research on the RTX-based treatment of essential cryoglobulinemic vasculitis or membranoproliferative GN but the low frequency of patients in individual centers would make

randomised controlled trials extremely difficult. Rituximab has surfaced as potential treatment option for some primary glomerular diseases and the HCV KDIGO Study Group[39] had already included rituximab among the recommended drugs (steroids, and cyclophosphamide) for the immunosuppressive treatment of HCV-associated kidney disease. The risks (and the predictive factors) of infections in kidney patients on RTX-therapy are not yet understood and are an area of active research. These patients should be monitored over the follow-up to avoid the occurrence of infectious episodes.

COMMENTS

Case characteristics

Two male Caucasian patients with progressive kidney failure.

Clinical diagnosis

Arterial hypertension, bilateral lower-extremity edema.

Differential diagnosis

Progressive kidney failure due to secondary glomerular disease.

Laboratory diagnosis

At presentation serum creatinine ranged between 2.5 and 2.9 mg/dL and proteinuria 3.6 and 9.2 g/d, microscopic haematuria with dysmorphic erythrocytes and red cell casts.

Imaging diagnosis

Computed tomography scan revealed normal sized kidneys bilaterally with normal echotexture in both the patients.

Pathological diagnosis

Renal biopsy (patient 2) showed intracapillary/extracapillary glomerular proliferation with several crescents and fibrinoid necrosis, in addition to uniform diffuse thickening of the glomerular basement membrane.

Treatment

Both the patients received one infusion of rituximab (375 mg/m^2) off-label.

Related reports

Various authors have claimed that rituximab use for glomerular diseases is effective and has minimal adverse effects.

Term explanation

Phase-contrast microscopy is a microscopy technique to analyze the morphology of urine erythrocytes.

Experiences and lessons

The risks and the predictive factors of severe infections in kidney patients on rituximab therapy are still unclear and appear an area of active research.

Peer-review

It is a good article.

Abstract

A 59-year-old nursing home patient with Down syndrome was brought to the internal medicine department of our hospital due to fever, cough without expectorate, and dyspnea. A thoracic computed tomography revealed the presence of bilateral basal parenchymal opacities. Her condition deteriorated after admission and troponin reached a peak serum concentration of 16.9 ng/mL. The patient was in cardiogenic shock. In addition to fluid resuscitation, vaso-active amine infusion was administered to achieve hemodynamic stabilization. The differential diagnosis investigated possible pulmonary embolism, myocardial infarction, and myocarditis. Furthermore, a second transthoracic echocardiogram suggested Tako-Tsubo syndrome. This is a septic patient. The purpose of this manuscript is to review studies which formerly examined the possible association between high levels of troponin and mortality to see if it can be considered a positive predictive factor of fatal prognosis as the case of thrombocytopenia, already a positive independent predictive factor of multiple organ failure syndrome, and generally to characterize risk profile in a septic patient.

Key words: Sepsis; Shock; Hypotension; Troponin; Myocardial dysfunction

Core tip: The importance of cardiac involvement during sepsis, when occurs, worsens prognosis. However, as myocardial dysfunction is reversible, an early diagnosis and treatment to improve the survival. The awareness of risk profile to develop a severe myocardial dysfunction in a septic patient would be suitable in order to enforce careful resources in this subset of patients. Moreover, other research are needful to perform the best therapeutic strategy of haemodynamic stay which,

sometimes, (*e.g.*, when Tako-Tsubo syndrome occurs) can call for intra-aortic balloon pump counter pulsation.

When sepsis affects the heart: A case report and literature review. *World J Clin Cases* 2015; 3(8): 743-750 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/743.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.743

INTRODUCTION

Sepsis is a syndrome caused by the inefficiency of the mechanisms of control and containment of the infection. It is characterized by symptoms and signs of systemic inflammatory reaction to infection and manifestations of organ dysfunction resulting from alterations in the microcirculation.

It is the second most common cause of death in non-coronary intensive units, and the tenth in high-income countries, with a mortality rate between 15% and 50%. Approximately 150000 deaths per year are caused by sepsis in Europe. The number of cases is expected to increase at a rate of 1.5% per year from the current prevalence of 3 cases for every 1000 inhabitants[1].

The most common pathogenic Gram positives (whose incidence is progressively increasing) are *Staphylococcus aureus* and *Streptococcus pneumoniae*, whereas among the most frequent Gram negatives it is possible to include *Escherichia coli*, *Klebsiella* spp., and *Pseudomonas aeruginosa*[2].

In a smaller percentage of cases, sepsis can be caused by mycobacteria, mycetes, protozoa (*Plasmodium Falciparum*) and viruses[1].

CASE REPORT

A 59-year-old nursing home patient with Down syndrome had high fever unresponsive to paracetamol, and unproductive cough for 4 d. Accordingly, cefriaxone was administered with some improvement (defervescence and reduction of cough). After the reappearance of fever associated with dyspnea, acrocyanosis, and her deteriorating condition, she was brought to the emergency room, and on initial evaluation she was admitted to the internal medicine department of our hospital. She had a ventricular (pacing), ventricular (sensing), inhibition (response) (and) rate-adaptive holder pacemaker because of a third degree atrioventricular block. Furthermore, her past medical history included chronic cerebrovascular disease due to previous ischemic strokes complicated by vascular dementia and epilepsy. The latter was possibly due to Alzheimer-like disease as is often seen in down syndrome patients.

On arrival in the internal medicine department the patient was drowsy, tachypneic, tachycardic, low blood pressure (80/50 mmHg) and hypoxemic (PaO_2 57 mmHg). The thoracic computed tomography (CT) revealed the presence of bilateral basal parenchymal opacities. The patient was treated empirically with piperacillin/tazobactam, levofloxacin, and vancomycin according to protocol for health care-associated pneumonia. An initial bed-side echocardiogram evaluation revealed severe left ventricular dysfunction with an ejection fraction of 36%, and dilatation of the right ventricle with medium-apical akinesis. In addition to fluid resuscitation, dopamine, dobutamin, and norepinephrine infusion were administred. At times simultaneous administration of two vaso-active amines was necessary to achieve hemodynamic stabilization and adequate diuresis. The first electrocardiogram showed regular activation of the pacemaker and subsequent evaluations revealed repolarization abnormalities of probable hypoxic nature in the inferior wall only (Figure 1).

The results of blood tests are shown in Table 1, reporting thrombocytopenia (80000 $10^3/\mu L$) and the peak serum concentration of troponin I (16.9 ng/mL - reference range < 0.012 ng/mL). Blood and urine cultures showed no growth.

A second transthoracic echocardiogram showed akinesis of medium-apical segments of both ventricles with moderate systolic dysfunction (E.F. 45%). This evidence does not rule out an acute ischemic event, but could be seen as suggesting Tako-Tsubo syndrome.

The differential diagnosis also concerned pulmonary embolism, myocardial infarction and myocarditis. The former was excluded through execution of CT angiography. In relation to myocardial infarction and myocarditis, it was not possible to perform coronary angiography or a myocardial biopsy. However, the absence of persistent regional abnormalities ruled out acute coronary syndrome. The third transthoracic echocardiogram showed complete remission of the regional abnormalities (E.F. 50%). The patient was discharged after gradual weaning from vaso-active amines in adequate clinical condition. Therefore, our patient had survived, in spite of severe cardiac involvement and possible Tako-Tsubo syndrome.

DISCUSSION

In our case there was a significant cardiac involvement associated with sepsis due to pneumonia, up to hearth failure which presented itself as an out-and-out cardiogenic shock. The "fluid resuscitation", the administration of vasoactive amines and early antibiotic therapy were needed to restore the hemodynamic stability, until the complete recovery of cardiac function, as indeed typically happens in Tako-Tsubo syndrome. The latter, in our patient, was induced by septic injury and characterized initially by hypokinesia of intermediate and apical segments of left ventricle and at a later stage by akinesis of the same with hyperkinesis of basal segment that typically characterizes the disease.

Nevertheless, the absence of head trauma, cerebral hemorrhage, pheochromocytoma, hypertrophic cardiomyopathy made the diagnosis of Tako-Tsubo syndrome

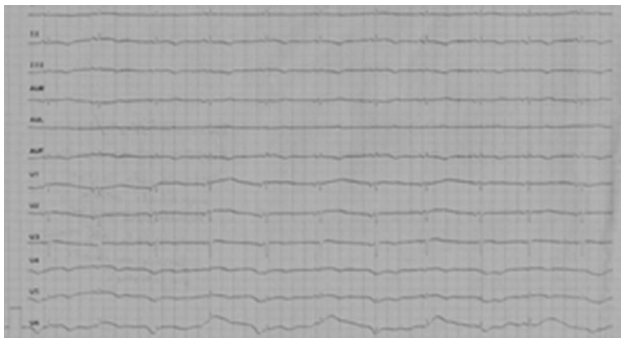

Figure 1 Electrocardiogram at the third day from presentation (showed repolarization abnormalities of probable hypoxic nature in the inferior wall).

plausible. Instead, it was ruled out obstructive atherosclerosis of coronary epicardial artery, since coronary angiography has not been carried out within 48 h, as suggested by Mayo Clinic's diagnostic criteria[3]. However, the disappearance of the alterations of the segmental kinesis at echocardiographic final assessment, allowed us to exclude this diagnosis. Endomyocardial biopsy would have been necessary for ruling out a myocarditis, in which the predominant involvement of right ventricle is quite, as it has been at any rate[4] initially in our case. The clinical presentation, at last, was not suggestive of Guillain-Barrè syndrome[5] nor electrocardiographic monitoring of recurrent ventricular tachycardia[6], conditions in which cases of reversible left ventricular dysfunction have been observed[7]. Therefore, differential diagnosis about Tako-Tsubo syndrome has been ruled out after analyzing anamnesis and clinical presentation. The latter (hypotension, tachycardia, hypoxiemia) also was suggestive of pulmonary embolism, excluded by CT angiography.

The principal cardiovascular manifestation of severe sepsis and septic shock is hypotension and myocardial dysfunction is often associated with them. Myocardial dysfunction does not seem to be caused by myocardial hypoperfusion[8,9] (coronary circulation is maintained or even intensified, although to observe disfunctions in the microcirculation is probable)[10] but rather by the action of depressant factors such as alpha tumor necrosis factor and beta interleukin 1 and does persist despite fluid resuscitation, as Court *et al*[11] have already shown. In addition to the effects of host's immuno-inflammatory responses (*e.g.,* cytokines and mechanisms related to nitric oxide)[12] circulating substances released by pathogens (*e.g.,* endotoxins) also seem to play an important role in provoking myocardial depression. In this sense, the first-line therapy is causal and consists of antibiotic therapy associate with the possible surgical excision of the infectious focus[13]. However, the restoration of hemodynamic stability is an important goal for the survival of the patient. Fluids remain a first-step therapy in clinical management of the cardiovascular failure in sepsis but it is arguable which of them would be the gold standard. Recent results indicate that

Table 1 Results of blood tests on admission and discharge

	Admission	Discharge	Reference range
Aspartate aminotrasferase (U/L)	94	17	< 37
Alanine aminotrasferase (U/L)	66	37	< 41
Calcaemia (mg/dL)	7.5	7.4	8.4-10.2
Gamma-glutamyltranspeptidase (U/L)	155	171	8-61
C-reactive protein (mg/dL)	14.6	3.2	0-0.5

Lactate dehydrogenase (UI/L)	755	511	240-480
Ferritin (ng/mL)	2440		15-150
D-dimer (ng/mL)	478	338	10-250
RB count ($\times 10^6/\mu L$)	3.72	3.53	4.5-5.5
Hemoglobin (g/dL)	12.5	11.7	12-18
Platelet count ($\times 10^3/\mu L$)	92	217	150-450
Myoglobin (ng/mL)	1031	99	0-62
Troponin I (ng/mL)	6.43	1.36	0-0.034

albumin also might be used with advantage in some specific subgroups of patients pending for the results of the ongoing trials on new generation starches[14]. Furthermore, thanks to its electrostatics properties, albumin reduces the endothelial permeability (sealing effect)[15-20]. Its efficacy is still now matter of debate. In patients with severe sepsis, treated with albumin and crystalloids compared with ones treated with crystalloids only, an increase in survival to 28 and 90 d was not observed[21]. As regards the methods of liquids' administration, according to Surviving Sepsis Campaign 2012, an initial fluid challenge in patients with tissue hypoperfusion and suspected hypovolemia, up to achieve $\geqslant$ 30 mL of crystalloids per kilogram of body weight. It would be needed to continue with the fluid-challenge technique until an actual hemodynamic improvement. Yet, a particular attention in balancing the fluids is necessary, inasmuch a positive fluid balance and elevated central venous pressure are associated with increased mortality[22,23].

With ongoing sepsis, advantageous effects, especially as for cardiac output, could be gained with administration of hypertonic saline solutions, as Oliveira *et al*[24] already suggested in their review. For the first time, this kind of therapy was employed in the treatment of hemorrhagic and traumatic shock, with quick restoration of central and peripheral blood flow[25]. Intravenous infusion of hypertonic saline solution summons fluids into vascular compartment and determines a redistribution of blood flow which, as for that matter our team has shown, in refractory heart failure enhances myocardial performance[26]. The proposed mechanism to explain these effects suggests a direct action on myocardial functionality and a decreased sympathetic tone[27]. Hence, infusion of hypertonic saline could be an alternative to early volume resuscitation of a patient with sepsis[28].

Furthermore, in a multicentric trial conducted in a tertiary care setting, protocol-based resuscitation of patients with septic shock diagnosed in the emergency

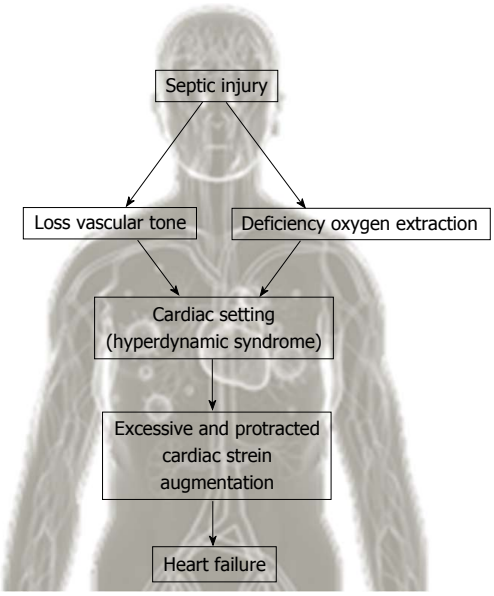

Figure 2 Synopsis of heart failure pathogenesis sepsis.

department, does not improve the outcomes[29].

Even more complex is the pathogenesis of heart failure that could occur during sepsis and which can provoke a significant increase of troponin.

The increase of troponin in sepsis is an event to be rationally expected. Its dosage, therefore, should not be taken for granted. Considering the heart's fundamental cardiovascular adaptation role in sepsis, a significant metabolic-inflammatory impairment can occur with high levels of troponin, associated with severe myocardial dysfunction. Moreover, a meta-analysis in "Intensive Care Medicine" a year ago evaluated the prognostic role of troponin in sepsis, showing that its elevated serum concentration was associated with a subset of patients at higher risk of death. Nonetheless, further studies are needed to determine an optimal troponin cut-off value[30]. B-type natriuretic peptides could also have a role in alerting clinicians to myocardial dysfunction. Their low serum values could exclude severe myocardial impairment. Yet echocardiography is the gold standard method to reveal cardiac dysfunction. Heart rate has also been proposed in the prognostic evaluation of septic patients. A rate of < 106 bpm on presentation suggested a favorable prognosis[31]. Concerning the latter, it is still debatable whether the use of β-blockers in septic tachycardial patients improves the survival. It has been observed that patients being in chronic treatment with β-blockers and later developed sepsis, and were admitted to the intensive care unit (ICU), could have advantages in terms of survival. However, physicians' doubts about using β-blockers in early stages of sepsis are licit[32]. Among other things, it is not still clear enough if in septic shock the increased cardiac rate is pathological or simply an expression of sympathetic hyperactivation. Instead, tachycardia is associated with a worse prognosis. In a prospective observational study in an ICU, esmolol's titrated administration for 24 h, maintaining a cardiac rate between 80 and 94 bpm in selected adult patients in septic shock after 24 h of hemodynamic stabilization, was able to maintain the microvascular blood flow and reduced the demand for epinephrine. However, patients with severe myocardial disfunction had been excluded from the study[33]. Recent results suggest that β-blockers' effects on metabolism, glucidic homeostasis, inflammatory feedback and cardiac function might be advantageous for septic patients[34,35]. In regard to the anti-inflammatory, antioxidant, immunomodulatory and anti-apoptotic actions, statins also might fall within preventing and treating patients with severe sepsis and septic shock[36,37].

However, beyond the value of troponin, B-type natriuretic peptides, and heart rate, the presence of myocardial dysfunction in sepsis is associated with higher mortality. It has been shown that cardiovascular disablement increased mortality from 70% to 90%, compared to 20% in septic patients without myocardial impairment[38].

Therefore, cardiac dysfunction in sepsis has prognostic value and coincides with its severity. Hence it's mandatory to know the pathophysiology of cardiovascular disease in sepsis. Microcirculatory disfunctions and mitochondrial derangement occurring in septic shock reduce the cellular energetic production[39]. Septic injury triggers a reaction in the cardiovascular setting that aims to increase the peripheral availability of oxygen and reduce the cellular effects of oxygen deficiency[40]. The cellular deficiency of oxygen and reduction in systemic vascular resistance give rise to hyperdynamic syndrome (increased stroke volume, heart rate, usage of oxygen)[41] (Figure 2). Alteration of cellular energetic production following to mitochondrial imbalances might be of great relevance in determining tissue injury and sepsis-associated multi organ failure. Future studies should focus on mitochondrial disfunction in order to comprehend the pathophysiological mechanisms of apoptosis and cellular protection to achieve a increasingly accurate treatment[42].

Such a hyperdynamic reaction, favoring adrenergic stimulation, can be hidden by hypovolemia due to insufficient fluid contribution or a mechanism of myocardial impairment[43] (Figure 3). The most frequent occurrence is heart failure with high cardiac index, which is in a phase of unbalance, but it is insufficient to increase metabolic requirements. Hyperdynamic syndrome endows an organism with the possibility to reduce septic injury and survival derives largely from that[44]. Hence the usefulness of administering inotropic positive drugs and to correct hypovolemia because a possible condition of circulatory failure, in the presence of increased oxygen requirements, is linked to a fatal prognosis[45].

The management of myocardial dysfunction sepsis-induced encompasses fluids's administration until the optimization of preload and, among positive inotropic agents, norepinephrine is the first choice[39]. The administration of dopamine should be reserved to carefully selected patients (those with a low risk of

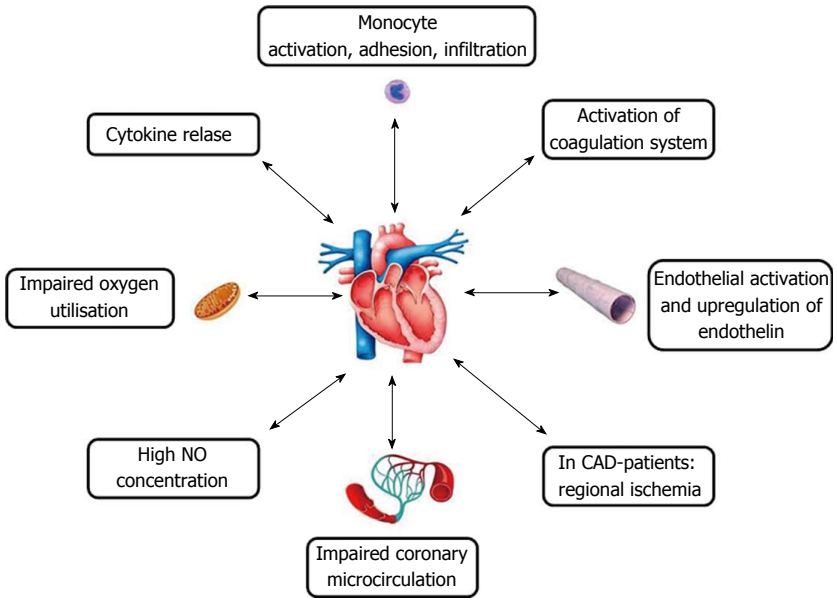

Figure 3 Possible mechanisms of myocardial impairment[43].

arrhythmias and either known grave left ventricular systolic dysfunction or low heart rate). The Surviving Sepsis Campaign guidelines 2012 promote either norepinephrine or dopamine as the first-choice vasopressor agent to maintain adequate perfusion tissue in septic shock[46,47]. Dobutamine also can be used in the early stages of sepsis in order to increase cardiac output. It has a certain selectivity for β_1-receptors[48]. Anyway, β1-agonists can be less effective in case of septic shock. It has been shown that its infusion improves the left ventricular ejection fraction more than 10% in 35% of patients affected by septic shock[49]. Its use requires careful clinical and instrumental monitoring for risk of tachycardia or arrhythmias and hypotension through beta$_2$-adrenergic receptors activation[50]. However, dobutamine is endorsed as the care's fundamental element of sepsis-related cardiovascular failure in international guidelines. Furthermore, it has been demonstrated that dobutamine enhances liver function and hepatic perfusion after experimental hemorrhagic shock[51]. Since one of the mechanisms of sepsis-induced myocardial dysfunction is the alteration of intracellular transport of calcium, a possibility of therapy might be represented by levosimendan[52], inotrope and peripheral vasodilator which is employed in acute congestive heart failure[53]. Levosimendan, acting with a mechanism of calcium-sensibilization in randomized studies comparing it with dobutamine in patients with severe heart failure with low cardiac output, has been observed as emodynamically more effective than dobutamine[54-56].

Another kind of heart failure associated with sepsis is Tako-Tsubo syndrome. For this reason it has been supposed that sepsis-induced systemic inflammation could have a role in starting the pathogenesis of the syndrome[57-59]. Myocardial dysfunction in sepsis could be a consequence of the direct action of different mediators of flogosis (cathecolamines responsible for hyperdynamic syndrome included) and of products of microbial derivation[13]. On the other hand, another pathogenic hypothesis for Tako-Tsubo syndrome is cardiac cathecolamine toxicity, as it could occur in sepsis, which would constitute the trigger[60].

Our case shows that exogenous support of vasoactive amines can be essential in facilitating hyperdynamic syndrome which characterizes sepsis in the pre-clinical phase. As for Tako-Tsubo syndrome, even though β-agonist agents have often been used, the results are conflicting[7], so intra-aortic balloon pump counter pulsation remains the first-line treatment if, after medical therapy (dopamine) and volume resuscitation, hypotension endures[61]. However, the disappearance of segmental kinesis's alterations and complete resolution of myocardial dysfunction, as in our case, if Tako-Tsubo syndrome is actually diagnosed, offer new perspectives that could improve our understanding of the physiopathology of this illness. Randomized clinical trials could demonstrate the possible efficacy of the treatment.

COMMENTS

Case characteristics

A 59-year-old nursing home patient with down syndrome presented fever, cough and dyspnea.

Clinical diagnosis

Main clinical findings were tachypnea, tachycardia and hypotension.

Differential diagnosis

Computed tomography (CT) angiography, thoracic CT, transthoracic echocardiogram were executed and differential diagnosis concerned pulmonary embolism, myocardial infarction, myocarditis, Tako-Tsubo syndrome and sepsi with severe myocardial involvement.

Laboratory diagnosis

The results of blood tests showed alterations of liver function (aspartate aminotrasferase: 94 U/L; alanine aminotrasferase: 66 U/L; gamma-glutamyl-transpeptidase: 155 U/L; alkaline phosphatase: 163 U/L); ferritin: 2240 ng/mL; myoglobin: 1031 ng/mL; C-reactive proteinmg: 14.6 mg/dL; lactate dehydrogenase: 755 UI/L; calcaemia: 75 mg/dL; D-Dimer: 478 ng/mL; thrombocytopenia (92000 × 10^{3}/μL); myoglobin: 1031 ng/mL; troponin: I 643 with peak serum concentration of 169 ng/mL.

Imaging diagnosis

Echocardiogram revealed severe left ventricular dysfunction with an ejection fraction of 36% and dilatation of the right ventricle with medium-apical akinesis.

Pathological diagnosis

The thoracic CT showed the presence of bilateral basal parenchymal opacities but blood cultures showed no growth.

Treatment

The patient was treated with piperacillin/tazobactam, levofloxacin, and vancomycin according to protocol for health care-associated pneumonia in add to fluid resuscitation and infusion of dopamine, dobutamin and norepinephrine.

Related reports

The sepsis-induced systemic inflammatory response syndrome can produce myocardial dysfunction that sometimes defines Tako-Tsubo syndrome.

Term explanation

The dosage of troponin and B-type natriuretic peptides, the monitoring cardiac rate can be helpful to identify setting risk of myocardial dysfunction during sepsis.

Experiences and lessons

This article points out the importance of early haemodinamic support with fluid resuscitation, vaso-active amine and catecholamines in sepsis-induced myocardial dysfunction, trying at the same time to define a risk profile of a septic patient with cardiac involvement whose mortality is high.

Peer-review

In spite of richness of literature about the cardiac involvment during sepsis and management of sepsis-induced myocardial dysfunction, other research to identify the more suitable therapeutic strategy is necessary.

Abstract

Cleidocranial dysplasia (CD) is an autosomal dominant syndrome which is characterized by several skeletal malformations such as non-closed fontanelles, skeletal abnormalities of the maxilla and mandible and absence of clavicles. Mid-facial hypoplasia and mandibular prognathism are mostly seen jaw abnormalities in CD. In this study, the combined orthodontic-surgical treatment of a patient with CD with class Ⅲ malocclusion and multiple unerupted primary and deciduous teeth is presented.

Key words: Cleidocranial dysplasia; Marie-Sainton syndrome; Forced eruption; Prognathism; Orthodontic extrusion

Core tip: Cleidocranial dysplasia is a syndromic disease with distinct craniofacial and maxillofacial manifestations. The satisfactory treatment of dental and

skeletal deformities in this disease can only be possible with combined orthodontic-surgical approach.

Çimen E, Dereci Ö, Tüzüner-Öncül AM, Yazıcıoğlu D, Özdiler E, Şenol A, Sayan NB. Combined surgical-orthodontic rehabilitation of cleidocranial dysplasia: 5 years follow-up. *World J Clin Cases* 2015; 3(8): 751-756 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i8/751.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i8.751

INTRODUCTION

Cleidocranial dysplasia (CD) is a syndromic disease which is also known as cleidocranial dysostosis or Marie-Sainton disease[1]. It is characterized by multiple or solitary supernumerary teeth, non-closed fontanelles, skeletal abnormalities of the maxilla and mandible, absence of clavicles, presence of open skull sutures, widening of pubic symphysis, multiple impacted permanent teeth and miscellaneous skeletal changes[2,3]. Mutations of the transcription factor RUNX2 which is one of the major regulators of bone maturation, are responsible for the occurrence of CD[2].

A multidiscipliner team approach is needed to overcome the dental abnormalities and facial deformities which are well-known complications that cause morbidity in CD patients. Combined treatment with orthognathic surgery and orthodontic therapy is the mostly-accepted treatment modality to correct mid-face hypoplasia and Class Ⅲ malocclusion in the treatment of CD patients.

In this study, the combined orthodontic-surgical treatment of a CD patient with class Ⅲ malocclusion and multiple impacted permanent teeth is presented.

CASE REPORT

Eighteen years old male with CD was referred to the department of orthodontics with complaints of ineffective chewing, biting and facial asymmetry (Figure 1). Orthopantogram, lateral cephalometric radiograph and antero-posterior radiograph were obtained for examination of skeletal and dental abnormalities (Figures 2 and 3). A diagosis of class Ⅲ, division 1 malocclusion was made and cone beam computerized tomography (CBCT) was taken to decide the exact shapes and positions of impacted teeth (Figure 4). Multiple permanent and 3 supernumerary impacted teeth were detected in CBCT sections and after orthognatic and surgical consultation, it was decided to erupt the impacted teeth and perform bimaxillary surgery to correct skeletal deformity.

The teeth 42, 31, 32, 33, 13, 12, 11, 21, 22, 23 were surgically exposed and orthodontic buttons were bonded for orthodontic traction under general anesthesia. Three impacted supernumerary teeth were extracted at the time of the exposure of permanent teeth. Missing teeth of the dentition were erupted in 10 mo (Figure 5). After eruption, orthodontic treatment was sustained and the alignment of dental arch was rendered at the end of 12 mo (Figures 6 and 7).

Bimaxillary orthognathic surgery was planned for correction of skeletal open-bite and class Ⅲ malocclusion. Patient was operated in general anesthesia. Post-operative recovery was non-eventful. Clinical outcome after surgery was satisfying according to the clinical point of view. Patient was undertaken in follow-up period with 6-mo intervals. Facial profile and occlusal appearance were normal and unchanged in 5th year follow-up control (Figure 8).

DISCUSSION

CD is associated with several heterogenous mutations in RUNX2 which is an osteoblast-specific transcription factor and also takes role in the tooth development[4]. The role of RUNX2 in tooth development partly accounts for dental abnormalities such as impacted permanent or supernumerary teeth[1]. However, the abnormal impaction of permanent and supernumerary teeth could not be fully explained since 40% of the CD cases do not have any apparent genetic mutation[2,5]. Most of CD patients are reported to have open sagittal sutures or fontanelles, multiple erupted or impacted supernumerary or primary teeth[5]. These symptoms are considered pathognomonic in the diagnosis of CD[2].

The treatment of CD varies due to the skeletal or dental abnormalities and the condition of impacted normal or supernumerary teeth. Daskalogiannakis *et al*[6] suggested that appropriate treatment of CD should be planned with careful consideration of age of the patient, expected duration of the treatment and patient expectation from the treatment. Dental management in CD is challenging in most cases and aims to achieve functional and esthetic results. Dental prosthesis is frequently used method for the functional rehabilitation of CD patients. With increasing attention to craniofacial anomalies in syndromic patients lately, collaborative orthodontic-surgical treatment of dental and skeletal anomalies of the jaws is suggested[6,7]. Several combined treatment regimens were proposed according to the timing and manner of approach to the impacted permanent teeth[8-12]. In our study, a technique similar to the Belfast-Hamburg[10,12] approach is applied to facilitate the eruption of impacted permanent teeth.

The traction of impacted teeth with elastics is a common method that is used in contemporary orthodontics, especially in syndromic cases such as CD. After surgical exposure of impacted or partially impacted tooth, a button or bracket is bonded and elastics are applied between impacted and opposing permanent erupted teeth[10,11]. If there are no opposing teeth or permanent erupted teeth are not suitable for traction, titanium screws may be used as anchorage

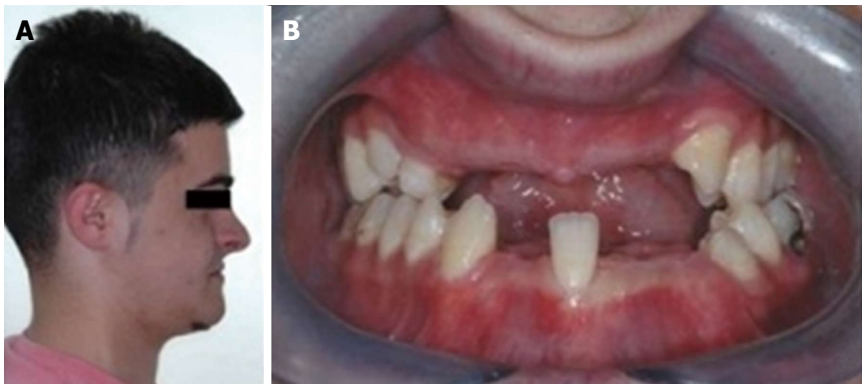

Figure 1 Clinical appearance before orthodontic treatment. A: Profile photo of the patient before orthodontic treatment; B: There were several missing teeth in the upper and lower dental arches.

Figure 2 Pre-orthodontic panoromic radiography reveals multiple impacted permanent teeth with impacted supernumerary teeth and retained deciduous teeth. Ten permanent teeth were impacted. There were 2 supernumerary impacted teeth in the mandible and 1 supernumerary impacted tooth in the maxilla.

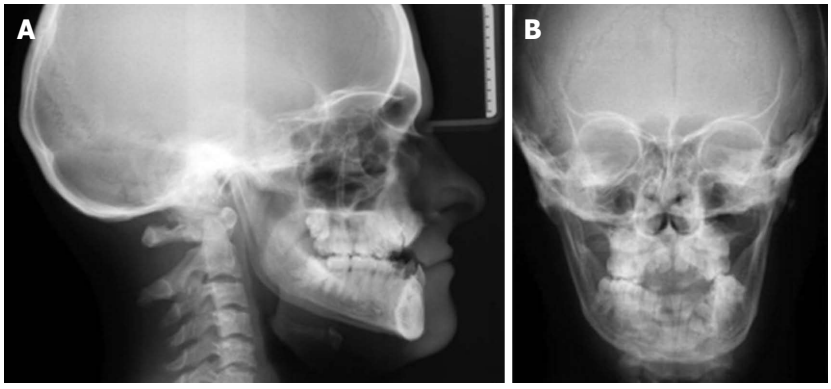

Figure 3 Sephalometric (A) and posterio-anterior radiographies (B) of the patient before orthodontic treatment.

for the application of traction elastics[13]. Rocha *et al*[14] suggested the use of a removable partial prosthesis to apply traction forces. In the current case, elastics were applied between lower and upper surgically exposed unerupted incisors and canines. The impacted teeth behaved as self-anchorage systems and full eruption of all impacted teeth were facilitated.

CD patients mostly have skeletal deformations leading to postural deformities. It is suggested that skeletal morphology may have a role in the development of temporomandibular joint (TMJ) disorders[15]. CD patients have jaw deformities and thus, tend to develop TMJ disorders. Physiotherapy or splint therapy is indicated in CD patients with TMJ disorders. The patient in the current study did not suffered from any myofacial pain or TMJ disorders and did not need any treatment on this matter.

CD is a syndromic disease with a prevalance of 1/1000000[16]. Dental manifestations of the disease is well-documented in the literature. Treatment planning in

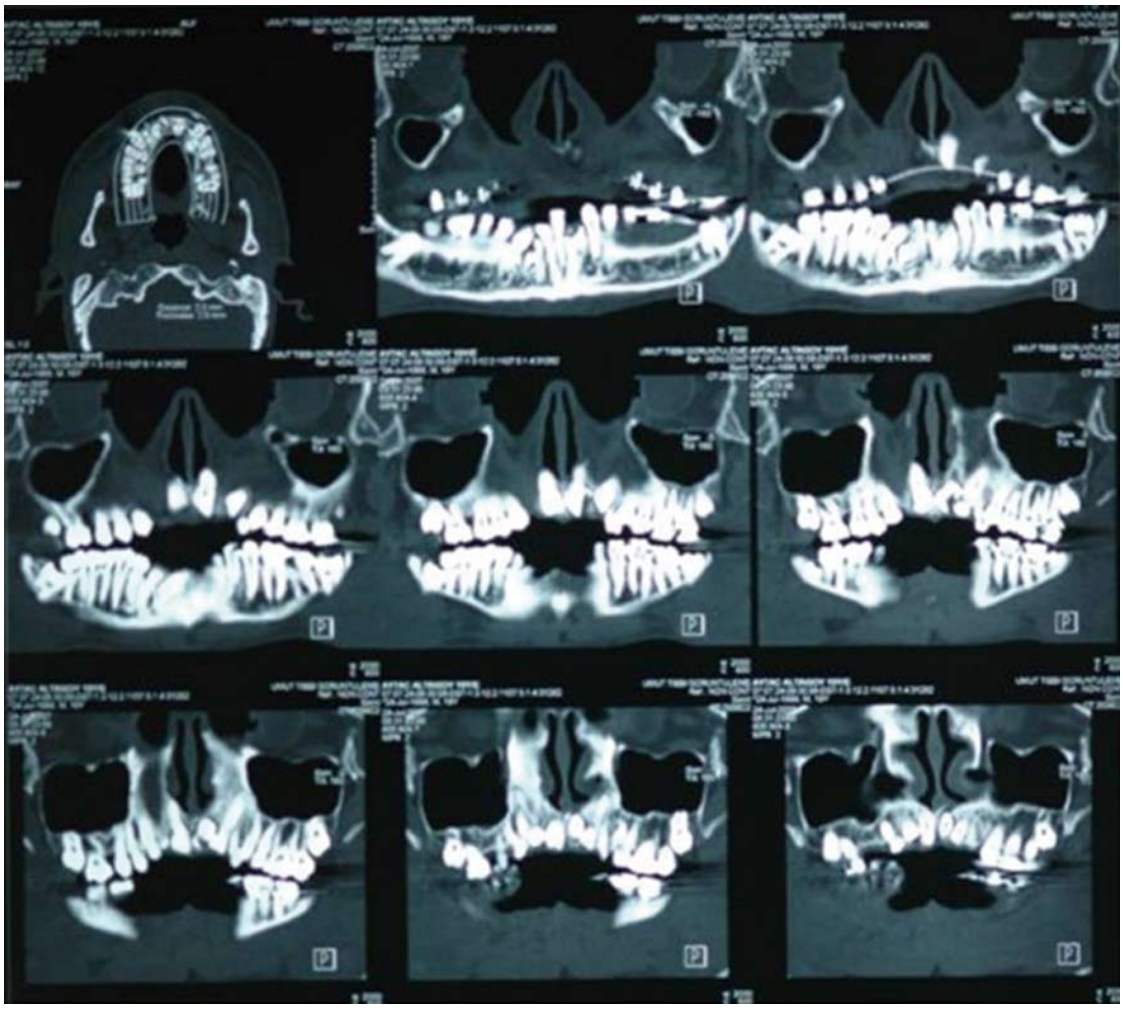

Figure 4 Frontal cone beam computerized tomography sections show impacted permanent and supernumerary teeth in detail.

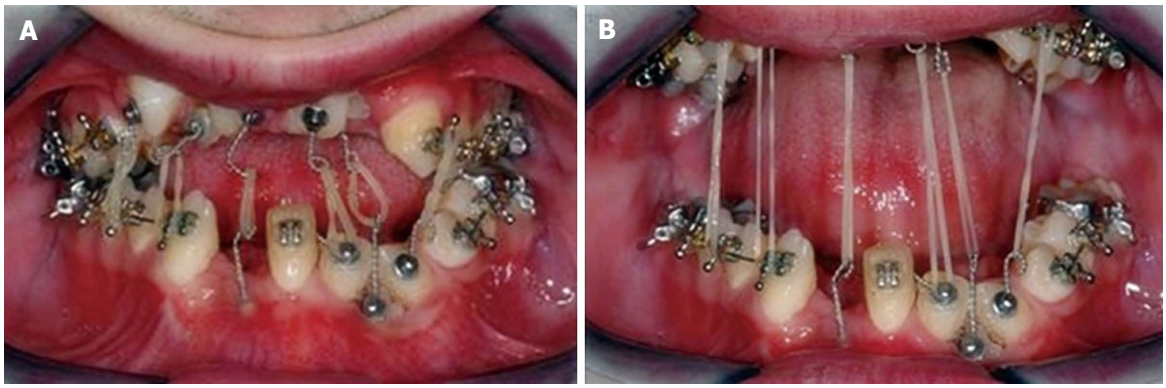

Figure 5 Intraoral elastics were applied between impacted teeth. A: Elastics remained passive when mouth is closed; B: They were activated when patient opened his mouth for daily activity such as speaking or drinking.

the rehabilitation of CD patients varies according to the degree of dental malocclusion, number of missing teeth and patients' expectations. The maintenance of force-aligned permanent teeth with elastic traction is also an important matter if the alignment of dental arches are provided with orthodontic treatment. Patients who are treated with combined surgical-orthodontic treatment should be monitored with continuous follow-up periods during early adulthood as in the current case.

ACKNOWLEDGMENTS

This study was presented as poster presentation in 20th. International Congress of Oral and Maxillofacial Surgery,

Santiago, Chile.

COMMENTS

Case characteristics

Cleidocranial dysplasia (CD) is a rare, dominantly inherited autosomal disease.

Clinical diagnosis

The main symptoms of CD includes hypoplastic or aplastic clavicles, supernumerary teeth, delayed eruption, impaction of permanent dentition and morphologic abnormalities of the maxilla and mandible.

Differential diagnosis

The differential diagnosis includes Crane-Heise syndrome, mandibuloacral dysplasia and pycnodysostosis.

Laboratory diagnosis

Laboratory testing methods are not needed in the diagnosis of CD.

Imaging diagnosis

Multiple impacted permanent or supernumerary teeth are detected in panoromic radiography or cone-beam computerized tomography sections of patients with CD.

Pathological diagnosis

Pathological examination is not needed in the diagnosis of CD.

Treatment

The treatment of CD includes orthodontics, orthognathic surgery or combined treatment modalities.

Experiences and lessons

The treatment of CD should be handled in a multidisciplinary basis. Follow-up is crucial after combined orthodontic-surgical therapy of cleidocranial dysplasia.

Peer-review

It is a well-written manuscript about a rare case.

Abstract

Vitamin K (VK), which was originally identified as a cofactor involved in the production of functional coagulation factors in the liver, has been shown to be involved in various aspects of physiological and pathological events, including bone metabolism, cardiovascular diseases and tumor biology. The mechanisms and roles of VK are gradually becoming clear. Several novel enzymes involved in the VK cycle were identified and have been shown to be linked to tumorigenesis. The VKs have been shown to suppress liver cancer cell growth through multiple signaling pathways *via* the transcription factors and protein kinases. A VK2 analog was applied to the chemoprevention of hepatocellular carcinoma (HCC) recurrence after curative therapy and was shown to have beneficial effects, both in the suppression of HCC recurrence and in patient survival. Although a large scale randomized control study failed to demonstrate the suppression of HCC recurrence, a meta-analysis suggested a beneficial effect on the long-term survival of HCC patients. However, the beneficial effects of VK administration alone were not sufficient to prevent or treat HCC in clinical settings. Thus its combination with other anti-cancer reagents and the development of more potent novel VK derivatives are the focus of ongoing research which seeks to achieve satisfactory therapeutic effects against HCC.

Key words: Hepatocellular carcinoma; Vitamin K; Steroid and xenobiotic receptor; Nuclear factor-kappa B; Protein kinase A; Protein kinase C; Drug repositioning

Core tip: Vitamin K (VK) is essential nutrient initially identified as a cofactor to produce functional coagulation factors. In addition to the roles in hemostasis, pleiotropic effects of VK in bone health, atherosclerotic diseases and cancer have been attracting. VK has been shown to play tumor-suppressive roles in several cancers including hepatocellular carcinoma (HCC) and reported to have beneficial effects in the treatment of HCC although its anti-tumor effects remain to be improved. Currently novel VK derivatives are under developing and will be

applied to cancer treatment in the future.

Jinghe X, Mizuta T, Ozaki I. Vitamin K and hepatocellular carcinoma: The basic and clinic. *World J Clin Cases* 2015; 3(9): 757-764 Available from: URL: http://www.wjgnet.com/2307-8960/full/v3/i9/757.htm DOI: http://dx.doi.org/10.12998/wjcc.v3.i9.757

INTRODUCTION

Vitamin K (VK) is a well-known lipid-soluble vitamin that includes two natural types: VK1 and VK2, and synthetic types, known as VK3, VK4, and VK5. VK1, also known as phylloquinone, was first accidently identified by Dam[1] and Dam *et al*[2] for its anti-hemorrhagic activities in 1929. VK1 is ubiquitous and abundant in green leafy vegetables because it plays a direct role in photosynthesis. It performs the classic functions of VK that help the production of blood-clotting proteins[3-5]. VK2 is also known as menaquinone (MK), the subtypes of which are mainly synthesized by limited bacteria. They are mainly stored in animal products. The VK2 subtypes, which are characterized by the isoprenoid side chain length. MK-4 differs from the other MKs, which are synthesized by bacteria, such as MK-7, MK-8, and MK-9, in that it is the most common VK2 subtype in animals. It is a unique subtype because it is normally synthesized from VK1 *in vivo*[6-8]. In addition to VK1 and VK2, VK3 is an efficient coagulant[9]. Unlike the safe natural forms and other synthetic forms of VK, VK3 (menadione) is considered to be toxic because large doses have been shown to cause various adverse effects, such as allergic reactions, hemolytic anemia, and cytotoxicity in liver cells[10]. Aside from its clinical use as a hemostasis medicine, VK4 has recently been reported to have inhibitory effects on prostate cancer[11]. VK5 is used in many areas including the pet food industry to inhibit fungal growth[12] and has been shown to mimic the effect of insulin[13].

OVERVIEW OF VK METABOLISM

Dietary VK is absorbed from the small intestine along with dietary fat[14]. The latest findings have demonstrated that a cholesterol transporter, Niemann-Pick C1-like 1, is a key regulator of intestinal VKs absorption[15]. Despite VK's rapid metabolism in tissue, which results in comparatively low body storage[16], primary VK deficiency is rare in healthy adults. In addition to the average diet, which provides plenty of VK, other mechanisms maintain its balance within the human body. The VK cycle plays a critical role in maintaining VK function. The cycle proceeds through the coupled carboxylation and epoxidation carried out by gamma-glutamyl carboxylase (GGCX) and VK epoxide reductase (VKOR)[17,18]. The product, VK epoxide, plays an important role as a cofactor in blood coagulation factor production and is then reconverted to VK by VKOR[19]. It is well-known that warfarin and other 4-hydroxycoumarins block the activity of VKOR to inhibit coagulation[20,21], however, the identification of the *VKOR* gene was a recent finding[22,23]. More recently, it was demonstrated that VKOR deficiency caused early postnatal lethality in a knockout mice model due to severe intracerebral hemorrhage[24]. For decades it was believed that VK1 had the potential to transform into MK-4 endogenously in animals[8,25]. This was proven by mouse experiments[26,27]. Recently, the same group found that UbiA prenyltransferase containing 1 (UBIAD1), a human homologue of prenyltransferase menA, is a human MK-4 biosynthetic enzyme. Furthermore, they demonstrated that UBIAD1 is located in the ER and that it is not suppressed by warfarin[7].

THE INVOLVEMENT OF VK IN CELL AND TUMOR BIOLOGY

In addition to the initially identified role of VK as a cofactor in the production of functional clotting factors through Gla residue formation in the liver, Gla protein was identified in the bone matrix proteins such as osteocalcin in 1975[28], and the involvement of VK in the bone physiology has been studied[29]. Furthermore, since the 1980s researchers have shown the anti-proliferative effects of VK in several cancer cell lines, including (HCC)[30-33]. Although the novel attractive functions of VK were reported, the mechanisms of VK function beyond their role in activating hepatic coagulation factors remained unknown. In 2003, Tabb *et al*[34] identified the steroid and xenobiotic receptor (SXR), also known as PXR, as a ligand of VK2 and showed that SXR mediated gene expression in an osteosarcoma cell line. Interestingly, this research group further demonstrated that SXR is abundantly expressed in the liver and that it reciprocally regulates nuclear factor-kappa B (NF-κB)-regulated gene expression[35].

The anti-tumor effects of VK were attractive to investigators studying cancer biology. Otsuka *et al*[36] reported that VK2 inhibited the growth of HCC cells as well as their invasiveness *via* the activation of protein kinase A (PKA) and the subsequent inhibition of Rho activation. They also demonstrated the activation of the transcription factors AP-2-, USF-1- and CREB in HCC cells by showing the nuclear accumulation of Ser-phosphorylated CREB, although the roles of these factors in the VK2-induced suppression of cell growth and invasion are not known.

We have revealed that VK2 inhibits the growth of human HCC cells by suppressing cyclin D1 expression through the inhibition of NF-κB activation by suppressing IKK activity[37]. The suppression of NF-κB activation by VK2 was also observed in lipopolysaccharide-mediated macrophage activation[38] and in the VK-mediated suppression of the osteoclastogenesis of bone cells through the RANK/RANKL pathway[39,40]. It has been

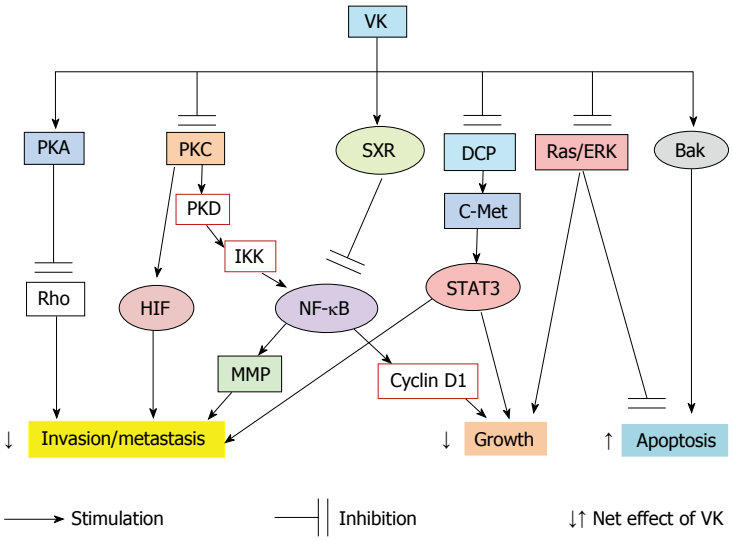

Figure 1 The effects of vitamin K on the multiple signaling pathways and the cellular behavior of liver cancer cells. PKA: Protein kinase A; PKC: Protein kinase C; PKD: Protein kinase D; DCP: Des-gamma-carboxy prothrombin; SXR: Steroid and xenobiotic receptor; ERK: Extracellular signal-regulated kinase; IKK: IκB kinase; NF-κB: Nuclear factor-kappa B; MMP: Matrix metalloproteinase; HIF: Hypoxia-inducible factor; VK: Vitamin K; STAT: Signal transducer and activator of transcription; Bak: Bcl-2 antagonist killer 1.

demonstrated that VK2 inhibits the expression of matrix metalloproteinases that contain NF-κB binding motifs in their promoter region[41], and augments the 5-fluorouracil-induced growth inhibition of HCC cells by inhibiting NF-κB activation[42]. Furthermore, we elucidated that VK2 inhibited the NF-κB activation through the inhibition of protein kinase C (PKC)-alpha and -epsilon kinase activities, as well as through the subsequent inhibition of PKD1 activation[43]. We have recently found that VK2 suppressed hypoxia inducible factor (HIF)-1 alpha activity through the inhibition of PKC by inhibiting the translocation of HIF to the nucleus[44].

Another interesting function of VK in the suppression of tumor development is its ability to induce apoptosis in certain cancer cells. Matsumoto *et al*[45] showed that VK2 induced apoptosis in Hep3B cells through the activation of AP-1. VK2-induced apoptosis is shown to be associated with p53 status in the human HCC cell line[46]. Recently Karasawa *et al*[47] demonstrated that VK2 covalently binds to Bcl-2 antagonist killer 1, a mitochondrial-mediated proapoptotic factor. The enhancement of apoptosis when VK2 was used in combination with acyclic retinoid (ACR) has been reported[48,49]. Kanamori *et al*[49] treated Huh7 cells with the combination of VK2 and ACR and found that VK2 plus ACR synergistically inhibited the growth of Huh7 cells by increasing apoptosis. When combined with ACR, VK2 inhibited Ras activation, followed by the inhibition of ERK phosphorylation. Interestingly, Suzuki *et al*[50] reported that des-gamma-carboxy prothrombin (DCP), also called protein induced by VK absence or antagonist Ⅱ, which is widely used as a tumor marker of HCC, has a binding affinity to c-Met, a hepatocyte growth factor receptor, and that it transmits aberrant STAT3 signaling[50]. They also reported the involvement of variant GGCX mRNA expression in the production of DCP in liver cancer[51]. Furthermore, Ma *et al*[52] showed the DCP-dependent growth advantage of HCC cells.

An interesting topic that has recently been reported in tumor biology is the role of UBIAD1, also called TERE1. UBIAD1 was recently identified as the menaquinone-4 biosynthetic enzyme[7]. UBIAD1 mRNA has been reported to be downregulated in prostate carcinoma cells and the overexpression of UBIAD1 inhibits the proliferation of tumor cell lines. UBIAD1 has therefore been considered to be a tumor suppressor in prostate cancer tumors[53]. Fredericks *et al*[54,55] reported that UBIAD1 controlled SXR-dependent gene expression in prostate cancer cells through several mechanisms. Since SXR transcription factor is a ligand of VK2 and because it has been shown to be involved in HCC cell growth[56,57], UBIAD1 expression might be linked to the effects of VK in HCC cells. More recently, UBIAD1 has been reported to be essential for embryonic development in mice[58] and VK2 has been shown to drive the metabolic maturation of pluripotent stem cells and fetal hepatocytes[59]. These findings suggest a novel role of VK metabolism in stem cells and that VK might be involved in cancer stem cell biology.

Collectively, the possible signal mechanisms of VK are summarized in Figure 1. VKs have been shown to have diverse effects on the phosphorylation states of various proteins[60]. Although the involvement of PKA, PKC, NF-κB, STAT, SXR and MAPK pathways are reported, the mechanisms by which VK2 modulates the protein kinases and/or phosphatases still remain to be elucidated. VK2 may reduce the growth and invasion of cancer cells through the modulation of protein kinases/phosphatases cascades.
